Nonmalignant respiratory disease arises as a result of the exposure of workers to airborne agents, mostly in the form of particulates or dusts. ${ }^{2}$ The primary route of exposure is inhalation, whereby these agents gain access to the respiratory system and are either deposited (in the case of dusts) or enter the circulatory system. For some exposures, there is a very clear connection between the exposure and the disease (for example, silicosis is only caused by exposure to silica). Some exposures cause more than one type of disease, and even more than one type of respiratory disease. For example, asbestos can result in malignant conditions of the lung and the pleura (the inside lining of the chest), malignant conditions of the peritoneum (the inside lining of the abdomen) and nonmalignant conditions of the lungs (asbestosis and COPD). Other exposures have not been well characterized, but are believed to result in certain conditions (such as some forms of occupational asthma).

### 3.1 Exposure variable

## Causative agents of asthma

Asthma, which is a narrowing of the upper respiratory passages resulting in difficult breathing and wheezing, has both nonoccupational and occupational causes. Many hundreds of occupational agents, including some inorganic and organic dusts, have been associated with occupational asthma (Balmes et al. 2003; Chan-Yeung and Malo 1994; Venables and Chan-Yeung 1997). Biological agents include grains, flours, plants and gums, fur, feathers and other animal parts, insects and fungi, drugs and enzymes and various types of wood. Chemical agents include chlorofluorocarbons, alcohols, metals and their salts, and welding fumes (CCOHS 1997). These agents are found in a variety of workplaces, including food and natural products processing, animal handling facilities, manufacturing and construction.

It would not be possible to conduct exposure assessments and to obtain relative risk data for all the factors contributing to this important occupational disease, especially since they often occur in combination. We therefore used occupation as a proxy for exposure to agents that are associated with occupational asthma. The basis for this approach was the work of Karjalainen et al. (2001, 2002), who conducted extensive epidemiological studies of the entire Finnish workforce and developed relative risks for specific occupations. A similar but less extensive study based in 12 industrialized countries was also used (Kogevinas et al.
1999). Relative risks were applied to these occupational data to produce estimates of the number of deaths due to work-related asthma.

Causative agents of COPD
The causative agents of COPD are non-specific dust and fumes, with dusts showing a more consistent relationship than fumes (Becklake 1989). Because of a lack of worldwide data on the prevalence of occupational exposure to dusts and their combinations, work in specific economic subsectors was used as a surrogate for dust exposure. Relative risks were applied to these workforce data to produce estimates of the number of deaths from COPD arising from work-related exposures.

### 3.2 Estimating risk factor levels

The general exposure assessment methodology was described earlier. Occupation was used for asthma (Equation 2) and economic sector for COPD (Equation 1). The theoretical minimum risk corresponds to no occupational exposure above background levels to airborne particulates or other agents that cause nonmalignant respiratory disease.

## AgENTS CAUSING ASTHMA

The proportion of the total population with occupational exposure to asthmagens was estimated using Equation 2. Estimates were made for each occupational category by determining the proportion of the population working in occupations that matched as closely as possible to those identified by Karjalainen et al. $(2001,2002)$ and for which relative risk values were provided (Table 21.23). Those not working and those employed in administration were together considered to be the nonexposed reference category (relative risk=1). These calculations were done separately for men and women for each subregion of the world. Relative risks and the proportions exposed by occupational category were applied across all age groups from age 15 to $\geq 80$ years.

Table 21.24 summarizes the age-adjusted distribution of the labour force into occupations matching the categories for which relative risks were identified by Karjalainen et al. (2002).

## Agents causing COPD

It is not possible to estimate the proportion of the world's population exposed to the large number of agents identified in occupation-specific and agent-specific studies. Community-based studies have therefore been preferred. The most common exposure in these studies is exposure to dust and/or gas/fumes (e.g. Korn et al. 1987; Kryzanowski et al. 1986; Xu et al. 1992). Unfortunately, there are also no data to estimate the proportion of the world's workers exposed to dust and/or gas/fumes. The study by Korn et al. (1987) provides a link between self-reported exposure to dust (current and past exposure) and some categories of economic activity ${ }^{3}$ among the currently employed. Categories of economic activity

among the currently employed are available worldwide, and can provide a broad approximation to the proportion of the world's population with current or past exposure to dust and/or gas/fumes. We based our estimates of exposed populations on data on employment in economic sectors of agriculture, industry and service from the World Bank (2001), supplemented by data from ILO (2000) on employment in economic activities. The proportions of the population with occupational exposure at medium and high levels to agents causing COPD were estimated using Equation 1.

Korn et al. (1987) defined as low-exposed those in finance, as mediumexposed those in the manufacture of non-durable goods, transport, utilities and the wholesale and retail trades, and as highly exposed those in the manufacture of durable goods, agriculture, mining and construction. Exposure was to "dusts" and to "gases", without these being further defined. We adopted these categories with some modification to account for our lack of data on the type of manufacturing industry and for the fact that agriculture in developed and developing countries probably involves different types of exposure to respirable dust. Lacking data that would have permitted us to divide manufacturing into medium and high potential for dust exposure, we have classified it as having potentially high dust exposure, given that in much of the world manufacturing involves more dust exposure than is typical in the United States where the Korn et al. study (1987) was done (Chien et al. 2002; Gomes et al. 2001). We have defined as nonexposed those not in the workforce and those in utility trade, finance and services. Those in agriculture, manufacturing and transportation were defined as having low exposure, while those in mining and construction were defined as having high exposure. Many workers in the medium and highly exposed economic activities are in fact not exposed to dusts, but on the whole the proportions in these industries are taken to represent the approximate proportion of those ever exposed to low and high levels of dusts in the general population. In Korn et al. (1987), the proportion of workers currently employed in the medium- and high-exposure industries listed above corresponded approximately to the proportion of those reporting ever having been occupationally exposed to dust in that study. This approach was followed in our study, in which it was assumed that the number of currently employed in specific industries corresponds roughly to the number ever occupationally exposed to dusts. The proportion exposed in different economic activities in each subregion was adjusted to account for an average labour force participation among the currently exposed in that subregion, which was applied across all ages. The results are presented in Table 21.25.

### 3.3 RISK FACTOR-DISEASE RELATIONSHIPS

## ASTHMA

Occupational asthma is a condition characterized by variable airflow limitation or bronchial hyper-responsiveness related to workplace exposure. However, the precise definition of occupational asthma has been widely debated. The most controversial issue concerns whether only immunologically-mediated asthma should be considered to be occupational asthma or whether asthma arising as result of workplace exposure to irritants, or exacerbation of pre-existing asthma by workplace irritants, should also be considered in the definition (Lombardo and Balmes 2000; Malo and Chan-Yeung 2001; Wagner and Wegman 1998). Recently, consensus seems to have been reached in favour of a broad definition (American Thoracic Society review: Balmes et al. 2003). A broader approach has been supported by others (Blanc and Toren 1999; Karjalainen et al. 2001; Kogevinas et al. 1999; Milton et al. 1998; Toren et al. 1999), and recent studies of occupational asthma have tended to use a more inclusive approach (Karjalainen et al. 2001, 2002; Milton et al. 1998).

Occupational asthma is probably the most common work-related respiratory disorder in industrialized countries (Kogevinas et al. 1999), and is either stable (Singh and Davis 2002) or increasing in incidence (Sears 1997). Many hundreds of occupational agents, including some inorganic and organic dusts, have been associated with occupational asthma (Balmes et al. 2003; Chan-Yeung and Malo 1994; Venables and ChanYeung 1997).

Until recently, there has been limited information on the total risk of developing asthma from workplace exposure. The United States magnitude of mortality study (Steenland et al. 2003) estimated that about $5 \%$ of mortality from nonmalignant work-related respiratory disease was due to asthma. Studies of substance-specific risks have helped to identify or implicate particular substances as likely causative agents (e.g. Monso et al. 1998), but these studies have generally focused on agents thought to be sensitizers, and usually on only a limited number of these. They are therefore not useful for determining the true extent of asthma occurring as a result of work-related exposure. Several population-based studies have partially rectified this problem (Karjalainen et al. 2001, 2002; Kogevinas et al. 1996, 1999; Ng et al. 1994; Toren 1996; Toren et al. 1999), focusing on occupation-specific rather than substancespecific risks because of the plethora of potential causative exposures and the difficulty in characterizing them. These studies provided measures of relative risk and/or population-attributable fractions. Recent studies in Finland have estimated population-attributable fractions for occupational asthma of $18 \%$ (Nurminen and Karjalainen 2001) and of $17 \%$ (for women) and $29 \%$ (for men) (Karjalainen et al. 2002). A comprehensive review undertaken before these two Finnish studies found a
median value for population-attributable fraction of $9 \%$ for all relevant studies, and a median value of $15 \%$ for the highest-quality studies (Blanc and Toren 1999). The American Thoracic Society (Balmes et al. 2003) has recently reviewed the literature and estimated that approximately $15 \%$ of asthma is attributable to occupational exposure, based largely on studies in developed countries.

Of these studies, only that by Karjalainen et al. $(2001,2002)$ provides useable risk information to cover the whole workforce, while that by Kogevinas et al. provides useful information for agriculture. The study by Karjalainen et al. $(2001,2002)$ was a longitudinal study over 13 years covering the entire Finnish population, and provided relative risks for a large number of broad occupational categories. In that study, asthma was defined by the occurrence of clinically diagnosed asthma ( $\mathrm{n}=49$ 575) during the follow-up period; national medical records were linked to census data on an individual's occupation. The study population was composed of all those currently employed, aged 25-59 years at baseline, without prior history of asthma. Relative risks were calculated by comparing the occupation-specific incidence to the incidence of occupational asthma in administrative, managerial and clerical workers, whose risk was assumed to be similar to the background population risk. The relative risks were adjusted for age, and separate risks were available for males and females, although these were very close to each other and certainly within the limits of random variation. The study by Kogevinas et al. (1999) was a cross-sectional study of asthma involving 15000 people in 12 European countries. In both studies, relative risks of asthma morbidity were assumed to apply for asthma mortality. This assumption is likely to be reasonable in most circumstances, but may lead to some underestimation or overestimation of asthma mortality, depending on whether exposure results in asthma incidence or exacerbation.

The approach used here was based on the work of Karjalainen et al. (2001, 2002). The work by Kogevinas et al. (1999) was also used for the relative risk of asthma due to occupational exposure in agriculture. While the Finnish study was large, prospective and covered all occupations, there was concern that Finnish exposures within specific occupations might be atypical of the rest of the world. In particular, this was considered likely to be true for agriculture, since Finnish agriculture might involve more indoor work where the relative risks for asthma were relatively high. Therefore the Kogevinas et al. results were used for agriculture since they were believed to be more generalizable to agriculture in the rest of the world, especially the developing world.

We assumed that the relative risk of asthma morbidity owing to employment in occupational categories was approximately equal to the relative risks of asthma mortality. Those not working and those employed in administration were together considered to be the nonexposed reference category (relative risk $=1$ ). These calculations were done separately for men and women for each subregion of the world. Rela-

tive risks and the proportions exposed by occupational category were applied across all age groups from age 15 to $\geq 80$ years. The relative risks by occupation are shown in Table 21.26.

## CHRONIC OBSTRUCTIVE PULMONARY DISEASE (COPD)

Tobacco smoking is clearly the most important risk factor, but many work-related exposures have been demonstrated to cause COPD (Hendrick 1996). A recent United States study estimating the magnitude of mortality due to occupational exposure (Steenland et al. 2003) used an estimate of $14 \%$ for the population-attributable fraction for COPD due to occupational dust exposure (based on a community study of severe COPD) (Korn et al. 1987), and found that COPD represented $87 \%$ of all fatal work-related nonmalignant respiratory disease, although some of the other types of respiratory disease may have been underestimated. A review of Finnish data also used a population-attributable fraction of $14 \%$ for men (and $5 \%$ for women) (Nurminen and Karjalainen 2001), and a similar figure ( $15 \%$ ) was recently used in a review by the American Thoracic Society (Balmes et al. 2003).

As for asthma, difficulties arise from the vast array of definite, probable and possible causes of work-related COPD. The role of smoking, particularly in causing possible confounding effects, makes interpretation of studies difficult. Apparently significant individual differences in susceptibility, and uncertainty about pathological mechanisms, also cause problems. This area has been the subject of several reviews (Attfield and Wagner 1998; Balmes et al. 2003; Becklake 1989, 1994; Hendrick 1996; NIOSH 1996; Oxman et al. 1993), some covering all exposures and some concentrating on mineral dusts.

As a result of difficulties in characterizing all the likely causative occupational exposures, few published papers provide information that com-
prehensively describes the risk of developing COPD as a result of work. The paper by Korn et al. (1987) has been used in this analysis, as it provides relative risk information covering all workplace exposures. This study (the methods of which were described in more detail in an earlier study by Ferris et al. 1979) used data from a random sample of white adults aged 25-74 years from six United States cities and their surrounding areas ( 8515 people were included in the final sample). The definition of COPD was $\mathrm{FEV}_{1} / \mathrm{FVC}<0.6$, representing reasonably severe disease. Logistical regression analyses were undertaken, determining the odds ratios for various respiratory conditions and controlling for age, sex, current and lifetime smoking history and city of residence. These odds ratios for COPD morbidity from Korn et al. (1987) were assumed to apply to COPD mortality.

The study by Korn et al. (1987) provides a strict definition of COPD and relative risks for both men and women, and was based on a large number of participants. This study was therefore used as the basis of the relative risk and attributable fraction estimates presented here. Relative risks for COPD prevalence were used as an approximation of the relative risks for COPD mortality.

Korn et al. (1987) found relative risks of COPD of 1.62 for men and 1.24 for women for a history of exposure to dusts. We partitioned these relative risks into high- and low-exposure categories, and also used slightly different relative risks for low exposure in developed and developing countries. In developing countries the great majority of low-exposure employment is in agriculture, where much dust is nonrespirable. In developed countries much of the exposure in the low categories is in industries other than agriculture, where a higher percentage of dust exposure may be respirable and toxic. It was assumed that the relative risks applied across all age categories. The estimated relative risks are shown in Table 21.27.

RISK REVERSIBILITY
As for carcinogens, there are limited data on risk reversibility. The studies from which the estimated risks arise are based on cohorts of people

Table 21.27 Annual risks of COPD mortality

| Relative risk | Developing countries |  | Developed countries (AMR-A, EUR-A, WPR-A) |  |
| :---: | :---: | :---: | :---: | :---: |
|  | Men | Women | Men | Women |
| Nonexposed | 1.0 | 1.0 | 1.0 | 1.0 |
| Low | 1.2 | 1.1 | 1.4 | 1.2 |
| High | 1.8 | 1.4 | 1.8 | 1.4 |

Source: Korn et al. (1987).
exposed for different periods of time, followed up for various periods of time and with various periods of time between exposure cessation and follow-up, with follow-up periods varying between zero (still exposed) and many decades. Therefore, most of the absolute and relative risks produced by the studies are already dependent on whatever change in risk might occur once exposure ceases. Indications of risk reversibility for COPD may be obtained from the literature on smoking.

## 4. Occupational noise

Noise is a common occupational hazard. The unit for sound (noise) level, whether measuring noise exposure or hearing loss, is the decibel (dB). Noise exposure levels as used in this document have the unit dBA. ${ }^{4}$ Noise-induced hearing loss is reported in dBHL. There is variability in the literature in the use of the terms to describe hearing ability. As used here, hearing loss refers to a decline in an individual's hearing ability. Hearing impairment refers to the effect of hearing loss on the individual's ability to function. The U.S. National Institute for Occupational Safety and Health (NIOSH) uses the term "material hearing impairment" ${ }^{5}$ to describe a hearing loss greater than 25 dB , and most occupational studies refer to 25 dBHL . The WHO definition used in this study is hearing loss greater than or equal to 41 dBHL . Therefore, extrapolations were made from the occupational studies to fit the requirements of the WHO study.

### 4.1 Exposure variable

The exposure variable used in this analysis is a direct measure of the risk factor, i.e. occupational exposure to noise, which is the causative agent of noise-induced hearing loss. As global data on the frequency of occurrence, duration and intensity of noise exposure do not exist, it was necessary to model this exposure for workers employed in various occupational categories. The theoretical minimum is based on expected background levels of noise, and consistency with national and international standards. Most experts agree that levels below 80 dBA would result in minimal risk of developing hearing loss.

For workers in various occupational categories, three levels of exposure were estimated:

- minimum exposure, less than 85 dBA ;
- moderately high noise, $\geq 85-90 \mathrm{dBA}$; and
- high noise, $>90$ dBA.

The choice of these levels was based on the recommended exposure limits (RELs) for occupational noise exposure around the world. In most developed countries the REL is 85 dBA as an eight-hour time-weighted average without hearing protection. In the United States the PEL is

90 dBA for an eight-hour day, although a hearing conservation programme is required for all employees exposed above 85 dBA for an eight-hour day. In developing countries, the REL is usually 90 dBA (Ahmed et al. 2001; Alidrisi et al. 1990; Hernandez-Gaytan et al. 2000; Hessel and Sluis-Cremer 1987; Osibogun at al 2000; Shaikh 1996; Sriwattanatamma and Breysse 2000).

