Current global situation
Cases reported to WHO as of 07 February 2021, 10:00AM CEST

- > 105 million cases
- > 2.3 million deaths

* Data are incomplete for the current week. Cases depicted by bars; deaths depicted by line
The immune system is the body’s natural ability to defend against pathogens (e.g., viruses, bacteria) and resist infections.

Two types of immunity are:
- Innate immunity
- Adaptive immunity

**Innate immune response**
- First line of defence
- General immediate response to ANY infection
- Innate immune response cells secrete interferons and other chemicals (cytokines)
- Interferons interfere with virus replication
- The innate response activates the adaptive immune response

**Adaptive immune response**
- Second line of defence
- Specific response to the infection
- Starts after 6 - 8 days
- Involves two types of white blood cells
  - T cells (cellular response)
  - B cells (antibody response)

1. Interferons and cytokines cause fever, muscle aches, etc – the typical early symptoms of infection
2. A ‘weaker’ innate response (e.g. in elderly people or those with underlying health problems) may result in delayed stimulation of the adaptive response
The innate immune response is immediate, whereas the cellular and antibody response usually starts after 6 to 8 days.
When a virus enters the body, cells can recognize markers present on the virus. This results in non-specific antiviral activity. Cells of the innate system (such as marcophasages, neutrophils, dendritic cells and others) are activated to remove pathogens and foreign cells from the body and activate the adaptive immune response.

**Cells involved in the innate immune response**

- **Marcophage**: Phagocytic cell that consumes foreign pathogens; Stimulates response of other immune cells.
- **Neutrophil**: First responder at site of infection. Most common type of white blood cells. Releases toxins that kill bacteria and recruits other immune cells to site of infection.
- **Natural killer cell**: Kills virus infected cells and tumor cells.
- **Dendritic cell**: Presents antigen on its surface, thereby triggering the adaptive immune response.

Adaptive immune response: T cells

**T cells** (cellular response)

- **T cells recognize cells that are infected with a specific virus** and rapidly increase in number to tackle the infection

- Types of T cells:
  - **CD4+ helper T cells** bring in other cells of the immune system and stimulate B-cells to produce antibodies specific to that virus
  - **CD8+ cytotoxic T cells** kill the cells in which the virus is multiplying and help to slow down or stop the infection

https://www.virology.ws/2020/11/05/t-cell-responses-to-coronavirus-infection-are-complicated/
Adaptive immune response: B cells

B cells (antibody response)

- **B cells produce antibodies** that are specific to the virus
- **IgM antibodies** are produced first and disappear after a few weeks
- **IgG antibodies** are produced at the same time or a couple days later, and titres (levels) usually remain for months or years

Memory cells

- **Once the infection is over**, the T cells and B cells decline in number, but some cells will remain (memory cells)
- Memory cells respond rapidly if they come in contact with the same virus again, killing the virus and accelerating an antibody response
Neutralizing antibodies bind to viral proteins

Components of the SARS-CoV-2 virus

Neutralizing antibody hypothesis: the antibody changes the viral spike protein and prevents entry of the virus via the ACE2 receptor into a targeted cell

Antibodies to other components may not effectively neutralize the virus

Antibodies that attach differently may not effectively neutralize the virus

Antibody response to SARS-CoV-2

- **Most COVID-19 patients who recover have antibodies** to SARS-CoV-2 detectable in their blood

- Most COVID-19 patients develop antibodies about 1-3 weeks after symptoms appear. Many patients start to recover during this time

- **Patients who have had more severe disease appear to have higher levels of neutralizing antibodies.** While, patients who had mild or asymptomatic COVID-19 have lower levels of neutralizing antibodies

- Several studies* show that antibodies **remain for several months in individuals who tested positive**, for example a study of more than 30,000 individuals with mild to moderate COVID-19 found that neutralizing antibody titers persisted for at least 5 months after SARS-CoV-2 infection

*The studies referenced are not an exhaustive list
T cell response to SARS-CoV-2

• It is possible that in persons with **low levels of neutralizing antibodies**, the innate immune response and the T cell response clears the virus

• Some studies show that persons exposed to SARS-CoV-2 may develop virus-specific T cell responses without detectable circulating antibodies
  
  ➢ This may mean that persons who have had mild COVID-19 or were asymptomatic can generate memory T-cell responses to prevent recurrent infection in the absence of antibodies

• Some T cells in persons without exposure to SARS-CoV-2 have been found to cross-react with SARS-CoV-2 (possibly due to prior exposure to other coronaviruses)
  
  ➢ This may mean that persons with reactive T-cells will get less severe disease if exposed to SARS-CoV-2

Re-infection of SARS-CoV-2

• Generally, a person who recovered from a viral infection is protected against a new infection

• It is not yet known how long protection will last after a SARS-CoV-2 infection

• To date, re-infection with SARS-CoV-2 seems rare but several cases of repeat SARS-CoV-2 infection have been reported

• Preliminary results from the SARS-CoV-2 Immunity and Reinfection Evaluation (SIREN) study conclude that past SARS-CoV-2 infection reduces the risk of re-infection by 83% for at least 5 months and that fewer than 1% of 6,600 study participants who had COVID-19 were re-infected

SARS-CoV-2 variants & re-infection

- Changes in the virus genomic sequence, called mutations, can make prior immunity less effective (e.g. as with the influenza virus)
- Recently, several SARS-CoV-2 variants have emerged that involve genetic mutations of the spike protein
- Studies are ongoing to investigate if some of these variants can evade the immune response to a previous SARS-CoV-2 infection and make people more vulnerable to re-infection
- In lab experiments, one of the mutations present in the variants identified in South Africa and Brazil has helped the virus evade antibodies generated after an initial infection
- In Brazil, studies are ongoing to determine if a new variant called P.1 may lead to more cases of re-infection

https://www.thelancet.com/journals/lancet/article/PIIS0140-6736(21)00183-5/fulltext?s=08
SARS-CoV-2 variants & COVID-19 vaccines

- Current variants involve mutations to the gene for the spike protein that is targeted by COVID-19 vaccines
- Several COVID-19 vaccines have reported reduced efficacy to protect against mild to moderate disease in people infected with SARS-CoV-2 variants, however the vaccines are still expected to protect against severe disease and death
- Studies are ongoing to examine if some vaccines may be more susceptible to effects of the variants than others
  - those using smaller epitopes (the receptor binding domain on the spike protein) may be more susceptible than those using a larger part of the virus such as the spike protein or the whole inactivated virus

COVID-19 protective measures

Protect yourself & others

- Keep your distance
- Wash your hands frequently
- Cough & sneeze into your elbow
- Ventilate or open windows
- Wear a mask
