Co-morbidity and treatment of attention deficit hyperactivity disorder in Saudi Arabia

F.A. Al-Haidar

ABSTRACT To review the experience of a child psychiatric clinic regarding co-morbidity and treatment characteristics of children with attention deficit hyperactivity disorder (ADHD), a retrospective study was done on patients under 19 years who were attending the clinic and were diagnosed with ADHD. Co-morbidity and treatment characteristics were also studied. ADHD was diagnosed in 25.5% of the patients. Of these, 28.3% had coexistent expressive language disorder and 38.7% coexistent mild mental retardation. A psychostimulant (methylphenidate) was prescribed to 23.6% while antidepressants (primarily imipramine) were prescribed to 35.9%. Behavioural therapy was the most commonly offered psychotherapy. Antidepressants were used more than psychostimulants. Psychotropics had a more beneficial effect than psychotherapy.

Comorbidité et traitement du trouble d’hyperactivité avec déficit de l’attention en Arabie saoudite

RESUME Afin d’examiner l’expérience d’une clinique de pédiopsychiatrie en ce qui concerne la comorbidité et les caractéristiques du traitement des enfants souffrant d’hyperactivité avec déficit de l’attention (HADA), une étude rétrospective a été réalisée auprès des patients de moins de 19 ans qui consultaient à la clinique et chez lesquels un diagnostic de HADA avait été posé. La comorbidité et les caractéristiques du traitement ont également été étudiées. Une hyperactivité avec déficit de l’attention a été diagnostiquée chez 25,5 % des patients. Parmi ces patients, 28,3 % avaient des troubles expressifs du langage coexistants et 38,7 % avaient une légère arriération mentale coexistante. Un psychostimulant (méthylphénidate) a été prescrit à 23,6 % des patients tandis que des ant dépresseurs (principalement l’imipramine) ont été prescrits à 35,9 %. La thérapie comportementale était la psychothérapie la plus fréquemment offerte. Les ant dépresseurs étaient davantage utilisés que les psychostimulants et les psychotropes ont montré un effet plus bénéfique que la psychothérapie.

Introduction

Attention deficit hyperactivity disorder (ADHD) is a disorder of childhood and adolescence characterized by a pattern of extreme pervasive, persistent and debilitating inattention, overactivity and impulsivity [1]. It is believed to be one of the most common reasons for mental health referrals to family physicians, paediatricians, paediatric neurologists and child and adolescent psychiatrists [2,3].

Although originally thought to remit during childhood, the symptoms of ADHD have also been shown to persist in patients through adolescence and into adulthood [4]. The disorder is often chronic, with one third to one half of those affected retaining the condition into adulthood [5–7].

It interferes with many areas of normal development and functioning in a child’s life [2]. Children with ADHD are more likely than their peers to experience educational underachievement, social isolation and antisocial behaviour during the school years [8] and to go on to have significant difficulties in the post-school years [9,10].

The aim of this study is to review the experience of a child psychiatric clinic regarding co-morbidity and treatment characteristics of children with ADHD. Evaluating our current clinical experience with ADHD and comparing it with others will allow us to offer better service to our patients in the future.

Methods

The case records of all patients (416) up to 18 years of age who attended the child psychiatric outpatient clinic at King Khalid University Hospital, Riyadh, Saudi Arabia over a period of 10 years (July 1990 to July 2000) were examined. Those who were diagnosed as having ADHD (106) were retrospectively reviewed with regard to co-morbidity, prescribed psychotropic medication and type of psychotherapy offered.

The diagnosis of ADHD and co-morbid disorders was based on the Diagnostic statistical manual of mental disorders [1].

The psychological tests used to determine the degree of mental retardation included the Wechsler Intelligence Scale for Children, the Stanford-Binet Intelligence Scale and the Vinland Adaptive Behavioral Scale.

Psychotherapy offered included behavioural therapy and family counselling. In behavioural therapy, parents were given strategies to modify their children’s behaviour (e.g. point/token reward system and time-out). In family counselling, parents had the opportunity to establish a positive relationship within the family and relieve guilt feelings through an external attribution of the cause and difficulties.

Results

Case records of 416 patients were reviewed; 106 (25.5%) were diagnosed as having ADHD, either as the only diagnosis, 53 (12.7%), or in combination with other psychiatric disorders, 53 (12.7%).

Demographic data are shown in Table 1. Boys accounted for 77.4% and girls 22.6%, a ratio of 3.4 males to 1 female. Adolescents accounted for only 3.7% of the boys and none of the girls.

The majority (93.4%) of the group were Saudi Arabian nationals. Most of the patients had not attended school (63.2%), while 30.2% had had some sort of education that varied from kindergarten to high school, and 6.6% were attending a special school for children with mental disabilities.

Table 2 lists the co-morbid psychiatric disorders. Half of the sample (53.0%) did
not show any co-morbid psychiatric disorder, the commonest associated disorder was expressive language disorder (28.3%) followed by nocturnal enuresis (10.4%).

A review of the co-morbidity of ADHD and mental retardation shows that nearly half of the sample (47.2%) did not show any degree of mental retardation while 38.7% had mild, 12.3% had moderate and 1.9% had severe mental retardation.

The prescribed psychotropic medications are listed in Table 3. Methylphenidate was the only psychostimulant given and was the most commonly prescribed drug. Imipramine was the most commonly prescribed antidepressant and the second most commonly prescribed psychotropic. Haloperidol was the most commonly prescribed antipsychotic and the third most commonly prescribed psychotropic. Only 6.6% of the group did not receive any form of medication.