Although the theoretical minimum exposure to noise was determined to be 80 dBA , it was not possible to estimate frequency of exposure by occupational category to occupational noise between 80 and 85 dBA . Therefore, persons with occupational exposure $<85 \mathrm{dBA}$ were included with the background population.

### 4.2 Estimating risk factor levels

## DATA SOURCES

Potentially useful studies were identified using the various approaches described in section 1. The key terms used were "occupational noise" and "occupational hearing impairment". Relevant studies were identified by critically appraising the references obtained. This included consideration of the approaches to selection, measurement, analysis and control of confounding. Potential confounders of noise-induced hearing loss include nonoccupational exposure to noise, undocumented occupational noise levels, use of personal protective equipment, use of some medicines, and outer- and middle-ear pathology. Recent review articles were used where available, and the main articles were obtained and appraised.

The main reason for excluding studies was that they did not contain data appropriate for determining risk of noise-induced hearing loss. Problems included an inappropriate (for this purpose) exposure measurement (such as reporting for only one or a few occupational groups or tasks); inappropriate (for this purpose) outcome measurement (such as dB per year loss with age or no data as to the number of cases vs total population); poorly characterized exposure or self-reported hearing loss; and inadequate control of confounding.

In the United States, about 9 million workers are exposed to timeweighted average sound levels of 85 dBA and above (Simpson and Bruce 1981, quoted in Suter 2000), and about 10 million have noise-induced hearing loss $>25 \mathrm{~dB}$ (USDOL OSHA 2002b). About 17\% of American "production workers" are exposed to average noise levels at or above 85 dBA (NIOSH 1998). In the European Union, $28 \%$ of workers surveyed reported that for at least $25 \%$ of the time they were occupationally exposed to noise loud enough to cause them to raise their voices during conversation (corresponding to approximately 85-90dBA) (EASHW 2000). The highest percentages of exposed workers were reported for mining, quarrying, manufacturing and construction. Australia compensates about 10000 people each year for noise-induced
hearing loss; evidence indicates that only one third of workers with noiseinduced hearing loss file compensation claims (NOHSC 1993). Summary statistics on noise exposure are not available for most industrializing and nonindustrialized countries. However, most published reports indicate that average noise exposure levels are well above the recommended occupational level in many industrialized countries, which is generally established at $85-90 \mathrm{~dB}$ for an eight-hour work day (Suter 2000; WHO/FIOSH 2001).

Information on noise exposures and noise-induced hearing loss in developing countries is given in Table 21.28. These studies are characterized by high occupational noise exposure levels, and many report hearing losses in exposed workers. The authors generally recommended engineering controls and hearing conservation programmes, including hearing protection, indicating that hearing protection is not widely used. Seventeen studies conducted in 12 countries in South America, Africa and Asia reported noise levels in a wide range of workplaces, including mining and the manufacture of food, fabrics, printed materials, metal products, drugs and watches. Most studies provided ranges of sound levels, with the lowest reported noise levels often below 80 dBA and the upper levels always above 90 dBA . All the studies that examined the hearing ability of workers revealed increased rates of hearing impairment in noise-exposed workers compared to nonexposed controls.

## Exposure estimation

Occupational exposure to elevated noise levels depends on a variety of factors, including (i) occupation and industry and (ii) workplace-specific factors such as type of facility and process, raw materials, machinery, tools, the existence of engineering and work practice controls, and the existence, condition and use of personal protective devices. Thus exposure assessment was conducted using the occupational category approach (Equation 2), modified to reflect different noise exposures in occupations in different economic subsectors.

Our estimation of the proportion of workers in each occupational category with exposure to noise at or above $85 \mathrm{dBA}(\operatorname{PEW}(\mathrm{oc}(\mathrm{r}, \mathrm{g}) \mathrm{i})$ ) was based on United States data on the prevalence of noise exposure at or above 85 dBA among production workers in nine economic subsectors (NIOSH 1998; USDHHS 1986) (see Table 21.29).

The prevalence values among production workers were calculated from the US National Occupational Exposure Survey conducted during 1981-1983 (NIOSH 1998), which estimated the number of production workers exposed to noise at or above 85 dBA , by economic subsector. All other prevalence values were estimated by us, based on the NIOSH values for production workers. The value of 0.20 calculated for production workers in agriculture was extrapolated to all agricultural workers in all economic subsectors. Similarly, the value of 0.12 for
Table 21.28 Studies of noise exposures and hearing impairment in selected developing countries

| Country or area | Facility/job | Sound levels | Hearing loss | Notes | Source |
| :---: | :---: | :---: | :---: | :---: | :---: |
| Brazil | Rotogravure printing workers | Continuous noise levels from 71 to 93 dBA | Some $49 \%$ of 124 workers exposed to noise and organic solvents had hearing loss ( $>25 \mathrm{~dB}$ ) in the high frequencies, significantly associated with age |  | Morata et al. (1997) |
| Egypt | Road traffic policemen in Cairo | Average 97 dBA with horns, 85 without; 97 at railway crossings | About 20-dB loss at all frequencies compared to office policemen |  | Kamal et al. (1989) |
| Egypt | Textile factory | 78-91 dBA in wool sorting and combing units | Compared to nonexposed controls, workers exposed to $<85 \mathrm{dBA}$ had only $1 \%$ increase in hearing impairment after 12 years. In workers exposed to $>85 \mathrm{dBA}$ the increased risk was $9.6 \%$ | Hearing impairment was defined as average of left and right ear thresholds at $0.5, \mathrm{I}$ and 2 kHz , $>25 \mathrm{~dB}$ | Moselhi et al. (1979) |
| Hong Kong SAR | Five industries: weaving, bottling, metal working, spinning, airport | $\mathrm{L}_{\text {eq }}$ (8-hour time-weighted average, dBA): weaving 102; bottling 94; metal working 96; spinning 97; airport 80-90 | Compared to controls, noise-exposed workers had significantly higher thresholds in most age groups and in all five industries, closely matching predicted values | No evidence was found for any ethnic differences between western groups and Cantonese Chinese, either in general hearing ability or in response to long-term noise exposure | Evans and Ming (1982) |
| India | Heavy engineering industry: machine shop and press divisions | Ranged from 83-116dBA. At selected work sites: press 94-110; machine shop 83-92; foundry 86-116 | Mean hearing threshold: 40 controls $4-24 \mathrm{~dB}$; 53 machine shop employees $14-40 \mathrm{~dB}$; 60 press employees 19-70 dB | Hearing impairment was progressive with age for all groups. Use of hearing protection was recommended | Raja and Ganguly (1983) |

| Country or area | Facility/job | Sound levels | Hearing loss | Notes | Source |
| :---: | :---: | :---: | :---: | :---: | :---: |
| Nigeria | Textile workers in five factories in Lagos | Continuous noise levels of 95-115dBA | Hearing thresholds of 61 noise-exposed workers were significantly higher than 90 nonexposed controls. After 7 years of employment, exposed workers lost $2-12 \mathrm{~dB}$ per year, compared to $0.6-1.8 \mathrm{~dB}$ per year in controls | No hearing protection worn. Exposed workers did not display $4000-\mathrm{Hz}$ notch, and the shape of the audiograms ${ }^{\text {a }}$ was convex upwards, indicating lower losses at the middle frequencies. (Typical audiograms with noise-induced hearing loss display a convex downwards shape, indicating higher losses at the middle frequencies) | Oleru (1980) |
| Pakistan | Polyester fibre plant | Average noise levels: filament take-up unit 93.2 dBA ; texturizing unit 94.8 dBA ; compressor house 99.5 dBA | - | Typical exposure is 48 hours per week in these areas. Author recommended engineering controls and hearing conservation, including use of hearing protection | Shaikh (1996) |
| Saudi Arabia | 78 factories producing food, chemicals, plastics, metals, paper and other products | $86 \%$ exceeded 85 dBA , at least in part of the factory. In 12\% all of the factory exceeded 85 dBA | - | None of the factories practised noise protection | Alidrisi et al. (1990) |
| Singapore | Audiometric testing of noise-exposed workers is mandatory in Singapore. Most cases of noise-induced | Noise dosimetry on 46 of these cases showed a mean time-weighted exposure of 90 dBA | 127 cases of NID identified from 1985-1994. On average, after 24 years of exposure, the mean hearing threshold at I, 2 and 3 kHz was 62 dB | Author stated that NID is the leading occupational disease in Singapore, with $>500$ new cases per year | Tay (1996) |

a Source: NIOSH (1998).
b Based on $1.5 \%$ of workers exposed to noise in "business services".
production workers in transportation was extrapolated to all sales and service workers. The value for professional, administrative and clerical workers was extrapolated from 0.02 indicated for production workers in business services. The remaining value, 0.05 for professional, administrative and clerical workers in agriculture, mining, manufacturing, electricity and construction, was based on expert judgement.

The prevalence values were then partitioned into moderately high and high noise exposures, i.e. $\geq 85-90 \mathrm{dBA}$ and $>90 \mathrm{dBA}$, to estimate the proportions of workers exposed to moderately high and high levels of noise (EPF(r), exposure partitioning factor). Data from the United States (USDHHS 1986), taken from the 1981 Occupational Safety and Health Administration Final Regulatory Analysis for the Hearing Conservation Amendment, provide the distribution of noise exposure of over nine million American production workers (see Table 21.30). Of the 6063000 production workers with exposure at or above 85 dBA , slightly over half ( 3407000 or $56 \%$ ) were exposed above 90 dBA . The distribution of noise exposure levels among workers exposed over 90 dBA was also used to determine that 95 dBA is a reasonable level of noise to estimate risks among the workers in the high-exposure group ( $>90 \mathrm{dBA}$ ).

The partitioning of workers by occupational category and noise level was assigned as follows, based on data in Table 21.30. Among production workers exposed at or above 85 dBA , half were considered to be exposed at $\geq 85-90 \mathrm{dBA}$ and half exposed at $>90 \mathrm{dBA}$. (Note that these partitioning values do not consider the use of personal protective equipment.) Of the agricultural workers and sales and service workers exposed at or above 85 dBA it was assumed, based on expert judgement, that approximately $70 \%$ are exposed at $\geq 85-90 \mathrm{dBA}$ and $30 \%$ at $>90 \mathrm{dBA}$.

All professional, administrative and clerical workers with noise exposure at or above 85 dBA were assumed to be at the $\geq 85-90-\mathrm{dBA}$ level. Tables 21.31 and 21.32 present the distribution of noise exposure levels among workers in the A subregions by occupational category within economic sectors.

In the absence of global data, it was assumed that the same proportion of workers in these occupational categories in the developing countries would be exposed to noise levels at or above $85 \mathrm{dBA}(\mathrm{B}, \mathrm{C}, \mathrm{D}$, and E subregions). Given the rarity of hearing conservation programmes in the developing subregions, it was assumed that $5 \%$ of production workers would be exposed in the $\geq 85-90 \mathrm{dBA}$ category and $95 \%$ in the $>90 \mathrm{dBA}$ category (as opposed to $50 / 50$ for the A subregions). Additionally, because mechanization is not widespread for D and E subregions, the majority ( $95 \%$ ) of the agricultural workers exposed at or above 85 dBA were assigned to the $\geq 85-90-\mathrm{dBA}$ level. Assignment of all

other occupational categories was the same as for the A subregions. Tables 21.33-21.36 reflect the different partitioning for the $\mathrm{B}+\mathrm{C}$ and D + E subregions.

Table 21.37 presents the proportions of workers exposed to moderately high and to high noise levels by subregion, age and sex. The proportions of males exposed to these noise levels were consistently higher than those of females, owing both to higher rates of participation in the labour force and to higher rates of females working in the services sector.

### 4.3 RISK FACTOR-DISEASE RELATIONSHIPS

High noise levels in the workplace may cause elevated blood pressure, sleeping difficulties, annoyance and stress. Excessive noise can interfere

with communications in the workplace, resulting in property damage or personal injury. Tinnitus ${ }^{6}$ and temporary threshold shift ${ }^{7}$ may also occur. However, the most serious effect is irreversible hearing impairment, resulting from damage to the delicate hearing mechanisms of the inner ear. Noise-induced hearing loss typically begins in the frequency range (pitch) of human voices and thus interferes with spoken communication.

Noise-induced hearing loss is caused by exposure to loud noises, such as those produced by woodworking equipment, chain saws, heavy machinery, gunfire, aircraft or amplified music. Permanent hearing loss from exposure to noise may happen quite early and an audiometric notch, or initial loss at or around 4000 Hz , may be noticeable within six

months to one year from starting a job with a hazardous noise exposure. There is significant variation in the susceptibility to noise damage, so that two workers with the same exposure may not experience the same hearing impairment. With prolonged exposure to the same noise, hearing loss continues to worsen. For a given noise environment, most of the hearing loss occurs in the first few years, although there is a slower continuing progression as long as the noise exposure continues.

When a person is removed from the noise, hearing loss does not worsen but does remain permanent. Any additional hearing loss after termination of work in a noisy environment is due to other causes, most often presbycusis (age-related hearing loss). Most people are subject to presbycusis, which is the most common form of sensorineural hearing impairment. Data show that from as early as 30 years of age, and gradually increasing in later years, some hearing loss occurs in the general population. Individual variation is great, with around $50 \%$ of the population maintaining good hearing into old age. Other factors, such as ear infection secondary to airborne contaminants, mechanical injury or chemical substances can lead to or aggravate hearing impairment in the workplace.

## DESCRIPTION OF STUDIES

In the literature review, only three studies were found that indicated the frequency of hearing impairment at different thresholds of hearing (Davis 1989; Malchaire 2000; Waitzman and Smith 1999). Malchaire compared the expected percentage of subjects who, at age 55 , presented with hearing impairment at 25 and 50 dBHL with the personal level of exposure (Lpe) to noise in dBA , in the absence of noises $>140 \mathrm{~dB}$. The exposure time frame was 35 years (Table 21.38).

Waitzman and Smith (1999) analysed data from the United States Health Examination Survey (1960-1961) and the National Health and Nutrition Examination Survey (NHANES I, 1971-1975). Hearing loss was rated by a scheme developed by Klockhoff et al. (1974). The Klockhoff analysis used four hearing loss levels (Slight, Moderate, Severe1, Severe2), which were related in this analysis to the standard hearing impairment scales by using typical noise-induced hearing loss curves. The categories developed by Klockhoff et al. were based on the frequencies used in the National Health Examination Survey (500, 1000, $2000,3000,4000$ and 6000 Hz ), and the NHANES I study (500, 1000, 2000 and 4000 Hz ). As an example of this conversion procedure, the criteria of Klockhoff et al. for slight hearing loss were based on a $30-\mathrm{dB}$ loss at 4000 Hz . Using audiometric data presented by Klockhoff et al. (1974), we estimated the equivalent hearing losses for each category as follows:

- Slight: $>21 \mathrm{dBHL}$
- Moderate: $>38 \mathrm{dBHL}$
- Severe1: $>41 \mathrm{dBHL}$
- Severe2: $>50 \mathrm{dBHL}$

Waitzman and Smith reported odds ratios calculated by multivariate regressions for two age groups for workers in construction, manufacturing/mining and other subsectors (see Table 21.39). Blue-collar construction workers experienced between 2 and $>3.5$ times the risk experienced by white-collar workers in "other industries". The pattern of their hearing loss at normal speech frequencies significantly disrupted their ability to communicate.

Davis (1989) reported on the prevalence of hearing loss as a function of age in the adult population of Great Britain. Audiometric analyses on adults ranging in age from 17 to $\geq 80$ years were conducted in four cities. Hearing impairment was reported for $>25,>45$ and $>65 \mathrm{dBHL}$. Davis found a "significant" level of hearing loss ( $>25 \mathrm{dBHL}$ ) in $16 \%$ of the adult population (17- $\geq 80$ years).

Table 21.39 Odds ratios from logistic multivariate regressions on audiometric measures of hearing loss, by age group

| Type of worker/industry | Ages 25-44 years |  |  |  | Ages 45-65 years |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | $\begin{gathered} \text { Slight } \\ >21 \mathrm{~dB} \end{gathered}$ | Moderate $>38 \mathrm{~dB}$ | Severe I $>4 I \mathrm{~dB}$ | $\begin{aligned} & \text { Severe } 2 \\ & >50 \mathrm{~dB} \end{aligned}$ | $\begin{gathered} \text { Slight } \\ >21 \mathrm{~dB} \end{gathered}$ | Moderate $>38 \mathrm{~dB}$ | Severe I $>41 \mathrm{~dB}$ | Severe 2 $>50 \mathrm{~dB}$ |

Several studies were found that presented relative risk estimates by specific occupation. The risk estimates were higher than those determined in this analysis for exposed workers, as they focused on occupations with generally high noise exposures. These studies were based in Canada (Hessel 2000), Germany (Arndt et al. 1996) and Great Britain (Palmer et al. 2001) (see Table 21.40).

In Germany, a prevalence ratio for hearing loss of 1.5 was found in construction workers vs white-collar employees. Hearing impairment was defined as the sum of thresholds at 2000,3000 and 4000 Hz greater than 105 dB at least in one ear. Hessel (2000), in a similar study in Canada, found that construction workers (with the exception of boilermakers) had a lower prevalence of hearing loss than the Germans. Also, prevalence of hearing impairment in the comparison group in Canada was lower than in Germany. According to the author, the differences found may be due to the year of the study. The Canadian study was carried out 7-9 years later than the German study, and there may have been lower occupational noise levels and/or use of personal hearing protection. These potentially confounding factors were not described in the German study.

