Abstract This paper synthesizes the rates, barriers, and outcomes of HIV serostatus disclosure among women in developing countries. We identified 17 studies from peer-reviewed journals and international conference abstracts — 15 from sub-Saharan Africa and 2 from south-east Asia — that included information on either the rates, barriers or outcomes of HIV serostatus disclosure among women in developing countries. The rates of disclosure reported in these studies ranged from 16.7% to 86%, with women attending free-standing voluntary HIV testing and counselling clinics more likely to disclose their HIV status to their sexual partners than women who were tested in the context of their antenatal care. Barriers to disclosure identified by the women included fear of accusations of infidelity, abandonment, discrimination and violence. Between 3.5% and 14.6% of women reported experiencing a violent reaction from a partner following disclosure. The low rates of HIV serostatus disclosure reported among women in antenatal settings have several implications for prevention of mother-to-child transmission of HIV (pMTCT) programmes as the optimal uptake and adherence to such programmes is difficult for women whose partners are either unaware or not supportive of their participation. This article discusses these implications and offers some strategies for safely increasing the rates of HIV status disclosure among women.

Introduction The prevention and control of human immunodeficiency virus (HIV) infection depends on the success of strategies to prevent new infections and to treat currently infected individuals. Voluntary HIV testing and counselling serve both goals. HIV testing and counselling provide essential knowledge and support to individuals at risk for contracting HIV, enabling uninfected individuals to remain uninfected and those infected to plan for the future and prevent HIV transmission to others (1, 2). Knowing their HIV status may also enable HIV-infected individuals to access early and appropriate treatment, care and support programmes. Furthermore, HIV-infected women who know their serostatus are in a better position to make informed choices about their reproductive lives and, if pregnant, to access specific interventions, such as antiretroviral prophylaxis and infant feeding counselling and support, which can significantly reduce the risk of mother-to-child transmission of HIV (3–5).

At present, the majority of HIV-infected individuals are unaware of the services they need. Disclosure of HIV status to sexual partners is an important prevention goal emphasized by the WHO (6) and the Centers for Disease Control and Prevention (CDC) (7) in their protocols for HIV testing and counselling. Disclosure offers a number of important benefits to the infected individual and to the general public. Disclosure of HIV test results to sexual partners is associated with less anxiety and increased social sup-

HIV serostatus disclosure: implications for pMTCT

Amy Medley et al.

port among many women (8). In addition, HIV status disclosure may lead to improved access to HIV prevention and treatment programmes, increased opportunities for risk reduction and increased opportunities to plan for the future. Disclosure of HIV status also expands the awareness of HIV risk to untested partners, which can lead to greater uptake of voluntary HIV testing and counselling and changes in HIV risk behaviours (1,2,9). It is clear from the literature that risk behaviours change most dramatically among couples where both partners are aware of their HIV serostatus (1,2,9). In addition, disclosure of HIV status to sexual partners enables couples to make informed reproductive health choices that may ultimately lower the number of unintended pregnancies among HIV-positive women (2).

Along with these benefits, however, there are a number of potential risks from disclosure for HIV-infected women, including loss of economic support, blame, abandonment, physical and emotional abuse, discrimination and disruption of family relationships. These risks may lead women to choose not to share their HIV test results with their friends, family and sexual partners. This, in turn, leads to lost opportunities for the prevention of new infections and for the ability of these women to access appropriate treatment, care and support services where they are available.

This paper reviews the current information available on HIV status disclosure among women in developing countries. The implications of non-disclosure are considered in the context of prevention of mother-to-child transmission (pMTCT) programmes. Programmatic and policy strategies that have been used to increase disclosure rates and minimize negative outcomes among women are also discussed.