The duration of medication use varied from 1 month to 60 months, with a mean of 17 months. Regular follow-ups were performed in 34.0% of patients, while 66.0% had irregular follow-ups. There was no significant report of side-effects that we could use for analysis.

Behavioural therapy was the most commonly offered type of psychotherapy (44 patients, 46.2%). Only 4 patients (3.8%) had family counselling, 9 patients (8.5%)...
had both therapies and 44 (41.5%) did not receive any formal psychotherapy.

Table 4 shows a comparison of the outcome for those patients who received psychotropic drugs, psychotherapy or both (assessment of the outcome was based only on the reported information in the clinical records). All 106 patients received some sort of intervention; the majority (52.8%) received both, while 38.7% received drugs only and 8.5% received psychotherapy alone. Among those who showed improvement, predominantly this was only partial improvement. Patients who received drugs showed the greatest improvement, while those who received both drugs and psychotherapy mostly showed partial improvement. Those who received psychotherapy alone did not show much improvement.

Discussion

The common heterogeneous disorder ADHD is conservatively estimated to affect 3%–5% of school-age children [11]. When the diagnosis of ADHD is made with standardized structured interview to parents or teachers however, then the prevalence has been reported as reaching 19% in primary school age boys [12], with a much higher prevalence (30% to 50%) in those attending child and adolescent psychiatric outpatient clinics [1,13]. This study was conducted in an outpatient psychiatric clinic, so a prevalence of 25.5% is in agreement with the results of previous studies of samples from similar populations.

In one study conducted in the United States of America (USA) using DSM IV, 22%–40% of referred children were diag-
nosed as having ADHD [10], compared to 1.2% in the United Kingdom which used the International Classification of mental and behavioural disorders, tenth edition (ICD 10) [14]. So the findings of our study (25.5%) correspond with the USA studies, explained at least partially by the employment of the same diagnostic measures, DSM III-R or DSM IV.

Although community-based studies have found male to female sex ratio for ADHD as low as 2.1:1, male to female ratio in referred samples (similar to this study sample) ranged from 4:1 to 9:1 [1, 15], comparable to the findings of this study (3.4:1).

There are several reasons for the greater vulnerability of boys. Adults are often more tolerant of hyperactivity in girls than in boys, at least before school age [16]. Also, compared with boys, girls with ADHD tend to have greater intellectual impairment and inattention, lower levels of hyperactivity and lower rates of conduct behaviour [17–20].

Attention deficit hyperactivity disorder is quite strongly associated with a range of abnormalities in psychological and motor development [14]. The typical abnormalities found are immature articulation and language delay [21].

Some of the sample (20.8%) were diagnosed to have enuresis and/or encopresis. This association may be related to delayed toilet training due to difficulty in learning because of inattention and hyperactivity, or related to associated mental retardation.

The association between ADHD and conduct disorder is so great that some reviewers consider that hyperactivity and conduct disorder are actually the same problem under different names [22–24]. However in this study, an association between ADHD and conduct disorder was not detected. Because conduct disorder is primarily a behavioural disturbance, the family and the community in general may perceive it as misbehaviour rather than a psychiatric disorder and may deal with it themselves, in which case children exhibiting this type of behaviour will not be referred to a psychiatric unit.

ADHD is associated with reduced verbal and performance intelligence [24]. In a study of mild mental retardation, ADHD accounted for 10%–14% of the whole group [24]. Some investigators have reported that as many as a quarter to one third of those with severe mental retardation manifest co-morbid hyperactivity

All patients received some intervention.
Other studies showed that as the mental retardation becomes more severe, the association with ADHD is more expected [24,25]. In this study, however, a greater association with mild mental retardation was found. This may be because the more severely retarded patients are dealt with by the institutes for the mentally retarded and rehabilitation centres, where they have their own psychologists and psychiatrists who rarely refer to other centres for psychiatric assessment or management.

A wide variety of treatments have been used for ADHD including, but not limited to, various psychotropic medications, psychosocial interventions, dietary management, training and educational programmes [27]. Psychostimulants such as methylphenidate, amphetamine, dextroamphetamine and pemoline are prescribed for about two thirds of children with ADHD [28,29], methylphenidate being the most often used [27,30]. Methylphenidate was the only psychostimulant prescribed in this study and was prescribed less (23.6%) compared to other studies [30,31].

The value of antidepressants in the treatment of ADHD, particularly imipramine, has been reported in several circumstances such as the coexistence of emotional disorders, failure to respond to psychostimulants and coexistence of tics [2,25]. Overall in this study, antidepressants (35.9%) were more often prescribed than psychostimulants (23.6%). This contrasts with the findings of other studies [27,28]. However, in accordance with the findings of other studies, haloperidol was the most commonly prescribed antipsychotic, and carbamazepine the most commonly prescribed mood stabilizer [2]. Haloperidol has been reported to be useful for those hyperactive children with Tourette's syndrome or tics [2]. Mood stabilizers, particularly carbamazepine and sodium valproate, do not seem to have a positive effect on core ADHD symptoms, however, they have been reported to be useful in controlling behaviour disturbance and aggression [2].

The finding of this study that behavioural therapy is used more than family counselling has been reported before [25]. However, both interventions have been found to be useful for many hyperactive children [25,27].

Comparing the beneficial effects of psychotropics and psychotherapy, the results of this study supported the superiority of psychotropics, a finding in agreement with previous reports [27]. In this study as well as others, combining psychotropics and behavioural therapy added little advantage overall over medication alone [27].