In contrast to the Canadian and German studies, prevalence ratios determined in Great Britain were based on self-reported hearing impairment. Prevalence of "ever employed in a noisy job" was compared against "never exposed in a noisy job". A noisy place was defined as one "where there was a need to shout to be heard". The questions used to define hearing impairment were modelled on those used in the Institute
Table 21.40 Prevalence ratio of occupational noise-induced hearing impairment in available studies

| Country | Reference | Definition of hearing impairment | Occupation | Prevalence ratio | 95\% Cl |
| :---: | :---: | :---: | :---: | :---: | :---: |
| Canada (Edmonton) | Hessel (2000) | Greater than 105 dB hearing | Plumbers | 2.91 | - |
|  |  | loss at $2,3,4 \mathrm{kHz}$ (corresponds | Boilermakers | 3.88 | - |
|  |  | to > 35 dBHL ) | Electricians | 1.46 | - |
| Germany | Arndt et al. (1996) | Greater than 105 dB healing loss at $2,3,4 \mathrm{kHz}$ (corresponds to $>35 \mathrm{dBHL}$ ) | Carpenters | 1.77 | 1.48-2.12 |
|  |  |  | Unskilled workers | 1.75 | 1.47-2.09 |
|  |  |  | Plumbers | 1.49 | I.19-1.85 |
|  |  |  | Painters | 1.2 | 0.96-1.49 |
|  |  |  | Plasterers | 1.29 | 1.05-1.59 |
|  |  |  | Overall | 1.5 | 1.29-1.82 |
| Great Britain | Palmer et al. (2001) | Severe: wearing a hearing aid or having great difficulty in both ears on hearing conversation in a quiet room $>45 \mathrm{dBHL}$ | Male | 2.9 | - |
|  |  |  | Female | 1.8 | - |
|  |  | Moderate and worse: reported | Male | 3.6 | - |
|  |  | moderate difficulty in hearing conversation in a quiet room equivalent to 45 dBHL | Female | 2.9 | - |

[^81]of Hearing Research national survey of hearing, in which those who reported moderate or worse hearing impairment were found to have a mean hearing loss of 45 dBHL . The mean hearing loss of 45 dBHL is similar to the cut-off of 41 dBHL used by WHO and the Global Burden of Disease study, whereas the cut-off used in the German and Canadian studies corresponded to slight hearing impairment ( $>35 \mathrm{dBHL}$ ).

NIOSH, in a re-analysis of the data from its Occupational Noise and Hearing Survey (Prince et al. 1997) derived excess risk ${ }^{8}$ estimates with a model that used the average of $1000,2000,3000$ and 4000 Hz and a hearing loss $>25 \mathrm{dBHL}$. We used this information to develop excess risk estimates for workers exposed at $85-90 \mathrm{dBA}$ (defined by us as moderately high exposure) and $>90 \mathrm{dBA}$ (defined by us as high noise exposure, equivalent to 95 dBA ). To estimate excess risks for workers exposed to moderately high noise, we used the observed exposure-response relationships developed by NIOSH (1998) for workers of different ages who were exposed at 80,85 and 90 dBA for various numbers of years. The data show that at any noise level, hearing impairment increases with age and/or length of exposure. Also, the highest risk is found at the highest levels of exposure. Prince et al. (1997) found a small increase in excess risk in workers exposed to $80-84 \mathrm{dBA}$ vs a $<80 \mathrm{dBA}$ control group; however, these risk estimates are imprecise owing to the low numbers of workers in the study exposed to noise at these levels.

NIOSH (1998) also provides two data points of excess risk for workers exposed at 95 dBA for prolonged periods. Table 21.41 illustrates our estimation of excess risk of material hearing impairment at $>25 \mathrm{dBHL}$ for workers exposed at 95 dBA , based on these two data points. The excess risk value of $38.3 \%$ at 95 dBA for a 65 -year-old worker after 10 or more years of exposure was taken from NIOSH (1998), Appendix Table IV. In addition, an excess risk value of $19.5 \%$ was taken from the table for 30 -year-old workers exposed to noise at 95 dBA and for a duration of exposure of $5-10$ years. The values for $30-, 40-$ and 50 -year olds with $>10$ years of exposure were interpolated using the ratios of change of hearing loss with age at 90 dBA between each age group in Table 21.41. All calculations of NIOSH exposureresponse relationships were based on material hearing impairment at $>25 \mathrm{dBHL}$ and were adjusted by us to reflect noise-induced hearing loss at $\geq 41 \mathrm{dBHL}$.

The International Organization for Standardization (ISO) has also developed procedures for estimating hearing loss due to noise exposure. Their most recent model (referred to as the "1990-ISO model") and the 1997 NIOSH model (NIOSH 1998) are reasonably similar. Table 21.42 summarizes the excess risk estimates developed separately by NIOSH and ISO for material hearing impairment $>25 \mathrm{dBHL}$ caused by occupational noise exposure.

Table 21.4I Excess risk estimates for material hearing impairment $>25 \mathrm{dBHL}$, by age and duration of exposure

## EXtrapolating from risks at >25dBHL TO RISKS at $\geq 41$ dBHL

Occupational hearing loss is usually denoted as $>25 \mathrm{dBHL}$ but WHO uses $\geq 41 \mathrm{dBHL}$ as a cut-off point to estimate prevalence of hearing loss. Therefore, extrapolations were made from studies of occupational risks at $>25 \mathrm{dBHL}$ to estimate risk to workers of hearing loss at 41 dBHL or greater. Data from the USDOL OSHA 1981 Final Regulatory Analysis for the Hearing Conservation Amendment (NIOSH 1991) provided a means of adjusting the various reports based on material hearing impairment $>25 \mathrm{dBHL}$ to $>40 \mathrm{dBHL}$, a level of hearing loss assumed for this project to be equivalent to the WHO definition of $\geq 41 \mathrm{dBHL}$. As presented in Table 21.43, OSHA estimated the number of workers with various levels of hearing loss or impairment. The number of expected

Table 21.43 Hearing levels (dBHL) of 9368000 United States production workers with noise exposure levels of $\geq 80 \mathrm{dBA}$

| Hearing threshold level <br> $(I, 2$ and 3 kHz$)$ | Cumulative cases | Expected cases | Excess cases |
| :--- | :---: | :---: | :---: |
| $>15 \mathrm{~dB}$ (mild hearing loss) | $3735000(40 \%)$ | $2111000(23 \%)$ | $1624000(17 \%)$ |
| $>25 \mathrm{~dB}$ (material hearing impairment) | $2025000(22 \%)$ | $965000(10 \%)$ | $1060000(11 \%)$ |
| $>40 \mathrm{~dB}$ (moderate to severe hearing | $718000(8 \%)$ | $245000(3 \%)$ | $473000(5 \%)$ |
| impairment) |  |  |  |

Table 21.44 Estimated excess risk of incurring hearing impairment at 41 dBHL or greater over a 40-year working lifetime and at various average noise exposures

|  | Excess risk (\%) |  |
| :--- | :---: | ---: |
| Average daily noise exposure (dBA) | ISO | NIOSH |
| 90 | 7.6 | 11.2 |
| 85 | 2.7 | 3.6 |
| 80 | 0.4 | 0.4 |

cases (based on hearing levels of a nationwide sample of adults in U.S. Public Health Service hearing surveys) was subtracted to derive the number of excess cases at various levels of hearing loss or impairment in United States production workers (OSHA 1981, reported in NIOSH 1991).

Using the data in Table 21.43, a factor to correct excess risk data at $>25$ dBHL to WHO's excess risk at $\geq 41 \mathrm{dBHL}$ was determined as a ratio of the number of excess cases at $>40 \mathrm{~dB}$ divided by the number of excess cases at $>25 \mathrm{dBHL}$; i.e. 473000 divided by 1060000 yields a ratio of 0.446 . This correction factor of 0.446 was used to correct excess risk at $>25 \mathrm{dBHL}$ from the reported excess risk in Table 21.42 to the excess risk at $\geq 41 \mathrm{dBHL}$ as presented in Table 21.44 . As no additional data were available, the hearing impairment of production workers at $>40 \mathrm{dBHL}$ was assumed to be equivalent to the WHO definition of hearing loss of 41 dBHL or greater used in this project.

Excess risk estimates for hearing impairment at $\geq 41 \mathrm{dBHL}$ are presented in Table 21.45. They were generated by applying the same correction factor of 0.446 to Table 21.41.

## RELATIVE RISK ESTIMATION FOR NOISE INDUCED HEARING LOSS AT $\geq 41 \mathrm{dBHL}$

 The relative risk values were extrapolated using the following formula:Table 21.45 Estimated excess risk for hearing impairment at $\geq 41 \mathrm{dBHL}$, by age and duration of exposure

|  | Excess risk (\%) |  |  |  |
| :--- | :---: | :---: | :---: | :---: |
| Average daily exposure (dBA) | Age 30 | Age 40 | Age 50 | Age 60 |
| $5-10$ years of exposure |  |  |  |  |
| 95 | 8.7 |  |  |  |
| 90 | 2.4 | 4.3 | 6.4 | 7.1 |
| 85 | 0.6 | 1.2 | 1.8 | 2.2 |
| 80 | 0.1 | 0.2 | 0.3 | 0.4 |
| $>10$ years of exposure |  |  |  |  |
| 95 | 10.7 | 13.8 | 16.9 | 17.0 |
| 90 | 4.6 | 7.8 | 10.7 | 11.0 |
| 85 | 1.0 | 1.9 | 3.0 | 3.5 |
| 80 | 0.1 | 0.3 | 0.4 | 0.6 |

## Relative risk $=1+($ excess risk $/$ expected risk $)$

Excess risk is defined in this study as "the percentage of workers with a hearing impairment in an occupationally noise-exposed population, minus the percentage who would normally incur such impairment from aging in an unexposed population". The expected risk is the prevalence for the general unexposed population. While the NIOSH document provides the excess risk of the exposed population, the expected risk is not reported by NIOSH. Data from Davis (1989) estimates prevalence as a function of age in the adult population of Great Britain. The average prevalence for both ears for a noise-induced hearing loss of $>45 \mathrm{dBHL}$ was calculated by us for the general population, using the data from Davis (1989) and the methods described above to adjust NIOSH data for noise-induced hearing loss at $>25 \mathrm{dBHL}$ to generate Table 21.45. The results are reported in Table 21.46.

In our study, relative risks for the age groups $0-4$ and $5-14$ years were not estimated, as occupational risks are not present and/or data are unavailable on levels or length of exposure. In the calculation of excess risk, the age group 15-29 years was assigned the lowest excess risk value of 8.7 in Table 21.45 for age 30 with $5-10$ years of exposure. For the category of workers with moderately high noise exposure ( $85-90 \mathrm{dBA}$ ), the excess risk estimate is the geometric mean of the excess risk estimates for 85 dBA and 90 dBA for each age group (see Table 21.45).

The older age groups ( $30-44$ years, $45-59$ years, etc.) did not neatly fit the age categories in Table 21.45, so worker-population-weighted averages were constructed for excess risk values at the required ages. For example, the excess risk estimate for the age group 30-44 years, at 85-90 dBA , was calculated by first taking the geometric mean of the excess risk

Table 21.46 Prevalence of hearing loss at $>45 \mathrm{dBHL}$ for the general population of Great Britain

| Age group (years) | Prevalence |
| :--- | :---: |
| $I 7-30$ | 1.25 |
| $3 I-40$ | 1.90 |
| $4 I-50$ | 4.75 |
| $5 I-6 I$ | 6.40 |
| $6 I-70$ | 9.35 |
| $7 I-80$ | 16.55 |
| $\geq 8 I$ | 25.35 |

Table 21.47 Relative risks by age group and level of exposure

|  | Age group (years) |  |  |  |  |  |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: |
| Level | $15-29$ | $30-44$ | $45-59$ | $60-69$ | $70-79$ | $\geq 80$ |
| $<85 \mathrm{dBA}$ | 1.00 | 1.00 | 1.00 | 1.00 | 1.00 | 1.00 |
| $85-90 \mathrm{dBA}$ | 1.96 | 2.24 | 1.91 | 1.66 | 1.12 | 1.00 |
| $>90 \mathrm{dBA}$ | 7.96 | 5.62 | 3.83 | 2.82 | 1.62 | 1.00 |

estimates at 85 and 90 dBA , for people with $>10$ years of exposure in the 30 - and 40 -year-old categories. These values were then weighted by the worker population in the age groups 30-39 and 40-44 years. In a similar procedure, the prevalence values in Table 21.46 for the general population were adjusted to the same age groups. Relative risks for the age groups $70-79$ years and $\geq 80$ years were calculated from figures in Prince et al. (1997) and the prevalence data from Davis (1989). Table 21.47 presents the relative risks by age group and level of exposure.

## RISK REVERSIBILITY

It was assumed that risk reversibility following exposure removal was immediate. In other words, for those previously exposed who have not developed noise-induced hearing loss yet, the risk is removed after exposure removal (no new cases). Those with the condition, however, will continue to be affected by it.

## 5. OcCupational ergonomic stressors

The physical ergonomic features of work that are most frequently cited as risk factors for MSDs include a rapid pace of work and repetitive motion patterns; insufficient recovery time; heavy lifting and other forceful manual exertions; non-neutral body postures (either dynamic or
static); mechanical pressure concentrations; vibration (both segmental and whole-body); and low temperature. For the present analysis, the risk factor is exposure to the combination of occupational exposures that are implicated in the etiology of low back pain, including physical stressors and possibly psychosocial or work organization features as well.

### 5.1 Exposure variable

Assessing the fraction of back pain disorders that can be attributed to occupation requires that an indicator be identified that can be measured on a global scale and that can also be matched with data on known exposure-risk relationship(s). The various reviews of low back pain epidemiology have implicated an overlapping set of occupational exposures, such as lifting, forceful movements, awkward postures, whole-body vibration and perhaps psychosocial stressors. However, such exposures are rarely assessed in surveillance activities on a large scale, and thus data are not available for risk assessment calculations at the global level.

In contrast, low back pain (and other MSD morbidity) is commonly reported by broad industrial or occupational groupings. Thus, even though occupation is a less precise indicator of risk than a specific exposure, its widespread availability in administrative data sets and some epidemiological studies makes it useful in this context. Some epidemiological studies have also provided sufficient data to relate back pain to the same occupational categories. Occupation was therefore considered as a proxy for specific risk factors. The exposure variable is an occupational category with its assigned level of risk (low, medium or high rate of low back pain). This method thus required the assumption that the distribution of the combined individual risk factors is similar within each occupational group across geographical regions. This argument applies to psychosocial as well as physical exposures.

Given that differences can occur within occupations, the assumed homogeneity of occupational groups in their total exposure to ergonomic risk factors implies that differences in exposure among occupations are substantially larger than differences among workers within the occupation. Although this assertion appears self-evident, only a few investigators to date have examined it explicitly. Burdorf (1992) evaluated the homogeneity of the exposure to postural load on the back within and among four occupational groups, and reported that the exposure variability within occupational groups was small compared with differences among groups. The estimated contribution of the variance for postural load between occupational groups was the largest source of variance. Hollman et al. (1999) and Paquet et al. (1999) have similarly shown that, even within one subsector (health care and construction, respectively), differences in ergonomic exposures among jobs can be large relative to the variability within jobs. These studies provide strong evidence in support of the approach taken in this analysis. Although the literature is less conclusive regarding their effects, to the extent that any specific
ergonomic factor is etiologically important it is assumed to be internalized in the relative risks by occupation. At the same time, specific analyses at the national or local level could increase the precision by assessing specific physical risk factors at the workplace.

### 5.2 Theoretical minimum risk

For low back pain, "theoretical minimum risk" is considered to represent the level of disease that would occur in the population if all excessive physical workload were abated by effective implementation of ergonomic control measures. While interventions to reduce ergonomic stressors have not yet been widely implemented on a global scale, studies are available from selected settings demonstrating the great potential of exposure (and disease) reduction in this area. Certain interventions have shown that removal of ergonomic stressors can practically lead to the removal of back pain (or its reduction to negligible levels), which justifies the choice of theoretical minimum. For example, in jobs where the entire work activity consists of manually handling materials, lifting equipment can successfully reduce both the biomechanical exposure to the lower back and the risk of low back disorders (Marras et al. 2000).

Westgaard and Winkel (1997) reviewed 89 studies on ergonomic intervention studies, of which 20 were classified as mechanical exposure interventions and 32 as production system interventions. Most mechanical exposure interventions target the ergonomic exposure level directly, through redesign of the work station and work methods. The reviewers concluded that in work situations whose mechanical exposure level is initially high, a reduction in the level of mechanical exposure may be beneficial for musculoskeletal health. For comparison, several other risk factors considered in this chapter have not yet shown that interventions can have such highly effective results when applied to selected population groups.

Since occupation represents a proxy for the composite of etiological exposures, rather than being the exposure per se, it is not necessary that persons leave one occupation for another in order to achieve the theoretical minimum risk. Reduction in relative risk would occur through improved job design to reduce exposures within each occupational category. The number of individuals working in each category could remain constant, even though the nature of the risk in each category would change.