Methods

We reviewed all published abstracts and journal articles from January 1990 to December 2001 identified through a comprehensive search of four medical and social science electronic databases including: PubMed, the National Library of Medicine's (NLM) Gateway database, Psych INFO, and Sociologic Abstracts. We also searched four HIV-related journals by hand: AIDS Care, AIDS, AIDS and Behavior, and AIDS Education and Prevention. Any article that qualified during these searches was then retrieved from the library and the bibliography searched for any additional references. The terms used during the computer-based searches include HIV counselling and testing and disclosure, HIV voluntary counselling and testing and disclosure, HIV serostatus disclosure and women, and pMTCT and disclosure. To be eligible for this review, the article must have included data on the rates, barriers or outcomes of HIV serostatus disclosure; the study must have been conducted in a developing country and have included only women. We also contacted several of the authors personally to clarify some of the findings and to bring ourselves up to date on current research. The 17 articles reviewed in this paper include 15 articles from sub-Saharan Africa and two articles from south-east Asia. The studies reported vary greatly in terms of their sample size, study design, and methods of data collection (see Table 1 and Table 2).

Results

Disclosure rates

Fifteen studies were identified reporting rates of disclosure to sexual partners among women in developing countries (Table 1). Fourteen of the published studies were conducted in sub-Saharan Africa (3 in the United Republic of Tanzania, 3 in Kenya, 2 in Burkina Faso, 1 in Uganda, 1 in South Africa and 1 in the Democratic Republic of the Congo). The remaining study was conducted in Thailand. The assessment period for disclosure in these studies ranged from two weeks to almost four years, and the rates of disclosure ranged from 16.7% to 86%.

Few studies assessed the length of time from diagnosis to disclosure. Among studies that did look at this correlation, it was found that as the length of time since diagnosis increases, the rate of disclosure also increases. For example, Antelman et al. found that disclosure to sexual partners among women attending an antenatal clinic increased from 22% within two months of diagnosis to 41% after nearly four years (10).

Data from these articles indicate that there is a core group of women who do not share their HIV test results with their sexual partners even after several months of follow-up. Kilewo et al. found that 77.8% of HIV-positive pregnant women participating in a perinatal transmission trial had not shared their HIV test results with their sexual partners 18 months after diagnosis (11). Working in Kenya, Galliard and colleagues found that 76.1% of the HIV-positive pregnant women who had not disclosed their results two months after diagnosis said that they never intended to disclose to their partners (12).

Barriers to disclosure

Table 1 includes a summary of the barriers to disclosure that women in developing countries identified. Either the study participants were asked directly about the perceived barriers to disclosure or the investigators identified the correlates associated with disclosure and non-disclosure of HIV test results through multivariate analysis.

The most common barriers to disclosure mentioned by participants included fear of abandonment, rejection and discrimination, violence, upsetting family members, and accusations of infidelity. Women's fear of abandonment was closely tied to fear of loss of economic support from a partner. In these settings where resources are extremely scarce and women's access to resources independent of their partner is uncommon, it is not surprising that fear of losing this instrumental support from a partner is a major consideration when deciding whether to share HIV test results or not.

Four of the studies reviewed used multivariate analysis to determine predictors of disclosure. Both Farquhar et al. and Galliard et al. found that younger women (under the age of 24 years) were more likely to disclose to sexual partners than older women (12,13). Additionally, Farquhar found women of lower socioeconomic status had a higher disclosure rate than women of higher socioeconomic status (13). Antelman et al. also found that women who had been in relationships for a longer period of time (defined as more than two years) were more likely to disclose than women who had been in relationships for a shorter duration (10). Women who reported fewer sexual partners and who personally knew someone with HIV/AIDS were also more likely to disclose (10). Issiaka and colleagues found that women with a higher level of education were more likely to share their results with their partners than women who were illiterate (14).

Outcomes of HIV status disclosure

Ten studies reported on the outcomes of HIV status disclosure, summarized in Table 2. The majority of the studies reported positive outcomes related to disclosure. Women reported receiving kindness, understanding or acceptance following disclosure in three of the studies. An important finding is that...

disclosure was not associated with the break-up of marriages. In fact, four of the studies reported that most marriages survived disclosure (12, 15–17).