### 5.3 Estimating risk factor levels

Since data were not available worldwide on the prevalence of specific ergonomic exposures, occupations were grouped here by their risk of low back pain. Thus, for this outcome, estimation of risk factor levels is not independent of the levels of disease assigned to them in the next step (see section 5.4). The exposure assessment by occupation was utilized, as described in the Introduction. Using managers and professionals as a
baseline for comparison, epidemiological studies have indicated that clerical and sales workers have a slightly elevated risk, operators and service workers have a moderate risk, and farmers have the highest risk of low back pain (see section 5.4 for details).

The basic approach was to determine economic activity by subregion, age and sex, and then to determine the distribution of the working population in the various occupational categories. As each occupational category was assigned a single relative risk factor (based on methodology described below), it was not necessary to partition exposures into "high" or "low" levels.

The estimates of occupations with risk of low back pain were based on the published literature. The 1968 International Standard Classification Codes for Occupations utilizes the term "production workers", whereas the epidemiological studies refer to "operators". Based on the literature, we made the following assignments.

- Background exposure: professional and administrative workers
- Low exposure: clerical and sales workers
- Moderate exposure: operators (production workers) and service workers
- High exposure: farmers

The non-working population is not considered in this analysis, and is attributed the same relative risk as the background exposure category. It is likely that younger workers are represented more often in the production occupations, and that older workers have more opportunities to move into management and administration positions.

As seen from Table 21.48, the majority of the working-age population is employed in occupations with exposure to factors linked to low back pain. Males have higher exposure in general, owing to higher rates of participation in the labour force. Exposures are higher for men in the less developed subregions, owing to a higher proportion of workers in agriculture than in the more developed subregions.

### 5.4 RISK FACTOR-DISEASE RELATIONSHIPS

Pain in the soft tissues of the back is extremely common among adults. In the United States, the National Arthritis Data Workgroup reviewed national survey data showing that each year some $15 \%$ of adults report frequent back pain or pain lasting more than two weeks (Lawrence et al. 1998). Back pain is widespread in many countries, and is associated with substantial financial costs and loss of quality of life. In Canada, Finland and the United States, more people are disabled from working as a result of MSDs-especially back pain-than from any other group of diseases (Badley et al. 1994; Pope et al. 1991; Riihimäki 1995a). MSDs also constitute a major proportion of all registered and/or

compensable work-related diseases in many countries, representing a third or more of all registered occupational diseases in the United States, the Nordic countries and Japan (Bernard 1997; Pope et al. 1991; Vaaranen et al. 1994).

Guo et al. (1995) estimated that $65 \%$ of cases of low back pain in the United States are attributable to occupational activities. To date, there have been no other published estimates of the fraction of back pain (specifically) in the total population that is occupationally induced. However, low back pain was identified by the Pan American Health Organization as one of the top three occupational health problems to be targeted by surveillance within the WHO Region of the Americas (Choi et al. 2001).

Among MSDs caused by occupational ergonomic stressors, only low back pain is currently a separate category in the GBD database and could be assessed. For purposes of this chapter, low back pain is defined as all pain in the back that is not secondary to another disease or injury cause (such as cancer or a motor vehicle accident). This includes disk prob-
lems (displacement, rupture), sciatica and other sources of back pain. Cervical spine problems, such as neck pain or neck torsion problems, are excluded. This category of conditions is considered equivalent to what others have termed non-traumatic MSDs affecting the lower back.

In the epidemiological literature, MSDs of the back are often defined on the basis of pain reported on interview, usually with standardized study criteria referring to time of onset, frequency and/or severity of pain. Physical examinations have sometimes been used to supplement questionnaires, particularly to help localize the symptoms reported on interview and to rule out other causes of those symptoms. However, an important proportion of epidemiologically relevant (exposure-related) back disorders are negative on physical examination (e.g. Punnett et al. 1991) as well as on X-ray (e.g. Riihimäki et al. 1990). Most cases of low back pain cannot be diagnosed by objective criteria and are typically designated idiopathic or non-specific (Frank et al. 1995; Riihimäki 1991, 1995b), even if there are findings on examination or severe symptoms and loss of function.

It is difficult to measure directly the validity of questionnaire responses, since no consensus exists regarding a single "gold standard" against which all other measurements could be compared. The sensitivity and reliability of physical examination manoeuvres for identifying low back pain range from good to poor; not all pain results from known mechanisms for which there is a corresponding objective test (Deyo et al. 1992; Viikari-Juntura and Riihimäki 1999). Deyo et al. (1992) suggested that as many as $85 \%$ of cases of low back pain cannot be diagnosed because of the poor performance of examination and imaging tests.

A recent review by NIOSH (Bernard 1997) (see also below) emphasized that health outcomes defined subjectively should be included in any consideration of work-related back disorders. In 24 of the 42 epidemiological studies on low back pain reviewed, the health outcome was defined by reported symptoms on questionnaires or interview, ranging from any back pain to specific symptoms such as those consistent with sciatica. In several studies, MSD cases defined by symptoms alone and those defined by findings on physical examination have shown very similar associations with the ergonomic characteristics of subjects' jobs. Symptom-based case definitions generally appear to be both unbiased and more sensitive than those that require documented abnormalities on physical examination (e.g. Bernard et al. 1993; Punnett 1998; Punnett et al. 1991; Silverstein et al. 1986, 1987).

Other case definitions sometimes used epidemiologically include low back impairment or disability, typically indicated by reduced ability to perform activities of daily living or occupational tasks, work absenteeism and the seeking of medical care for back pain. Such behavioural measures, however, are less desirable than low back pain per se, because they are more distal from the direct morbidity and more likely to be affected by interpersonal variability (e.g. tolerance of pain before seeking medical
attention) or by differences in job demands (e.g. pain of the same severity may cause more low back disability in persons whose jobs are more demanding).

At the same time, there is a strong correlation between the frequency of musculoskeletal symptoms by occupation and the frequency of workers' compensation claims and recorded work-related repetitive trauma disorders in those same occupations (Fine et al. 1986; Silverstein et al. 1997). Outcomes such as days of restricted activity, long-term disability, health care utilization and use of medication are very common among people with back pain, indicating the public health importance and cost of these disorders even when self-reported pain is not confirmed objectively (Badley et al. 1994, 1995; Guo et al. 1999; Miedema et al. 1998; Punnett 1999; Westgaard and Jansen 1992).

Back pain has been defined operationally in various ways in epidemiological studies, including both prevalent and incident conditions. Variations in the definition are related to the recall period (e.g. pain now, or within the last week or the past year), the frequency or duration (e.g. at least three times in the past year, or lasting at least one week) and the severity (e.g. at least a "4" on a 7 -point pain intensity scale), among others. Even among studies that use similar definitions, prevalence estimates can vary substantially (Loney and Stratford 1999). However, for the purpose of evaluating the exposure-response relationship, as long as comparisons are made within a study population that has been evaluated with a consistent case definition, estimates of relative risk do not appear to be greatly affected (Ozguler et al. 2000).

## Evidence of causality

The evidence on low MSDs, including back pain, in relation to workplace factors has been thoroughly reviewed by NIOSH (Bernard 1997). The National Research Council, with the Institute of Medicine, has also published a comprehensive review of the evidence on MSDs in the workplace (National Research Council 2001). Strong or sufficient evidence was found for a number of risk factors at the workplace to be associated with back pain (Table 21.49). The National Research Council report (2001) summarized ranges of risk estimates for specific occupational stressors (Table 21.50).

In addition to these two comprehensive reviews from the United States, numerous other authors from Europe, Asia and Canada reviewed the same epidemiological literature or variously defined subsets, and most reached similar conclusions (e.g. Burdorf and Sorock 1997; Frank et al. 1996; Garg 1992; Hagberg et al. 1995; Hales and Bernard 1996; Hoogendoorn et al. 1999; Hulshof et al. 1987; Jensen 1988; Jin et al. 2000; Johanning et al. 1991; Lagerström et al. 1998; Nachemson and Jonsson 2000; Riihimäki 1991, 1995a; Viikari-Juntura 1997; Wikstrom et al. 1994). For example, in a systematic literature review that focused on 28 cohort and three case-control studies of highest methodological

# Table 21.49 Rating of evidence for causal relationships between specific occupational stressors and back disorders according to the NIOSH review 

| Strength of evidence | Specific stressor |
| :---: | :---: |
| Strong evidence ${ }^{\text {a }}$ | Lifting and forceful movements Whole-body vibration |
| Evidence ${ }^{\text {b }}$ | Awkward postures Heavy physical work |
| Insufficient evidence ${ }^{\text {c }}$ | Static work postures |
| Evidence of no effect ${ }^{\text {d }}$ | Other stressors |

|  | Strong evidence. A causal relationship is shown to be very likely between intense or long-duration exposure to the specific risk factor(s) and MSD of the back when the epidemiological criteria of causality are used. A positive relationship has been observed between exposure to the specific risk factor and MSD of the back where chance, bias and confounding factors could be ruled out with reasonable confidence in at least several studies. |
| :---: | :---: |
|  | Evidence. Some convincing epidemiological evidence shows a causal relationship when the epidemiological criteria for causality for intense or long-duration exposure to the specific risk factor(s) and MSD of the back are used. A positive relationship has been observed between exposure to the specific risk factor and MSD of the back in studies in which chance, bias and confounding factors are not the likely explanation. |
|  | Insufficient evidence. The available studies are of insufficient number, quality, consistency or statistical power to permit a conclusion regarding the presence or absence of a causal association. |
|  | Evidence of no effect. Adequate studies consistently show that the specific workplace risk factor is not related to development of MSD of the back. |
| Note: | In this review, 42 epidemiological studies were selected on the basis of the following criteria: (i) exposed and reference populations were well defined; (ii) MSDs of the back were measured by well defined, explicit criteria determined before the study; (iii) exposure was evaluated so that some inference could be drawn regarding repetition, force, extreme joint position, static loading or vibration and lifting tasks; (iv) study participation of more than $70 \%$. Thirty studies used a cross-sectional design and five a prospective cohort, four were case-control studies and two were retrospective cohorts. Full descriptions of these studies appear in Table 6-6 of the NIOSH review. Criteria for causality were based on strength of association, consistency, specificity of effect or association, temporality, exposure-response relationship and coherence of evidence. |
|  | Bernard |

quality, Hoogendoorn et al. (1999) found strong evidence for manual material handling, bending and twisting and whole-body vibration as risk factors for back pain. They found moderate evidence for patient handling and heavy physical work, and no evidence for standing or walking, sitting, sporting activities and total leisure-time physical activity. Specific psychological stressors, supported by weaker evidence, were reviewed by Burdorf and Sorock (1997), and are shown in Table 21.51.

Some of the results of these reviews on specific stressors were obtained from studies that were conducted within various occupational groups, such as operators, mine workers, dentists, office workers and nurses. The evidence presented above implies that preventive interventions reducing the exposure to these risk factors would decrease the occurrence of back disorders considerably, even within an occupation.

Table 21.50 Summary of epidemiological studies with risk estimates of null and positive associations of work-related risk factors and the occurrence of back disorders

| Work-related risk factor | Risk estimate expressed in relative risk or odds ratio |  |  |  | Attributable <br> fraction (\%) |  |

Table 21.5I Summary of epidemiological studies on associations between specific occupational psychological risk factors and the occurrence of back disorders

Furthermore, there is sufficient evidence on biomechanical risk factors to conclude that many cases of low back pain could be prevented by workplace changes. For example, Marras et al. (2000) showed that lifting equipment and other engineering controls had demonstrable effects on lowering both biomechanical exposure to the lower back (compressive force, torque, etc.) and reported rates of low back disorders in 36 repetitive manual material handling jobs at 16 different companies.

The reviews by the National Research Council (2001), Westgaard and Winkel (1997) and Frank et al. (1996) each cited a number of well designed studies that identified opportunities to prevent risk of low back pain by reducing exposure to biophysical and psychosocial factors. To illustrate the improvements that can be obtained by reducing ergonomic stressors at work, selected interventions and their impact are shown in Table 21.52. Certain interventions have practically completely removed ergonomic stressors from the workplace.

Despite this extensive literature, some still dispute the importance of these factors, especially in relation to nonoccupational causes (e.g. Battie and Bigos 1991; Nachemson 1999; Waddell 1991). There are probably several interrelated reasons for the continuing controversy, many of which have been discussed by others (Frank et al. 1995, 1996; ViikariJuntura and Riihimäki 1999). The available epidemiological evidence still consists largely of cross-sectional and retrospective case-control investigations. With regard to assessment of morbidity, the use of selfreported symptoms for end-points has also generated discussion, as described above. Sparse longitudinal data leave important gaps in knowledge concerning latency of effect, natural history, prognosis and potential for selection bias in employed populations (e.g. the "healthy worker effect"). Few studies have attempted systematically to describe these features of back disorders in populations with defined levels of exposure to ergonomic stressors. Specific, quantitative comparisons of conclusions based on prevalence and incidence data within the same population are rare, and knowledge is still sparse as to the factors that predict recovery or persistence among workers who continue in their jobs after the onset of a disorder. No study has been identified that compares current and former workers with reference to both prior MSD morbidity and exposure status.

In addition, there are many known or suspected nonoccupational risk factors; some study populations have not provided enough statistical power to address potential confounding and effect modification of expo-sure-response relationships. Exposure assessment has often been limited, with too few exposures characterized to rule out confounding, or the use of crude exposure indicators leading to potential misclassification and unreliable conclusions. Attempts to partition risk between physical and psychosocial domains have obscured the overlap between the two and the distinction between preventable and nonpreventable risk factors (Bongers et al. 1993; MacDonald et al. 2001; Volinn and Punnett 2001; Volinn et al. 2001).

In the light of these issues, it is important to restate that the issue is not whether all back disorders are caused by work; there is a clear consensus that this is not the case. Nevertheless, most investigators and reviewers have concluded, equally clearly, that a large proportion of back disorders among persons with high exposure to ergonomic stressors at work could be prevented by reducing those exposures.
Table 21.52 Selected intervention studies on occupational ergonomic stressors and reduction of occurrence of low back pain

| Job title/activity | Intervention: engineering/administrative control | Outcome | Study ${ }^{\text {a }}$ |
| :---: | :---: | :---: | :---: |
| Nursing assistants (in two nursing home units) | Introduction of walking belts, mechanical hoists and shower chairs | Back injury incidence reduced from 83 to 42 per 100 full-time equivalents | Garg and Owen (1994) [Ex. 26-14I5] |
| Poultry processing employees | Introduction of workstation analysis and redesign, including altering heights of products, providing workstands, and installing tank tilters to reduce manual handling | Back injury rates declined from 4.4 to 3.0 per 200000 hours | Stuart-Buttle (1994) [Ex. 26-1045] |
| Office furniture manufacturing assembly workers | Scissor lifts installed to aid in packaging file cabinets of different sizes; small-assembly workstations altered to eliminate twisting and bending during lifting | Back injuries cut by 50\% | LaBar (1991) <br> [Ex. 26-1078] |
| Metal castings, unpacking operation | Crates modified by adding gates at each end and installing scissors lift to lift crates; changes made in the way castings were stacked in the crates to permit workers' arms to remain close to the body while unpacking | Back injuries associated with this operation eliminated | Oxenburgh (1994) [Ex. 26-104I] |
| Palletizing operation | Scissors lift table with turntable tops installed alongside each packing station | Five out of six back injuries eliminated | $\begin{aligned} & \text { Benson (1987) } \\ & \text { [Ex. 26-1062] } \end{aligned}$ |
| Lamp manufacturing | Addition of vacuum hoist; reduced equipment height; reduced box size and weight; introduction of back awareness programme for employees | Back and upper extremity disorders eliminated in the last four years | Carreau and Bessett (1991) [Ex. 26-107I] |
| Unpacking car parts | Plywood sheets modified to reduce weight and permit them to slide more easily in the grooves | Back injuries associated with this operation eliminated | Oxenburgh (1991) [Ex. 26-I04I] |

## OTHER OUTCOMES

Although the present analysis was limited to low back pain, the evidence on MSDs caused by occupational ergonomic stressors is broader. MSDs affecting the neck and the upper and lower limbs result from the same risk factors as are implicated in low back pain. For example, in a study of over 10000 manufacturing employees, the effect of "greater physical demands" of the job on low-back musculoskeletal injuries (relative risk of $1.6,95 \%$ CI 1.2-2.1) was only slightly higher than that for all other musculoskeletal injuries combined (relative risk of 1.4, $95 \%$ CI 1.1-1.7) (Tsai et al. 1992). De Zwart et al. (1997), studying over 7300 men in the Netherlands, found higher prevalences of shoulder disorders among employees in heavy physical work (e.g. heavy lifting and frequent stooping) and steeper increases over four years than among employees in less physically demanding jobs. The magnitude of these effects was very similar to those for low back injuries. The work-relatedness of upper and lower extremity MSDs has been discussed extensively, again by European as well as North American reviewers (e.g. Armstrong et al. 1993; Bernard 1997; Bongers et al. 1993; Buckle and Devereaux 1999; Hagberg et al. 1995; National Research Council 2001; Sluiter et al. 2000).

Also excluded here are other types of health effects related to ergonomic stressors, such as acute workplace injuries, cardiovascular disease, mental health and adverse reproductive effects (Punnett 2002). Thus, the total impact of excessively strenuous work activities on morbidity and related quality of life is greater than that estimated in this risk assessment.

## Hazard estimates

## Data sources

For the purposes of this analysis, studies were sought that compared the risk of low back pain among broad occupational groups (defined similarly to the economic subsectors explained above) and comprehensively enough to cover the range of paid occupations. Smaller, more specific studies limited to relatively narrow occupational groups (e.g. nurses, dock workers, drivers) were checked for consistency with the larger data sets. Studies where the reference groups were also engaged in substantial physical activity (e.g. house painters) were excluded. The most recent literature (1997-2001) was searched for exposure data and exposurerisk relationships, and published statistics of national occupational health and safety institutes were consulted.

In addition to this systematic search, a number of reviews and studies were identified to provide evidence supporting the selected approach. Search strategies were described in the Introduction. Medline was searched for articles more recent than 1985, using any of the keywords back pain, back disorder, back or musculoskeletal combined with any of
the following: occupation, occupational, workplace, work, workers, risk factors, risk.

## Description of literature

The studies specifically referred to in this section are summarized in Table 21.53.

The report of the National Research Council (2001) stated that the occupations with the highest risk among men were construction labourers, carpenters and industrial truck and tractor equipment operators, while among women they were nursing aides/orderlies/attendants, licensed practical nurses, maids and janitor/cleaners. Other high-risk occupations were hairdressers and automobile mechanics, often employed in small businesses or self-employed. No rates were listed against occupations in the report. The report stated that the highest-risk industries for men were lumber and building material retailing, crude petroleum and natural gas extraction and sawmills/millwork. Among women, the highest-risk industries were nursing and personal care facilities, beauty shops and motor vehicle equipment and manufacturing. No rates were listed for industries in the report.

Leigh and Sheetz (1989) measured low back pain on the basis of a national survey and a self-reported statement regarding "trouble with back or pain during the last year". They estimated relative risks by comparing the outcome frequency among occupational groups, using managers as a reference group (Table 21.54). This chapter places great weight on this study, because it was relatively large ( 1404 participants) compared to many others, it covered a comprehensive sample of occupations, and the results were adjusted for potential confounding variables. One important limitation, however, is that the multivariate analyses simultaneously included two ratings of physical exposure, socioeconomic status and occupational title. Since physical exposure is hypothesized to be the primary pathway through which occupational differences are manifested, these analyses would certainly lead to an underestimation of the effect of occupation on MSDs.

Although operators and service workers have very similar relative risks, it is common that intervention strategies differ among these occupational settings. For that reason, the relative risks and exposure assessments for those two occupational groups are presented separately throughout this analysis.

Within the limits of the available literature, the results of the Leigh and Sheetz analyses appear to be generally consistent with other reported relative risk values (Table 21.55). Since many other studies used office workers or other sedentary occupations as the reference group, it is appropriate to adjust the Leigh and Sheetz findings for comparative purposes. This can be done by dividing the relative risks for categories 3, 4, and 5 by 1.38 (the relative risk for clerical or sales work), in order to estimate a relative risk with clerical jobs as the reference group. The new
Table 21.53 Key studies and reviews on work-related back pain

Source: Based on data from Leigh and Sheetz (1989).
values would be $1.73,1.93$ and 3.75 , respectively. Keeping in mind that these estimates represent the average values for the entire occupational category, it can be seen that the other studies cited fall within the CIs, with very few exceptions, and in fact generally have similar point estimates (Table 21.55).

The only study that can directly and numerically be compared to that of Leigh and Sheetz (1989) is that by Leino-Arjas et al. (1998). However, the only value corresponding directly to one of the categories of Leigh and Sheetz is that for farmers. The relative risk is lower (2.13) than the one put forward by Leigh and Sheetz (5.17), which may reflect better working conditions for farmers in Finland. For this analysis we therefore used the average of these two results (see below).

Also available are administrative statistics from several countries on the number of cases of back conditions. These are generally compiled from employers' surveys or compensation statistics and typically report lower rates than those assessed by population surveys. Rates for certain occupations, as compared to managers and professionals, can be estimated on the basis of these statistics. Table 21.56 summarizes administrative workplace statistics on conditions involving the back, based on reports by employers in the United States of work-related injuries (Bureau of Labor Statistics 2001) and compensation statistics of the Australian workforce (National Occupational Health and Safety Commission 2001) and of the German national workforce (Bundesverband der Betriebskrankenkassen 2001).

All three of these data sets show higher risks for occupations other than managers and professionals, although the point estimates vary somewhat. None of these frequency estimates is adjusted for potential confounding variables. The incidents assessed in the first two data sets are limited to cases that have been recognized as work-related cases and involve behaviour such as absence from work or filing a claim against the employer. In contrast, the German study sought to assess the health status of the population more comprehensively and these data are

Table 21.57 Exposure categories and relative risks of low back pain for occupational groups selected for this analysis, with managers and professionals as the reference group

| Exposure category | Relative risk | $95 \% ~ C l$ | Occupational activity |
| :--- | :---: | :---: | :--- |
| Background | 1.0 | NA | Managers and professionals |
| Low | 1.38 | $0.85-2.25$ | Clerical and sales workers |
| Moderate | 2.53 | $1.09-5.69$ | Operators and service workers |
| High | 3.65 | $1.57-17.0$ | Farmers |
| NA Not applicable. |  |  |  |
| Source: Exposure level adapted from Leigh and Sheetz (1989). |  |  |  |

therefore likely to be more comparable to those reported by Leigh and Sheetz. The values are, in fact, relatively close except for agricultural workers.

Given that the study by Leigh and Sheetz (1989) best fits the format required for this analysis, and the supporting evidence displaying very similar quantitative values, the proposed exposure categories and attributed relative risks are displayed in Table 21.57. The value for farmers is provided by an average of the relative risks for farmers in the Leigh and

Sheetz (5.17) and Leino-Arjas et al. (2.13) studies, resulting in a relative risk of 3.65. The CI, however, remains the same, because the CI from the Leigh and Sheetz study (1.57-17.0) includes the CI provided by Leino-Arjas et al. (1.6-2.9) and is wider, which is probably a truer representation of the statistical uncertainty of this estimate.

## Methodological quality of the literature

Many of the reviews cited above used systematic criteria to evaluate the potential for selection bias, information bias and confounding in the individual investigations. Several of them identified the methodologically stronger studies and relied primarily or exclusively on those to draw conclusions about the strength of the evidence.

Potential confounding by nonoccupational factors such as sex, age, anthropometry, smoking, heredity and general medical history was extensively investigated in the great majority of studies cited above. All of the studies on which NIOSH relied most heavily, as being rigorous and methodologically sound, controlled for multiple potential confounding variables, permitting the conclusion that physical job factors cause low back pain independently of other factors. Burdorf and Sorock's (1997) review also summarized the associations between low back pain and specific occupational exposures, and relied more heavily on data with adjustment for important covariates. For example, Smedley et al. (1995) adjusted for age, height and nonmusculoskeletal symptoms (the only nonoccupational factors associated with low back pain-see below) in their analysis of low back pain and patient handling demands among female nurses. Tsai et al. (1992) examined the effect of greater vs less physical demands in the job, adjusting for six nonoccupational covariates.

Leigh and Sheetz (1989) adjusted for sex, race, education, height and smoking. In addition, they included terms for occupation and for physical effort and repetitive work; this means that the effect of occupation is likely to be underestimated, since the primary intermediate variable (physical effort) was also included. There is also a great deal of discussion in the epidemiological literature about the mechanisms of the effect of socioeconomic status (see below). It could easily be argued that the inclusion of terms for education also results in overadjustment, since a lower level of education is strongly associated with employment in "unskilled" jobs with higher physical exposures and is likely to act at least in part through such limited job opportunities.

Ozguler et al. (2000) analysed multiple low back pain case definitions. The same set of covariates was examined for each one, and all those nonoccupational factors (sex, age, obesity, psychosomatic "well-being") that were associated with low back pain were kept in the model. Like that of Leigh and Sheetz, this study overadjusted the estimates for occupation, because exposure variables such as carrying heavy loads and bending posture were entered in addition to the occupation indicators.

Many investigators have treated socioeconomic status and sex as potential confounding variables that require adjustment in statistical analysis of MSD etiology. However, to the extent that these factors act through or are surrogates for working conditions, both physical and psychosocial, such analyses may in fact serve to obscure the role of those exposures. Both the incidence and the severity of low back pain show an inverse gradient with socioeconomic status (blue collar vs white collar jobs, income, education level) in both men and women (Bergenudd and Nilsson 1988; Broersen et al. 1996; Heistaro et al. 1998).

It seems highly plausible that a large part of the gradient of socioeconomic status in MSDs is due to differences in the work performed, since jobs with lower socioeconomic status consistently involve more physically strenuous and repetitive work (Behrens et al. 1994; Hollman et al. 1999). In a large study of metal working employees, psychosocial conditions at work and physical load were generally correlated with each other and were worse for blue-collar than for white-collar employees, as well as for women compared with men (Leino and Hänninen 1995). In each of these subgroups, adverse working conditions predicted the development or worsening of MSDs over a 10-year follow-up period. The effect of social class was not explained by "lifestyle" factors such as smoking, leisure-time physical activity, body mass index, alcohol consumption or marital status (Leino-Arjas et al. 1998).

## Sex differences

Sex is also often described as a "risk factor" for MSDs. In the great majority of studies relied on here, either the population was restricted to one sex or relative risks were adjusted for sex. However, in most studies of low back pain the prevalence was the same or only slightly higher in men than in women (e.g. Behrens et al. 1994; Guo et al. 1995; Morken et al. 2000; Tsai et al. 1992). Skovron et al. (1994) found a higher prevalence among men than among women aged 20-49 years, whereas from 50 years of age the prevalence in women gradually increased relative to that in men. Thus sex is not a strong risk factor for low back pain in any case, and confounding of these effect estimates is not of concern.

Women and men typically experience qualitatively and quantitatively different working conditions (Punnett and Herbert 2000). Women are overrepresented in "light", monotonous jobs that require precise, repetitive hand motions with less latitude for decision-making. Men are more often found in jobs with heavy whole-body workload, such as manual materials handling. In general, once job assignments and the consequent occupational exposures are taken into account, sex differences become negligible (Punnett and Herbert 2000).

Table 21.58 Prevalence and attributable risk of joint pain at 6 and II years after retirement, among workers with prior exposure to "heavy physical work"

|  | Interview I (after 6 years) | Interview 2 (after II years) |
| :--- | :--- | :---: |
| Men |  |  |
| Exposed | $58 \%$ | $75 \%$ |
| Unexposed | $49 \%$ | $57 \%$ |
| $\quad$ Attributable risk | $15.5 \%$ | $24.0 \%$ |
| Women |  |  |
| Exposed | $87 \%$ | $91 \%$ |
| Unexposed | $68 \%$ | $79 \%$ |
| Attributable risk | $21.8 \%$ | $13.2 \%$ |

Source: Derriennic et al. (1993).

## Estimates of risk reversibility

Although no explicit studies have been carried out on low back pain attributed to occupational factors before retirement, it has been assumed that leaving the job would reduce the risk of back pain. The burden of work-related back pain would diminish gradually once the theoretical minimum exposure was reached. Since the theoretical minimum is zero, no new cases would arise. However, morbidity from past exposure might persist or worsen after retirement (Derriennic et al. 1993; Holte et al. 2000; Sobti et al. 1997).

Derriennic et al. (1993) defined a closed cohort of retirees from mixed occupations in France, with an average elapsed period of six years from retirement (at age 63) to the baseline survey. A follow-up survey was conducted after five years. Joint pain was reported by $29 \%$ of men and $42 \%$ of women at baseline. At 11 years post-retirement, the attributable risk was even higher among men, although it decreased in women because of the high prevalence of joint pain among unexposed persons (Table 21.58).

In summary, there are few or no epidemiological data on whether or not new back disorders develop after leaving work that can be attributed to ergonomic stressors in previously high-exposed (vs low-exposed) workers. Thus, we have assumed the work-related incidence to be zero after retirement from paid employment. However, we do have the high impact of interventions on exposed workers, which supports a reversibility of $100 \%$. This means that the incidence of low back pain is zero for chronic and acute cases of low back pain after exposure ceases. However, chronic low back pain will continue (i.e. the incidence will be zero, but those who have already developed it will continue to experience it).

## Extrapolation of risk factor-disease relationships from one subregion to another

Because occupational group was used as an indicator of the average level of combined risk factors for low back pain within each occupation, differences in distribution of risk factors that might exist within occupations or between countries are an important consideration. Risk ratios among occupations vary somewhat from one country to another. This could be due to differences in distributions of risk factors for low back pain, or regional or cultural divergences in symptom reporting. These discrepancies become even more difficult to interpret when the comparisons are made between developing and developed countries. Unfortunately, the data are sparse regarding cross-national differences, both in exposure distributions (within similar types of job) and in reporting of low back pain.

One important element is the extent to which ergonomic interventions have been implemented in the various countries or regions. Although there are insufficient data to quantify the extent of effective ergonomic programmes in each region, it is generally true that occupational health and safety legislation, enforcement and adaptation of engineering controls (ergonomic changes) tend to be more widespread in developed countries, especially in northern Europe followed by North America. If this is correct, then application of occupation-specific relative risks from developed countries (e.g. Leigh and Sheetz 1989) to developing countries would produce conservative estimates.

Similarly, it would be easy to assume that, because of mechanization and other changes in production technology, more developed countries would typically have fewer ergonomic stressors in the same type of work than developing countries, even without intention to reduce ergonomic stressors. For example, Bao et al. (1997) compared shoulder-neck ergonomic exposures in a Chinese and a Swedish assembly line workplace. The Swedish workplace had a better ergonomic workstation design and was better balanced, as well as less sensitive to production irregularities, than the Chinese workplace. The Swedish operators were less exposed to awkward postures during work.

However, in contrast to the general assumption that low back pain rates should be higher in low-income than in high-income countries, a systematic review by Volinn (1997) showed 2-4 times higher rates among Belgian, German and Swedish general populations than among southern Chinese, Philippine, Indonesian and Nigerian farmers. Mentioning that the prevalence of low back pain is higher in the urban populations of low-income countries, and sharply higher in enclosed workshops in low-income countries compared to low-income rural populations, Volinn suggested that low back pain might be associated with urbanization and rapid industrialization, which imply more repetitive movements and loss of control over work pace and scheduling. The author noted that interpretation of the findings requires consideration of

Table 21.59 Comparison of ranges of effect estimates for selected risk factors for low back pain in some working populations of China, India and the Russian Federation

|  | China, India, Russian Federation |  |  | Developed countries $^{\mathrm{a}}$ |  |
| :--- | :---: | :---: | :---: | :---: | :---: |
| Risk factor | Studies (n) | POR range |  | Studies (n) | POR range |

[^82]the methodological quality of population surveys, such as sampling procedure, formulation of questions, procedures for administration of the survey, and nonresponse bias.

Little information on risk of low back pain by occupation is available from developing countries, in particular studies that would pass the quality criteria of the NIOSH or National Research Council reviews. One summary of the literature from China (Jin et al. 2000) reported risk factors for back pain similar to those reported in developed countries. However, in a comparison of the effect estimates for specific risk factors, the authors found slightly higher prevalence odds ratios (POR) in Chinese low back pain studies than other studies (Table 21.59). Alternative explanations would include unmeasured confounding or effect modification. Studies on occupational back pain performed in developing countries do generally report prevalences of back pain within specified occupations, but without comparing them to a reference group (Chiou and Wong 1992; Chiou et al. 1994; Joshi et al. 2001; Kumar et al. 1999; Muruka 1998; Omokhodion et al. 2000; Toroptsova et al. 1995; Yip 2001). Prevalences were generally high for the studied groups, but the lack of comparison to reference groups did not allow conversion into relative risk information, which was necessary for this analysis.

In summary, plausible arguments can be and have been advanced in favour of low back pain rates in specific occupational groups (farmers, factory workers, etc.) being both higher and lower in developing countries compared with developed countries, but the available data permit neither confirmation of this nor quantification of the differences in risk.

## 6. Occupational risk factors for injuries

Workplace injuries are a common hazard for workers. Deaths due to occupational injuries are defined as any potentially avoidable death due
to an external cause resulting from an exposure related to the person's work. The definition excludes death during commuting to or from the workplace. Workers travelling for work purposes are included.

Data in developed countries indicate that differential risks for injury exist by sector, being highest in agriculture and production, less in sales and service, and lowest in professional, administrative and clerical sectors. But similar data are unavailable for developing countries. At the same time, occupational registries provide some indication of injury out-comes-vs risk factor exposure-which can be used to assess the mortality associated with occupational factors. Applying the fatality rates due to occupational injuries per 100000 insured workers (Table 21.60) to the number of persons in the EAP, as defined earlier in the chapter, gives an indication of total deaths from injuries among workers. The rates reported here for fatal injuries were reported in most countries only for insured populations. Thus, we made the assumption that the same rates applied to all in the EAP, whether or not they were insured, despite some evidence that fatality rates are higher in uninsured populations (Dror 2001; Forastieri 1999; Loewenson 1998). Unfortunately, there is a lack of adequate data on work-related injuries in developing countries to make it possible to generate plausible rates for economic sectors by age, sex and subregion. Mortality outcomes were distributed in the same age pattern as reported in the United States for unintentional injuries.