Of concern is the proportion of women reporting negative outcomes following status disclosure (ranging from 4% to 28% of respondents). Negative outcomes included blame, abandonment, violence, anger, stigma and depression. The proportion of women reporting violence as a reaction to disclosure ranged from 3.5% to 14.6%. The true incidence of violence related to HIV status disclosure was hard to determine from these studies, as there were no base rates of violence obtained at the beginning of the studies. Furthermore, most studies did not define violence or describe its severity, therefore making direct comparisons across studies difficult.

Interestingly, several studies mentioned that fear of consequences such as abandonment, violence and discrimination...

were major barriers to disclosure. When the study participants were asked the outcomes of disclosure, however, these fears were seldom realized among women who chose to disclose their status. In Kilewo’s study from the United Republic of Tanzania, 46.4% of women who did not disclose their HIV status to their partners reported that fear of divorce was a major barrier to disclosure, but 91.7% of women who did disclose their results reported that their relationship continued afterwards (11). Heyward found a similar trend in Kinshasa: 63% of women who did not disclose their HIV status reported fear of divorce as the major barrier, yet, 12 months after disclosure, no woman in the study reported divorce or separation (17). This finding can mean one of two things. It may mean that only women who are confident in the safety and strength of their relationship actually disclose their results, and women who are less confident choose not to. It could also mean that women perceive the risk of a negative outcome to be more likely than it is in fact.
Discussion

A review of the rates of disclosure found that between 16.7% and 86% of women choose not to disclose their HIV status to their partners. The majority of women who disclosed HIV test results to their partners reported supportive reactions from partners. Negative outcomes were less common and included shock, disbelief, abandonment, and violence. Fear of negative outcomes was nonetheless the barrier to HIV status disclosure most often mentioned by women.

Disclosure rates of HIV status reported in these studies are impossible to compare directly because the studies differed in how they measured rates of disclosure and in the time frames used. It is nevertheless possible to identify trends for rates of HIV status disclosure. It is clear from these studies that the lowest rates of HIV status disclosure were reported among women in antenatal care. This article has therefore chosen to focus on women attending antenatal clinics, as the low rates of disclosure seen there have several implications for pMTCT.

WHO has outlined a four-pronged approach to prevent HIV infection in mothers and their infants. The four elements are: the reduction of HIV transmission to potential mothers; the reduction of unintended pregnancies among women and girls living with HIV; the reduction of mother-to-child transmission of HIV; and the provision of care, treatment and support for mothers and their infants, partners and families.

The low rates of disclosure seen in many of these studies have implications for each component of the strategy, as outlined in Fig. 1. First, disclosure of HIV status between HIV-uninfected women and their sexual partners is necessary to initiate discussions about HIV/AIDS that raise both partners’ awareness of the risk of infection and may ultimately lead to behaviour change to reduce HIV risk. Secondly, disclosure can be an important starting point for HIV-infected women to begin discussing the use of contraception with their partners and reduce the number of unintended pregnancies among HIV-infected women. Thirdly, disclosure plays an important role in women’s uptake of pMTCT programmes and in their participation in treatment and care and support programmes. In order to benefit from interventions that can reduce HIV perinatal transmission, women must be willing to be tested for HIV, and if they are HIV-positive they must be willing to accept and adhere to pMTCT prophylaxis. The optimal uptake and adherence to pMTCT programmes is difficult for women whose partners are either unaware or not supportive of their participation. Finally, it has been well documented in Africa that women often lack the power to make independent decisions with regard to their own health care and that of their children (18–20). It is therefore difficult for HIV-infected women to seek social and medical support from care and treatment programmes for themselves and their infants without first disclosing their HIV status to their partners.