Because no risk factor exposure is defined in this approach, the counterfactual risk (e.g. theoretical minimum risk level) was defined based on the outcome rather than risk factor exposure. To approximate the safest working conditions observed where all avoidable injury hazards are controlled by effective preventive measures, we chose the injury fatality rate of 0.1 (per 100000 workers) in the age group 16-17 years and in the occupation category "service" from the National Traumatic Occupational Fatalities surveillance system for the United States for the period 1980-1995 (Marsh and Layne 2001).

### 6.1 Outcomes considered

The outcomes considered were unintentional injuries, which include motor vehicle accidents, poisonings, falls, fires, drownings and the category "other unintentional injuries". Other unintentional injuries comprise exposure to inanimate mechanical forces, exposure to mechanical forces, other accidental threats to breathing, exposure to electric current, radiation and extreme ambient air temperature and pressure, contact with venomous animals and plants, exposure to forces of nature and accidental exposure to other and unspecified factors. Homicide at the workplace was not assessed owing to a complete lack of data from developing countries. To estimate the impact of the disability produced by nonfatal injuries, years lived with disability (YLD) were estimated using

Table 21.60 Fatality rates due to occupational injuries (per 100000 insured workers) by country and year

|  |  | Fatality rate <br> per 100000 | Source |
| :--- | :--- | :--- | :--- |
| Country | Year(s) | I982-1984 | 8.06 |
| Australia | $1998-1999$ | 4.0 | Harrison et al. (1989) <br>  <br>  <br> Wustria |
| Worker's Compensation Cases |  |  |  |
| (NOSHC 2002) |  |  |  |

the same attributable fractions as for mortality (age and sex) (i.e. it was assumed that an occupational injury had the same likelihood of being fatal as injuries caused by other factors).

### 6.2 UNDERREPORTING

Conventional sources of data on fatal injuries at work are compensation registries, insurance companies, death certificates and autopsy reports based on mortuary records. Data from compensation registries and insurance companies underestimate the magnitude of fatal injuries, either because they do not cover some sectors of the workforce or because they refer only to successful claims. To improve the accuracy of the reporting of fatal injuries at work, many countries gather data from different systems and data sources (death certificates, insurance companies, labour inspectorates, coroners' files, medical examiners' files) or develop specific projects. Wide disparities exist regarding the accuracy of these sources in identifying fatal injuries at work.

Despite the usefulness of the death records, data from the United States reveal that such records identify only between $67 \%$ and $90 \%$ of fatal injuries at work. A similar underreporting $(72.3 \%)$ has been found in the Mortality Registry of Tuscany in Italy (Chellini et al. 2002). The only study in a developing country that analysed underreporting showed that $28 \%$ of occupational fatalities in Cape Town, South Africa had not been reported in terms of statutory regulations (Lerer and Myers 1994). The level of underreporting increases to between $78 \%$ and $85 \%$ in rural areas (Schierhout et al. 1997). On the other hand, special registries also underreport; the National Fund for Occupational Diseases in Italy, for example, has a reporting rate of only $56.4 \%$ (Chellini et al. 2002).

To our knowledge, the most accurate system currently in place that uses multiple data sources to identify and classify work-related injuries is in the United States. Data are gathered from death certificates in two surveillance systems: the National Traumatic Occupational Fatality System (NTOF) of NIOSH and in the Bureau of Labor Statistics CFOI system. Thus it would appear that the United States has fairly complete records of occupational deaths due to injury (CDC 2001). Although, owing to paucity of data, we did not use the estimates of underreporting to calculate the rates of fatal injuries due to risks at work, this does indicate likely underestimation.

## 7. Results

Tables 21.61-21.63 present the overall attributable fractions, mortality and burden of disease for the selected occupational risk factors considered here.

In total, occupational risk factors considered here were responsible for 775000 deaths worldwide in 2000. There were five times as many deaths in males as in females: 647000 vs 128000 . The leading occupational

Table 21.6I Attributable fractions (\%) for the disease burden due to occupational exposure

cause of death was COPD (41\%) followed by unintentional injuries $(40 \%)$ and trachea, bronchus or lung cancer ( $13 \%$ ). Workers who developed outcomes related to occupational risk factors lost about 22 million years of healthy life. By far the main cause of years of healthy life lost, within occupational diseases, was unintentional injuries (with $48 \%$ of the burden). This was followed by hearing loss due to occupational noise ( $19 \%$ ) and COPD due to occupational agents ( $17 \%$ ). Among the occupational factors analysed in this study, these three conditions accounted for $84 \%$ of years of healthy life lost. DALYs were almost five times greater in males than in females. Low back pain and hearing loss have in common the fact that they do not directly produce premature mortality, but substantial disability. This feature differentiates these conditions from the others analysed in the study. Results for specific risk factors are provided below.

### 7.1 Carcinogens

Tables 21.64-21.68 summarize the attributable fractions, mortality and burden of disease for the occupational carcinogens considered here.

For lung cancer, the attributable fraction varied from $5 \%$ in AMR-A to $14 \%$ in EUR-C, with overall attributable fractions for lung cancer estimated to be $10 \%$ for men and $5 \%$ for women ( $9 \%$ overall). For leukaemia, estimates of the attributable fraction varied from $1 \%$ in EMR-D to $3 \%$ in several subregions. There were estimated to be approximately 7000 deaths from leukaemia each year, with a much more even proportion between males and females than was seen for lung cancer, although approximately two thirds of the DALYs are due to male cases.

It was estimated that 38000 deaths ( 23000 men and 15000 women) and 1.6 million DALYs result from occupational asthma each year. One quarter to one third of the asthma deaths and DALYs occurred in SEAR-D. The attributable fraction for mortality from asthma varied between subregions from $11 \%$ in AMR-A and EUR-A to 20\% in AFR-E, with worldwide attributable fractions estimated to be $21 \%$ for men and $13 \%$ for women ( $17 \%$ overall). The overall attributable

fraction for asthma morbidity plus mortality was about two thirds of that for mortality, reflecting the fact that globally a great deal of asthma occurs at younger ages and is nonfatal and nonoccupational in origin.

For COPD mortality, the attributable fraction varied between subregions from 9\% in AMR-D to $16 \%$ in EUR-C and WPR-A (Table 21.69).

Table 21.74 Age-specific mortality attributable fractions, deaths and DALYs for asthma and COPD, females

|  | Age group (years) |  |  |  |  |  |  |
| :--- | ---: | ---: | ---: | ---: | ---: | ---: | ---: |
|  | $15-29$ | $30-44$ | $45-59$ | $60-69$ | $70-79$ | $80-89$ | All ages |

| $\quad$ Asthma | 6 | 5 | 5 | 6 | 6 | 6 | 6 |
| COPD |  |  |  |  |  |  |  |
| Deaths (000s) | 2 | 3 | 4 | 2 | 2 | 2 | 15 |
| $\quad$ Asthma | 0 | 1 | 6 | 13 | 28 | 30 | 78 |
| COPD |  |  |  |  |  |  |  |
| DALYs (000s) | 228 | 95 | 81 | 28 | 15 | 5 | 511 |
| Asthma |  |  |  |  |  |  |  |
| COPD | 45 | 133 | 149 | 152 | 166 | 69 | 713 |

Worldwide attributable fractions for COPD were estimated to be $18 \%$ for men and $6 \%$ for women ( $12 \%$ overall). Overall attributable fractions (based on DALYs and reflecting mortality and morbidity) were very similar to the mortality-based fractions (see Tables 21.69 and 21.70). The estimated number of deaths is almost an order of magnitude higher for COPD than for asthma, with an estimated 318000 deaths (240000 men and 78000 women) and 3.7 million DALYs resulting from occupational COPD each year. Half of the COPD deaths and half of the DALYs occurred in WPR-B, owing in part to the large population of the subregion, high background COPD mortality rates and the relatively high employment in mining.

For both asthma and COPD, males predominated. Compared to females, males had nearly $50 \%$ higher attributable fraction for asthma mortality and three times that for COPD mortality. The ratio was about two for disease burden. Similar ratios were seen for the estimated numbers of deaths and DALYs due to these conditions. Asthma deaths were fairly evenly spread among all age groups from 30 to 79 years of age, whereas DALYs predominantly involved persons aged $30-59$ years. For COPD, the majority of deaths occurred in persons aged $\geq 60$ years, whereas DALYs were more evenly spread among all age groups from 30 to 79 years of age (see Tables 21.73 and 21.74).

### 7.3 Noise

Occupational noise-induced hearing loss accounted for more than four million DALYs, all of them produced by the disability associated with hearing loss (YLD). Worldwide, the burden of hearing loss attributed to occupational noise is $16 \%$, ranging between $7 \%$ in WPR-A and $21 \%$ in WPR-B. By sex, the effects of exposure to occupational noise are larger for males than for females in all subregions (Table 21.75). Attributable fractions are related to age group and sex in all subregions. Males usually

[^84]experience greater exposure to noise at work than females, owing to differences in occupational categories, economic sectors of employment and working lifetime. In this study, the attributable fraction decreased with age group after 30-44 years, indicating the heavy impact of occupational noise on the burden of hearing loss at younger ages (Table 21.76). The $30-44$-year age group accounted for the highest number of DALYs and the $70-79$-year age group for the lowest ( 1673000 vs 32000 ).

Table 21.77 provides estimates of the number of DALYs (in thousands) produced by occupational noise-induced hearing loss by subregion in the year 2000. Overall, four million DALYs were lost owing to noise-induced hearing loss. SEAR-D and WPR-B accounted for more

than half of the years of healthy life lost ( 1.1 million each in SEAR-D and WPR-B). Males lost twice the number lost by females (2788000 vs 1362000).

### 7.4 Ergonomic factors

The attributable fractions for low back pain ranged from $22 \%$ to $41 \%$ among the subregions (Table 21.78). Differences by age group were quite small, and the attributable fractions for the total working population (ages 15-65 years) were rather consistent. In most geographical regions, women have a lower attributable burden of low back pain than men, although the difference is most pronounced in the eastern Mediterranean region and the less developed countries in the Americas.

Occupational ergonomic stressors caused 818000 DALYs due to low back pain in 2000 (Table 21.78). Globally, $37 \%$ of low back pain was attributable to occupational causes. The occupational contribution to the burden of low back pain varied relatively little between subregions, with $22 \%$ being the lowest (EMR-B) and $41 \%$ the highest (EUR-C and WPRB). The attributable fraction in men ( $41 \%$ ) was slightly higher than that in women $(32 \%)$, which is mainly due to the type of work men perform, involving more vibration, heavy physical loads or handling of materials.

### 7.5 Risk factors for injuries

Work-related risk factors for unintentional injuries represent $8 \%$ of the burden of unintentional injuries. In all regions, the highest attributable fractions were found in males, reflecting the high number of males exposed to hazardous conditions in the workplace. Overall, the attributable fraction for males was $12 \%$ and for women $2 \%$. Occupational injuries were responsible for 310000 deaths ( 291000 males and 19000 females).

In 2000, there were 10496000 years of healthy life (DALYs) lost among exposed workers (Table 21.79). Overall, males lost about 90\% of healthy life years owing to unintentional injuries at work.

## 8. <br> Discussion

We have attempted to estimate the burden of disease due to selected occupational risk factors by considering exposure, rather than the
common actuarial approach. In this study, a methodology based on the EAP, economic sectors and subsectors and occupational categories was developed to quantify the exposure. Assignment of exposure (low/high) within these categories allowed us to make estimations about the amount of exposure to a given risk factor or groups of risk factors causing an outcome. The dominant source of uncertainty in this analysis was characterizing exposure, which was solely based on economic subsectors and/or occupations and involved a large number of extrapolations and assumptions. High-quality exposure data are lacking, especially in developing countries, and European and American exposure estimates were thus applied in many instances in developing regions (B, C, D and E subregions). This extrapolation could have substantial impact on the accuracy of analysis for the developing regions if exposures, as usually occur, vary from place to place and over time. Diseases with long latency (e.g. cancers) are those that are more susceptible to the assumptions and extrapolations. In addition to problems produced by the length of the latency period, the magnitude of the excess risk may vary depending on the age of the person when exposure began, the duration and strength of exposure and other concomitant exposures. The turnover of workers is another problem that affects both exposure and risk assessment.

The accuracy of the exposure data is fairly coarse because exposures vary greatly within an occupation. This indirect estimation of exposure may cause misclassification of the true exposure situation. The proportions of exposed workers with high exposure in the A and in the $\mathrm{B}, \mathrm{C}$, D and E subregions were less than the published data would indicate. This may be partly because the published literature often focuses on industries and/or occupations with high exposure, but may also indicate an underestimation of true exposure.

Sources of uncertainty in hazard estimates (relative risk and mortality rates) include variations determined from the literature (once again caused by the use of different exposure proxies), extrapolations to regions with different working conditions, the application to females of risk measures from male cohorts, and the application of the same relative risk values to all age groups (e.g. carcinogens).

Restricting the analysis to persons aged $\geq 15$ years excludes the quantification of child labour. The exclusion of children in the estimation was due to the wide variation in the youngest age group for which countries reported EARs. In addition to inconsistent data on EARs for children, there was virtually no data available on their exposure to occupational risk factors or the relative risks of such exposures. Specific, focused research on children is needed to quantify the global burden of disease due to child labour and the resulting implications.

Owing to lack of global data, we could not analyse occupational contributions to the global burden of infectious diseases, cardiovascular dis-
orders, MSDs of the upper extremities, skin disorders and other conditions with recognized occupational etiologies.

### 8.1 Occupational carcinogens

For each condition, deaths were predominantly in older persons up to 79 years, whereas DALYs tended to be highest in the younger age groups. The estimated overall attributable fractions for lung cancer of $10 \%$ for men and $5 \%$ for women ( $9 \%$ overall) are similar to those from a recent United States study, based on a review of relevant studies, in which the attributable fraction for lung cancer was estimated to be between $6 \%$ and $17 \%$ for men, and to be about $2 \%$ for women (Steenland et al. 2003). A similar Finnish study used estimates of $29 \%$ (men) and $5 \%$ (women) but these included a contribution from environmental tobacco smoke, which the study estimated to be about $2 \%$ or $3 \%$ (Nurminen and Karjalainen 2001). (The United States study did not include any contribution from environmental tobacco smoke, but separately estimated the contribution of workplace environmental tobacco smoke to be $5.7 \%$ [Steenland et al. 2003]).

The estimated $2 \%$ attributable fraction for leukaemia compares with $0.8-2.8 \%$ for the United States (Steenland et al. 2003) and $18 \%$ (men) and $2 \%$ (women) for Finland (Nurminen and Karjalainen 2001). The higher Finnish estimate seems to arise from the inclusion of occupational exposure to electromagnetic fields, from the reliance on different studies for relative risk estimates, and from the exposure patterns in the Finnish population.

### 8.2 NONMALIGNANT RESPIRATORY DISEASES

Many of the issues relevant to a discussion of the results for particulates are also relevant to carcinogens, and were discussed in detail under that rubric. The estimated attributable fractions for asthma mortality of $21 \%$ for men and $13 \%$ for women ( $17 \%$ overall) are similar to those from two recent reviews, both of which found an occupational attributable fraction of $15 \%$ (Balmes et al. 2003; Blanc and Toren 1999). The Finnish study on which most of the occupational relative risk estimates used in this study were based had higher estimates for men ( $29 \%$ ) and women ( $17 \%$ ) (Karjalainen et al. 2002), but these estimates are based on Finnish workforce patterns, which are likely to differ from those in most other countries.

Estimates of the attributable fraction for COPD mortality varied between subregions from $9 \%$ to $16 \%$. The overall value of $12 \%$ is very close to the few published estimates of occupational attributable fraction for COPD of $14 \%$ in the United States (Steenland et al. 2003, based on Korn et al. 1987), $14 \%$ for men and $5 \%$ for women in Finland (Nurminen and Karjalainen 2001) and $15 \%$ in a recent review by the American Thoracic Society (Balmes et al. 2003).

### 8.3 Noise

Occupational noise-induced hearing loss accounted for more than four million DALYs, all of them produced by the disability associated with hearing loss (YLD). Worldwide, the burden attributed to occupational noise is $16 \%$, ranging between $7 \%$ in WPR-A and $21 \%$ in WPR-B. By sex, the effects of exposure to occupational noise are larger for males than for females in all subregions. The attributable fraction decreased with age group after 30-44 years, indicating the heavy impact of occupational noise on the burden of hearing loss at younger ages.

In addition to causing irreversible hearing loss, high noise levels in the workplace cause elevated blood pressure, sleeping difficulties, annoyance and stress. Our findings indicate that occupational noise has multiple consequences, both for the individual and for society, and particularly for those suffering hearing loss at young ages. Most occupational noise exposure can be minimized by the use of engineering controls to reduce the generation of noise at its source, within complete hearing loss prevention programmes that include noise assessment, audiometric monitoring of workers' hearing, appropriate use of hearing protectors and worker education.

### 8.4 ERgonomic factors

Human capacity for work depends on many functions and attributes: body size, muscle strength, aerobic fitness, sensory perception and cognitive capacity. Features of the work environment that do not accommodate these needs may produce physical or psychosocial stressors on the human system. Work features that have received attention because of their adverse health effects include heavy manual handling and other types of strenuous work, and awkward body postures.

For this analysis, the exposure variable was work in an occupational category with its assigned level of risk (low, medium or high rate of low back pain). This exposure variable is the "proxy" for the combination of occupational exposures found in the specified occupation that are implicated in the etiology of low back pain.

Occupational ergonomic stressors caused 818000 DALYs from low back pain in 2000. The attributable fractions of low back pain ranged from $22 \%$ to $41 \%$ among subregions, with the global fraction amounting to $37 \%$. The African countries had the highest attributable fraction of low back pain for all age groups analysed. Fractions of $40 \%$ or above were reached in EUR-B and EUR-C and in SEAR-B. The attributable fraction in men ( $41 \%$ ) was slightly higher than that in women $(32 \%)$, which is mainly due to the type of work men perform, involving more vibration, heavy physical load or material handling. Subregional variations reflect differences in occupational types and exposure. Over half of the working population in AFR-D and AFR-E was employed in agriculture. In contrast, about one third of the working populations in the AMR
and EUR subregions were employed in production occupations ("operators") and another large fraction ( $40 \%$ or more) in professional, sales and clerical jobs. In general, males are more exposed than females because they constitute a higher proportion of the labour force. In the less developed subregions, males are generally more exposed because of the higher proportions of workers in formal agriculture than in the developed subregions. The proportion of females in the labour force was particularly low in EMR-B and EMR-D.

The available literature demonstrates the feasibility and benefits of workplace ergonomic interventions (training and engineering controls) that have been implemented by employers in numerous economic sectors. Effective abatement measures include redesigning workstations to eliminate the need for bending and twisting; installing material or patient hoists and other lifting devices; a greater variety of work tasks, to avoid repetitively loading the same body tissues; and improving the mechanical isolation of seating to reduce transmission of whole-body vibration. Training programmes are most effective when they address job design, target supervisory and management personnel along with the manual labour force, and take place in a setting where workers are empowered to utilize the knowledge imparted. In general, the coordination of multiple activities-workstation improvements, training, enhanced medical surveillance and management-within an intervention programme appears to be the most effective. This is consistent with the conclusions of Shannon et al. $(1996,1997)$ that lower injury rates are associated with workplace characteristics such as general workforce empowerment and top management's active leadership, together with delegation of decisionmaking authority regarding occupational safety.

### 8.5 Risk factors for injuries

To our knowledge, this is the first study to estimate attributable fractions of work-related risk factors for unintentional injuries within the overall burden of DALYs. Lack of data on exposure did not allow a risk based approach and the estimates were based on occupational injury registries. This will limit the applicability of these estimates to preventive purposes which are based on exposure. Our findings show that the overall attributable fraction of $9 \%$ reported in this study is above the upper range of values reported by Chen et al. (2001) in the United States. Chen et al. reported an overall attributable fraction of $3.8 \%$, varying between $1.5 \%$ in Arizona and $9.8 \%$ in Alaska. The difference in the findings between the two studies is explained by the heavy burden of mortality in the DALY estimation in developing countries, especially when deaths occur in younger populations.

Our findings understate the importance of the impact of occupational risk factors leading to injuries in the overall burden of disease due to injuries. A major factor in the underestimation was our use of data from an insured population from one country. There is some evidence that
mortality can be greater in uninsured populations, but in the absence of consistent evidence, a similar mortality in the insured and uninsured populations was assumed (Dror 2001; Forastieri 1999; Loewenson 1998). Lerer and Myers (1994) found that $28 \%$ of occupational fatalities in Cape Town, South Africa, were not reported despite a statutory requirement to do so. Using this fraction, we may have missed about 100000 occupational injury deaths due to underreporting. Also, we did not estimate the injury mortality due to intentional injuries such as homicides in the workplace, owing to the lack of data from developing countries. However, current evidence shows that intentional injuries must be present in such countries; thus the lack of an estimation of deaths due to this cause increases the degree of underestimation of the number of deaths due to injuries (e.g. by approximately $4 \%$ in Australia and New Zealand).

Analysis of the full contribution of injuries at work within the overall burden of injuries requires indicators that measure not only mortality but also morbidity. In some countries and regions, with constant or slightly decreasing mortality patterns, it has been observed that the decline in mortality is balanced by an increase in the severity of injuries and morbidity, especially long-lasting or permanent disabilities (CDC 2001; Guerrero et al. 1999). In these cases, evaluation of the effectiveness of preventive measures is also hampered.

Injuries are largely preventable by improvements to make work safer and healthier. Engineering controls, administrative policies, health and safety information and education to promote safety-conscious attitudes and behaviour are needed. Surveillance data must be developed to provide the basis for targeting preventive measures towards high-risk groups of workers. The distribution of burden by type of external cause of mortality has allowed the developed countries to focus on preventive actions at work, resulting in a reduction in injury rates over time. Similar analysis and preventive actions in other countries could greatly reduce injuries at the workplace.

### 8.6 Conclusion

The aim of this study was to estimate the attributable fractions of selected occupational exposures. The risk factors were selected according to the availability of data, the strength of evidence linking the occupational exposure and the outcome, and the amount of risk arising from the exposure. An important feature of these risk factors and the resulting disease burden is their concentration among the working population, especially those in high-risk occupations and sectors. Hazards at workplaces and the resulting illness and injury are understood most accurately in the formal sector, and even there much undercounting occurs. The burden in the informal sector in developing countries, where large proportions of the population work, is high and largely lacks description. Neither household and family agricultural work by women nor child

labour were addressed in our study. Due primarily to lack of data in developing countries, we were unable to include important occupational risks for infectious diseases, dermatitis, reproductive disorders, some cancers, ischaemic heart disease, musculoskeletal disorders of the upper extremities, and other conditions such as workplace stress.

The estimated burden of occupational risk factors can be diminished by improving working conditions, as many examples from different countries have shown. Work-related diseases are largely preventable. For example, many dusty activities can be made safer by using wet methods, thus reducing workers' exposures to silica. Work surfaces can be adjusted to a worker's height, thereby reducing suffering from low back pain. Substituting safe chemicals for known carcinogens can prevent many cancers. A change of process can reduce noise levels, thus protecting workers' hearing. Attention to electrical safety or machine guarding can eliminate tragic injuries at the workplace.

## 9. Projections of future exposure

In the next 50 years, the population of the developing regions will steadily rise, whereas that of more developed regions is expected to change little because fertility levels will remain below replacement level (UN 2001). There will also be differences in growth rates between the
sexes. A negative growth rate among economically active males is expected to occur between 2000 and 2010 in developed regions such as Europe, while comparable female rates will continue increasing in most of the regions, including the developed ones (ILO 2002a) (Table 21.80).

The expected changes in the world population will affect the EAP as well as the median age of workers (Fullerton and Toosi 2001). These changes in the characteristics of the working population will be accompanied by a different distribution of employment in the economic sectors (agriculture, industry and services). Currently, the service sector of many economies is growing at a fast rate, while the agricultural sector is rapidly declining in developing countries and remains at a stable low level in developed countries. It is expected that these different patterns of growth within the economic sectors will continue in the coming years. Moreover, the expected changes will affect the distribution of occupations within an economic sector. In developed countries in which a change in the structure of the economy has been observed, there has been a shift in the proportion of workers from the "production" category in favour of professional, managerial, clerical and sales occupations.

### 9.1 Exposure estimation for the years 2010, 2020 AND 2030

As mentioned above, the EAP by economic sector was used to estimate the working population exposed to some risk factors, including car-

cinogens, while occupational category within a sector was used for others, including noise and ergonomic stressors. Therefore, to project the exposed population for the years 2010, 2020 and 2030 a three-step procedure was followed: (i) the EAP was estimated; (ii) the EAP was distributed among economic sectors; and, where needed, (iii) occupational categories were distributed within the economic sectors.

## EAP Estimation

To obtain the EAP for the year 2010, we multiplied the overall population (2010) by the EARs by subregion for the year 2010 as estimated by ILO (See Table 21.81). Then, in the absence of other data, the same EAR by subregion was used for the years 2020 and 2030 to generate the EAP (see Equation 4). Calculations were restricted to persons aged $\geq 15$ years by sex and subregion, thus allowing regional patterns to be preserved.

$$
\begin{align*}
& E A P_{15+j}=\sum\left[E A R_{2010}(\text { for each age group } \geq 15\right. \\
& \left.\left.\quad \times \text { Population }_{i}(\text { for each age group } \geq 15)\right)\right] \tag{4}
\end{align*}
$$

where
$\mathrm{EAP}_{15+\mathrm{j}}=$ economically active population $\geq 15$ years, $\varphi=$ year (2010, 2020, 2030)

Population $_{\mathrm{i}}=$ population year 2010, 2020, 2030
EAR $\quad=$ economic activity rate, year 2010
The EAP will increase steadily towards 2010, 2020 and 2030, but the amount of the increase and the patterns are somewhat different between developed and developing countries, as well as among countries having a similar degree of development. The percentage distribution of the EAP by subregion reflects the growth of the overall population, with greater growth in developing countries. WPR-B and SEAR-D will contribute $49.4 \%$ of global EAP in the year 2010, whereas developed subregions will contribute only $13.1 \%$ (Table 21.82).

## EAP DISTRIBUTION AMONG ECONOMIC SECTORS FOR 2010, 2020 AND 2030

The basic approach to estimating the EAP among economic sectors was to use regression analysis to identify the relationship between the distribution of the economic sectors and the projected years of interest. The dependent variables (proportion of EAP employed in agriculture, industry or services) were separately compared to the independent variable time, ${ }^{10}$ using the following model:

$$
\begin{equation*}
\text { PEAPA }=\ln \left(a Y_{T}\right)+\ln b \tag{5}
\end{equation*}
$$

where

Figure 21.3 Projected distribution of the agricultural sector by year and subregion, 2010, 2020 and 2030

PEAPA $=$ proportion of EAP in agriculture (similarly, PEAPI and PEAPS for industry, or service) in Year T
$\mathrm{Y}_{\mathrm{T}} \quad=$ Time (Year T)
The slope factors and intercepts obtained by regression analysis, using the EAP proportion by economic subsector for the years 1990-2000, were then used to estimate the proportion of the EAP for the years 2010, 2020 and 2030, separately for each economic subsector. We did not include economic development (e.g. measured as GDP per capita) as an additional variable in the analysis, assuming that previous trends capture the effects of trends in GDP. Given the economic and social factors that determine occupational distributions, the changes in the EAP in the future are subject to behavioural decisions by individuals, policy decisions in home countries and abroad, and developments in education. The project distribution of EAP among economic sectors showed different patterns among different subregions. As an example, Figure 21.3 presents the distribution of EAP in agriculture.

## Occupational categories adjustment

No data were available to develop trends for employment in occupational categories in 2010, 2020 and 2030. Therefore, proportions of exposed workers within occupational categories were adjusted according to the distribution pattern of the year 2000, adjusted only for the new proportions employed within economic sectors in the year of interest.

## Notes

1 See preface for an explanation of this term.
2 Dusts are technically defined as dry particle aerosols produced by mechanical processes such as breaking, grinding and pulverizing (Johnson and Swift 1997). Particle sizes range from less than $1 \mu \mathrm{~m}$ to over $100 \mu \mathrm{~m}$. The smaller particles present a greater hazard, as they remain airborne longer and are more likely to enter the respiratory tract. Dusts may be organic (e.g. grain dust) or inorganic (e.g. silica, asbestos and coal dust).
3 Economic activities comprise agriculture, mining, manufacturing, utilities, construction, trade, transport, finance and services.

4 dBA is the unit of sound pressure level in decibels that has been A-weighted, i.e. measured with an A-weighted sound level meter. Sound levels measured in dBA have been widely used to evaluate occupational and environmental exposures because of the good correlations between the "A" scale and human hearing ability at different frequencies, hearing damage and environmental annoyance.
5 The average of the hearing threshold levels for both ears that exceeds 25 dB at $1000,2000,3000$ and 4000 Hz .

6 Tinnitus is noise originating in the ear rather than in the environment. The noise may be a buzzing, ringing, roaring, whistling, humming or hissing in the ears. Ringing in the ears is an extremely common phenomenon experienced by up to a third of the adult population at one time or another.
7 A temporary increase in the threshold of hearing for an ear caused by exposure to high-intensity noise.
8 The percentage of workers with a hearing impairment in an occupationally noise-exposed population, after subtracting the percentage in an unexposed population who would normally incur such impairment owing to ageing.
9 Year was the predictor of the data.

## Chapter 22

# Contaminated injections in 

## HEALTH CARE SETTINGS

Anja M. Hauri, Gregory L. Armstrong and Yvan J.F. Hutin

## Summary

Injections given in health care settings with injection equipment reused in the absence of sterilization have been associated with infection with hepatitis B virus (HBV), hepatitis C virus (HCV) and HIV.

Input parameters included the annual number of injections per person, the proportion of injections administered with equipment reused in the absence of sterilization, the probability of transmission following percutaneous exposure, the age-specific prevalence of active infection, the prevalence of immunity (i.e. antibody to the hepatitis B core antigen or HbcAg [anti-HBc], anti-HCV and anti-HIV) and the incidence of HBV, HCV and HIV infections. We used mathematical models to transform diverse sources of data available into the prevalence of contaminated injections and the relative risk associated with these practices.

Four subregions ${ }^{1}$ (AMR-A, EMR-B, EUR-A and WPR-A) where reuse of injection equipment in the absence of sterilization was negligible were assumed to have zero risk. In the remaining 10 subregions, the annual number of injections per person ranged from 1.9 to 11.3 and the proportion of injections administered with reused equipment ranged from $1.2 \%$ to $75 \%$.

In 10 subregions, in 2000, injections caused an estimated 21 million HBV infections, two million HCV infections and 260000 HIV infections, accounting for $32 \%, 40 \%$ and $5 \%$ of new infections, respectively. Thus, the burden in 2000 due to past and present exposure accounted for 501000 deaths and 10461000 disability-adjusted life years (DALYs).

Injection overuse and unsafe practices are common worldwide and account for a high burden of infections with bloodborne pathogens. There is a need for policies and programmes for the safe and appropriate use of injections in countries where poor practices occur.

## 1. Introduction

During the twentieth century, injection use increased tremendously and today injections are probably the most common health care procedure (Drucker et al. 2001). Poor injection practices, including injection overuse and unsafe practices, have been reported in many developing and transitional countries (Simonsen et al. 1999). Many injections given for curative purposes in developing and transitional countries are unnecessary as they are prescribed for the treatment of conditions that could be treated with oral drugs or for which medications are not needed (Reeler 1990; Simonsen et al. 1999). In addition to being unnecessary, many injections are unsafe. Of particular concern is the reuse of injection equipment in the absence of sterilization. A common practice consists of rinsing injection equipment between injections in a pot of tepid water (Figure 22.1).

Unsafe injection practices constitute an important route of infection for bloodborne pathogens. Recently, a study suggested that the spread of HCV through unsafe injections in Egypt may represent the largest nosocomial outbreak ever reported (Frank et al. 2000). Epidemiological studies have reported an association between contaminated injections and infection with bloodborne pathogens, including HBV, HCV and HIV

Figure 22.I Injection equipment soaked in tepid water before reuse in the absence of sterilization, Africa, 2000

[^85](Simonsen et al. 1999). The causal nature of this association is supported by many criteria. First, transmission through unsafe injection practices is biologically plausible because all three viruses are present in blood and body fluids of infected individuals (Choo et al. 1989; Molina et al. 1994; Shikata et al. 1977). They can be transmitted by transfusion (Aach et al. 1991; Busch et al. 1996; Senior et al. 1974) and other percutaneous routes, including needle-stick injuries among health care workers (Cardo et al. 1997; CDC 1997; Seeff et al. 1978). Second, several studies in developing countries have demonstrated an association between receiving injections and infection with bloodborne pathogens. Third, the measures of association (e.g. odds ratios) often exceed 2 (Luby et al. 1997; Narendranathan and Philip 1993; Quigley et al. 2000) and show a dose-response relationship (Khan et al. 2000; Ko et al. 1991a; Quigley et al. 2000). Fourth, studies have also reported an association between recent, incident cases of infection with HBV (Hutin et al. 1999), HCV (El-Sakka 1997) and HIV (Quigley et al. 2000), and exposure to injections during the time period that patients were likely to have been infected, indicating that the exposure preceded the outcome.

The proportion of new infections with HBV, HCV and HIV attributable to unsafe injection practices in specific populations can be estimated from case-control and cohort studies. A total of 12 studies (Table 22.1) were identified to examine the association between HBV infection and injections, with population attributable fractions ranging between $21 \%$ and $61 \%$ (Anonymous 1998; Hsu et al. 1993; Hussain 2001; Hutin et al. 1999; Ko and Chung 1991; Ko et al. 1991a; Luby et al. 1997; Narendranathan and Philip 1993; Simard et al. 2000; Singh et al. 2000; Thuring et al. 1993; Val Mayans et al. 1990). Of these eight ( $67 \%$ ) were based upon recent, incident cases. A total of 10 studies (Table 22.2) were identified to examine the association between HCV infection and injections, with population attributable fractions ranging between $20 \%$ and 84\% (Chang et al. 1996; Chen et al. 1995; El-Sakka 1997; Ho et al. 1997; Khan et al. 2000; Luby et al. 1997; Mohamed et al. 1996; Sun et al. 1999, 2001; Thuring et al. 1993). Of these, three were based upon recent, incident cases. A total of four studies (Table 22.3) based upon recent, incident cases were identified to examine the association between HIV infection and injections, with population attributable fractions ranging between $8 \%$ and $45 \%$ (Bultreys et al. 1994; N'Galy et al. 1988; Quigley et al. 2000; Wawer et al. 1994). (Studies based upon prevalent cases of HIV infection are not included in this report as the high frequency of HIV transmission through sexual exposure raises the possibility of reverse causation.)