Voluntary testing and counselling protocols were originally designed for clients seeking HIV testing and counselling services at specialized clinics or in the context of consultations for sexually transmitted infections. They need to be tailored for use in antenatal care services to focus specifically on the decisions that women have to make in the context of their antenatal care and, more importantly, to reflect the fact that women in these settings are not voluntarily seeking HIV testing and are likely not to have considered being tested for HIV prior to attending antenatal clinics. There is, at present, considerable interest in adapting the standard HIV testing and counselling protocols for use in different service settings. In a recent WHO technical consultation report, participants concluded that there is a need to re-evaluate the testing and counselling approaches used in health care settings such as antenatal clinics (21). Furthermore, the report suggests that there is a need to streamline counselling for women in antenatal care by tailoring it to the individuals, based on their HIV test results (21). One approach to streamlining is to provide HIV-negative women with the option either to opt out of counselling altogether or to receive a shorter counselling session focused primarily on prevention of future infections. This would enable counsellors to have more time for discussions with HIV-positive women or HIV-negative women at high risk of infection. Post-test counselling for HIV-positive women would be more comprehensive, including pMTCT, a discussion of partner notification and disclosure, options for family planning, and strategies for increased partner involvement in pMTCT programmes. This recommendation arises from the fact that, in most developing countries, antenatal clinics are...
short-staffed and counsellors are overburdened. Requiring counsellors to extend post-test counselling to discuss the importance of disclosure for all women would put intolerable strains on an already overstretched system. Therefore, it is necessary to focus limited resources on the women who stand to benefit the most from extended counselling.

There are several strategies to consider when modifying current voluntary HIV testing and counselling protocols in order to increase the rates of safe HIV status disclosure among HIV-positive women who are tested during antenatal care. The standard protocols for HIV testing and counselling offered by WHO (6) and CDC (7) do not dedicate sufficient time to considering the challenges of HIV status disclosure that are faced by many clients, particularly women. In the CDC protocol, the total counselling time allotted to discussing partner notification and disclosure in pre-test and post-test counselling sessions is between five and seven minutes. Standard counselling protocols need to be enhanced for HIV-infected women, concentrating on barriers to partner notification, and additional counselling needs to focus on helping women identify the pros and cons of disclosure. If women mention fear of violence as a barrier to disclosure during counselling, counsellors should be prepared to refer women to domestic violence services in areas where they are available.

One way of targeting the best use of resources for counselling support would be to identify the women most at risk for negative outcomes following disclosure through the use of screening tools. Such screening tools would ask women about prior communication with their partners regarding HIV and HIV testing, prior experience with violence, and anticipated reactions of partners to HIV status disclosure. Based on results of the screening, counsellors may present women with alternative options; these would include opting not to disclose, or deferring disclosure until a time when the woman feels it is safe to do it.

Counselling tools such as role-play scenarios may also be useful to help women develop the self-confidence and communication skills they need to share HIV test results safely with their partners. In addition, post-test clubs initiated by the AIDS Information Centre in Uganda have been shown to be highly effective in encouraging individuals to share their HIV test results with others and in reducing the stigma associated with HIV counselling and testing. These results suggest that implementing post-test clubs as part of voluntary counselling and testing may help women gain the support they need to disclose their test results to their sexual partners (30, 31).

Broader community-based initiatives to deal with underlying gender norms and social attitudes about HIV/AIDS and violence against women must accompany individually focused initiatives in order to create safer and more comfortable environments for women to share their HIV test results. For example, fear of stigma was one of the barriers to disclosing HIV test results most often mentioned by women. It is therefore important to initiate community-based programmes that would normalize HIV testing in the community and reduce the amount of stigma women perceive towards people infected with HIV. This, in turn, would allow women to feel more comfortable disclosing their own HIV status to others.

As the HIV epidemic continues to grow, there is an urgent need to identify innovative strategies to prevent new infections and to improve the quality of life for individuals who are already infected. In addition, there is a dearth of information on women’s experiences with HIV status disclosure from areas other than sub-Saharan Africa. Studies need to be conducted in other regions of the world, such as Latin America and central and south Asia, to describe the variability in rates, barriers and outcomes of HIV status disclosure to sexual partners.

Access to voluntary HIV testing and counselling is crucial in order to allow individuals to discover their status and take advantage of important prevention and care interventions. It is clear from the literature that women, in particular, face a number of significant barriers to disclosure and that some women face negative outcomes as a result of disclosure. Strategies are now needed to support women who want to disclose their HIV test results safely to their sexual partners, and to enable these women to avail themselves of prevention and treatment programmes where they exist.