Two limitations were common among the studies of the association between injections and infections. A first limitation was that studies of persons with prevalent, chronic infections are generally unable to distinguish the direction of the causal relationship between injections and infection. While study subjects could have acquired infections because

they received injections, they could also have received injections as a result of complications of their infection. Studies examining risk factors for HCV and HIV infections are more often affected by this bias because recent, acute cases of infection with these two pathogens are difficult to identify. However, three elements suggest that reverse causation is unlikely. First, most case patients in these studies were asymptomatic and therefore unlikely to seek injections for treatment of their infection. Second, a study that included prevalent cases of infection and examined the association between injections received during different time periods reported that injections received in a distant past were more strongly associated with infection than those received in a recent past, precisely the opposite of what could be expected if the hypothesis of reverse causation were true (Luby et al. 1997). Third, studies that included incident, recent cases of infections have reported similar associations (Chen et al. 1995; El-Sakka 1997; Sun et al. 2001). This includes a prospective cohort study examining the risk factors for HCV infection that validated the results of a cross-sectional survey conducted in the same population (Sun et al. 2001).

A second limitation was that the association between injections and infections with bloodborne pathogens may have been confounded by a number of other exposures, including sexually transmitted infections (STIs). In some cases, the apparent association between injections and infection may be secondary to two hidden associations-between STIs and injections on the one hand, and between STIs and infection on the other. However, confounding is unlikely to explain the associations observed because most studies also examined risk factors other than injections, including STIs, and a number of studies used stratification and multivariate analysis to control for these potential confounders. Nonetheless, there is still a need for research to determine the degree to
which STIs and injections confound each other's relationship with bloodborne pathogens, particularly in the case of HIV infection.

Because information from epidemiological studies was too limited to permit estimation of the global burden of disease attributable to unsafe injections, a global mass action mathematical model was generated in 1995 (Aylward et al. 1995) and further developed to formulate regional estimates in 1999 (Kane et al. 1999). This model included input parameters reflecting injection frequency, injection safety, the percutaneous transmission potential of bloodborne pathogens and the epidemiology of infection with HBV, HCV and HIV. Results of this analysis suggested that each year, in the world, reuse of injection equipment in the absence of sterilization accounts for 8 to 16 million HBV infections, 2.3 to 4.7 million HCV infections and 80000 to 160000 HIV infections (Kane et al. 1999).

This mass action model had three main limitations. First, it did not address variations of input parameters (i.e. injection frequency, prevalence of immunity and incidence of HIV infection) across age and sex groups within subregions. Second, no systematic procedure was used to review the literature and generate subregional estimates for injection frequency and injection safety. In this work, we used a new mathematical model to estimate the global burden of disease from unsafe injection practices, which although based on the same general approach as Kane et al. (1999) improves on some of the data limitations. In our analysis, we considered only HBV, HCV and HIV infections because of the substantial information on their association with unsafe injections and because these pathogens probably account for the majority of injectionassociated infections. Other complications of unsafe injections not included in this model include abscesses (Fontaine et al. 1984; Soeters and Aus 1989), septicaemia (Archibald et al. 1998), malaria (Abulrahi et al. 1997) and infection with viral haemorrhagic fever viruses (FisherHoch et al. 1995; WHO 1976).

## 2. Methods

### 2.1 Definitions

## Health care injection

We defined a health care injection as a procedure that introduces a substance into the body through a piercing of the skin or of a mucosal membrane, including intradermal, subcutaneous, intramuscular and intravenous injections, for curative or preventive health care purposes, whether administered in a formal health care setting (e.g. clinic, hospital) or other settings (e.g. homes, pharmacies). Injections of illicit drugs were not considered in this work (see chapter 13).

## Reuse of injection equipment in the absence of sterilization

We defined reuse of injection equipment as the administration of an injection to a recipient with a syringe or needle that had been previously used on another person and that was reused in the absence of sterilization. In this chapter, reuse of injection equipment in the absence of sterilization will simply be referred to as "reuse of injection equipment".

## Choice of exposure variable contaminated injections

Reuse of injection equipment in itself would not be a risk factor in the absence of source patients infected with bloodborne pathogens. Thus, contaminated injections were the risk factor of interest. An injection contaminated with a bloodborne pathogen was defined as an injection given with a needle or a syringe used on an infected patient and reused on a second patient. The exposure under consideration for this study was defined as receiving at least one injection contaminated with HBV, HCV or HIV in one year. Exposure status would therefore depend on reuse of equipment, injection frequency and prevalence of active infection with HBV, HCV and HIV in the population. Persons receiving no contaminated injection in one year were considered unexposed. Four subregions (AMR-A, EMR-B, EUR-A and WPR-A) where reuse of injection equipment in the absence of sterilization was negligible were assumed to have zero risk.

## Theoretical minimum level of EXposure

The theoretical minimum level of exposure was zero contaminated injections per person and per year. This theoretical minimum is also an achievable goal as there are no reports of reuse of injection equipment in many industrialized countries.

### 2.2 Transmission model

Data on the risk associated with contaminated injections are generally not available as relative risks, especially since these can change from one place or time to another due to changes in background prevalence. Instead, information from diverse sources such as case-control studies, cross-sectional studies and observational studies of injection practices were brought together and integrated by means of mathematical models to develop internally consistent estimates of prevalence and hazard. The hazard estimates were based on the mass action principle, which states that

$$
I_{u}=p_{s}\left[1-\left(1-p_{t} p_{r} p_{v}\right)^{n}\right]
$$

where $p_{s}$ is the proportion of the population susceptible to infection (in most cases, 1 minus prevalence of antibody to the virus), $p_{t}$ is the probability of transmission after percutaneous exposure to a particular
pathogen, $p_{r}$ is the probability that injection equipment will have been reused, $p_{v}$ is the prevalence of active infection and $n$ is the annual number of injections per person. This model implicitly assumes that the whole population is equally likely to be currently infected or receive an injection. For HBV, HCV and HIV, the three pathogens under consideration, this incidence is small enough that the equation can be simplified to

$$
I_{u}=p_{s} \times p_{t} \times p_{r} \times p_{v} \times n
$$

which can be further reduced to

$$
I_{u}=p_{s} \times p_{t} \times n_{c}
$$

in which $n_{c}$ is the average annual number of contaminated injections and

$$
n_{c}=p_{r} \times p_{v} \times n
$$

All parameters were assumed to be different for each of the three pathogens except the annual number of injections per person ( $n$ ), which was assumed to be constant within a particular age, sex and subregional stratum and the probability of reuse of injection equipment $\left(p_{r}\right)$, which was assumed to be constant within a particular subregion. The probability of transmission $\left(p_{t}\right)$ was based upon studies estimating the risk of infection with HBV, HCV and HIV following a needle-stick exposure from an infected patient. For HBV, $p_{t}$ was assumed to vary according to the proportion of the infected population that was negative for hepatitis B e-antigen ( HBeAg ), ( $p_{t}=0.06$ ), or HbeAg positive ( $p_{t}=0.3$ ), (Seeff et al. 1978). For HCV, $p_{t}$ was assumed to be 0.018 (CDC 1997). For HIV, the generally accepted value of $p_{t}$ of 0.003 (Cardo et al. 1997) for needle-stick injuries was too low, since most injuries on which this estimate was based were superficial and did not involve hollow-bore needles. At the same time, the estimated risk from a deep needle-stick injury that can be estimated from the same study, 0.021 , was too high (it is higher than the estimated $p_{t}$ for HCV) because time can elapse during which HIV can be inactivated between the initial use and the reuse of a syringe on a second patient. As a compromise, the mean of the estimates for superficial and deep injuries, 0.012 , was used in the model as $p_{t}$ for HIV.

### 2.3 Estimates of the proportion of the population exposed to contaminated injections from THE MASS ACTION MODEL

If $n_{c}<1$ and each person in the population could receive only one injection, then the probability of receiving a contaminated injection, $p_{c}$, would equal $n_{c}$. However, it is possible for someone to receive two, three or more contaminated injections in any given year. Because contaminated
injections are small probability events (Table 22.6), it can be assumed that the number of contaminated injections per individual follows a Poisson distribution in the population with a mean of $n_{c}$ per individual, then the probability of receiving zero injections would be exp $\left(-n_{c}\right)$, and the probability of receiving at least one injection would be

$$
p_{c}=1-\exp \left(-n_{c}\right)
$$

Thus when $n_{c}$ is very small, $p_{c}$ is approximately equal to $n_{c}$ and each exposed person will receive on average only one contaminated injection per year, as noted above. In most other situations, $p_{c}$ will be slightly smaller than $n_{c}$ and each exposed person will receive on average $n_{c} /\left(1-\exp \left(-n_{c}\right)\right)$ contaminated injections per year.

## $2.4 \quad$ Estimates of the relative risk from the mass ACTION MODEL

For the purposes of the model, we considered the total incidence of infection in the population, $I_{t}$, to be composed of two components: the incidence due to contaminated injections, $I_{u}$, and the baseline incidence, $I_{b}$, which can also be thought of as the incidence in the population if contaminated injections could be eliminated. $I_{t}$ can be estimated from incidence or prevalence surveys and $I_{b}$ can be estimated if $I_{t}$ and $I_{u}$ are known:

$$
I_{b}=I_{t}-I_{u}
$$

and the proportion of infections attributable to unsafe injections is

$$
A F=I_{u} / I_{t}
$$

As this proportion of infections would have occurred only among the exposed proportion of the population $\left(p_{c}\right)$, the risk among the exposed relative to the unexposed, by back-calculation from attributable fraction (AF) relationship, would be:

$$
R R_{c}=1+A F /\left(p_{c} \times(1-A F)\right)
$$

In most situations where the necessary variables are available or can be estimated from existing data, this equation can estimate the relative risk. However, in situations where a substantial proportion of infections are attributable to contaminated injections (i.e. situations where $I_{u}$ approaches $I_{t}$ ), this equation produces unstable estimates of the relative risk, and other methods were used, as below.

### 2.5 Estimates of relative risks from analytical EPIDEMIOLOGICAL STUDIES

Cohort and case-control studies that examined the association between injections and infection defined exposure as receiving at least one injection, contaminated or not, and the absence of exposure as receiving no injections. If $R R_{i}$ is the estimate of relative risk from such a study and $n_{i}$ is the average number of injections received by the cases, then $\left[1+\left(R R_{i}-1\right) / n_{i}\right]$ is the relative risk attributable to one injection. Only a portion ( $p_{r} \times p_{v}$ ) of the injections received are contaminated and persons who do not receive contaminated injections are at no increased risk. Therefore, the relative risk of infection in a person who receives only one contaminated injection is $\left[1+\left(R R_{i}-1\right) /\left(n_{i} \times p_{r} \times p_{v}\right)\right]$. In practice, this often underestimates the relative risk because persons who receive injections are more likely to have been infected in the past and are therefore less likely to be susceptible to infection. Because of this phenomenon, the calculated $R R_{i}$ will be an underestimate of the true $R R_{i}$ if nonsusceptible controls are not excluded from the relative risk calculation. To account for this phenomenon, we assumed that the number of injections received in the prior year was approximately proportional to the probability of having been previously infected, such that the relative risk from receiving a single contaminated injection is $\left[1+\left(R R_{i}\right.\right.$ $\left.-1) /\left(n_{i} \times p_{r} \times p_{v} \times p_{s}\right)\right]$. This method was used to estimate hazard in cases where a substantial proportion of infections was attributable to contaminated injections, as described above.

### 2.6 Data sources

## InJECTION PRACTICE PARAMETERS

Sources of information available to estimate the annual number of injections per person ( $n$ ) included, by decreasing order of data quality, pop-ulation-based injection frequency surveys and other population-based data providing injection frequency estimates. Sources of information for estimating the proportion of reuse ( $p_{r e}$ ) included, by decreasing order of data quality, observational studies of injection practices using the World Health Organization (WHO) standardized injection safety assessment survey tool (WHO 2002), studies of injection practices conducted using other, non-standardized methods, and back-calculations in published analytical epidemiological studies using the mass action equation and the relative risks of infection with bloodborne pathogens associated with receiving injections.

Sources of information were obtained through Medline searches, searches in WHO unpublished documents, including evaluations of the Expanded Programme on Immunization (EPI) and unpublished reports made available through the electronic mail list server of the Safe Injection Global Network (SIGN) (Bass 2000; Hutin and Chen 1999). All studies were reviewed using a standardized study abstraction instrument
and entered in a database. Estimates were generated for each subregion for proportion of reuse ( $p_{r e}$ ) or number of injections per person for each age, sex and subregional stratum ( $n$ ) using a standardized decisionmaking algorithm to use the best source of data available.

The frequency distribution of the annual number of injections per person that was available from two studies conducted in EUR-B (CDC 1999) and in EUR-C (WHO 1999) indicated that a small proportion of the population above the 90th percentile received more than 20 injections per year. To avoid overestimating the attributable fraction, we made the conservative assumption that those receiving such a high number of injections had already been infected and were already immune. Thus, for these two subregions (EUR-B and EUR-C) where the injection frequency distribution was available, we excluded those who had received more than 20 injections per year (approximately above the 90th percentile), thereby reducing the annual number of injections per year. For the other subregions, data were available in tabulated form in published reports. This format already eliminated the upper $10 \%$ of the frequency distribution and no adjustment was necessary (e.g. persons reporting more than seven injections per year were all considered to have received eight injections per year). When more than one source of information regarding injection frequency or reuse of equipment was available for one age, sex and subregion stratum, all were used to compute an estimate.

## Prevalence and incidence of HBV, HCV and HIV infection

We used the prevalence of active infection in the general population to estimate the proportion of patients representing a source of contamination for reused syringes and/or needles $\left(p_{v}\right)$. Therefore, we did not assume the prevalence of active infection to be higher in a health care setting, nor considered different strata according to selected settings (e.g. immunization vs clinic for the management of STIs) (see discussion). Estimates for the proportion of the population chronically infected with HBV, HCV and HIV were obtained from the WHO programmes on HBV (C. Nelson, personal communication, 2000) and HCV (D. Lavanchy, personal communication, 2000), and from the Joint United Nations Programme on HIV/AIDS (UNAIDS 2000). In the case of HBV and HCV, catalytic models in which the annual risk of infection was constant over time and over age groups were generated. These models were fitted so that annual risk of infection led to region-specific estimates of the prevalence of active infection. Once the annual risk of infection was obtained, it was used to estimate the age-specific prevalence of susceptibility and the total incidence of infection among susceptible individuals. In the case of HIV, incidence estimates were obtained from UNAIDS (2000).

### 2.7 Estimates of the proportion of the population exposed TO CONTAMINATED INJECTIONS

## Proportion of reuse

Sources of information used to generate the estimates (Table 22.4) included observational studies of injection practices using the WHO standardized injection safety assessment survey tool (AFR-D, AFR-E and EUR-B), observational studies of injection practices conducted using non-standardized methods (SEAR-B, SEAR-D and WPR-D), backcalculations using the mass action equation and the relative risks of infection with bloodborne pathogens associated with receiving injections (EUR-C), and a combination of the second and the third methods (EMRD). No quantitative data were available for six subregions. For two of them, AMR-B and AMR-D, there were qualitative reports of reuse. For AMR-B, these reports suggested that reuse was uncommon (Flaskerud and Nyamathi 1996; Ugalde and Homedes 1988; Villanueva et al. 1997). Thus, estimates from the other subregion with the lowest frequency of reuse (EUR-B) were extrapolated. For AMR-D, as qualitative reports suggested that reuse was more common than in AMR-B (Janszen and Laning 1993), estimates from EUR-C, with the second lowest frequency of reuse, were extrapolated. For EUR-A, EMR-B, AMR-A and WPR-A, representing mostly countries with high per capita gross national product, the proportion of reuse was considered negligible. Among subregions for which quantified estimates were available, SEAR-D had the highest proportion of reuse ( $75 \%$ ), followed by EMR-D ( $70 \%$ ) and WPR-B ( $30 \%$ ). EUR-B had the lowest proportion of reuse (1.2\%). (See Figure 22.2.)

## ANNUAL NUMBER OF INJECTIONS PER PERSON

Sources of information used to generate subregional input parameters (Table 22.5) included population-based injection frequency surveys, and other population-based studies that provided information about injection frequency. No injection frequency estimates were generated for those subregions for which reuse was considered negligible as no risk applied. Among subregions with quantified information available, EUR-C was the subregion with the highest injection frequency ( 11.3 injections per person and per year), followed by EUR-B ( 5.2 injections per person and per year) (CDC 1999; WHO 1999). However, when the top 10th percentile of injection frequency was removed, EMR-D was the subregion with the highest injection frequency ( 4.3 injections per person and per year), followed by SEAR-D (4 injections per person and per year). The subregions with the lowest annual number of injections per person were AMR-B (1.7 injections per person and per year) and AMR-D (1.9 injections per person and per year).
Table 22.4 Subregional estimates of the proportion of injections administered with reused equipment and data sources used,

[^86]Figure 22.2 Number of injections per person and per year, and proportion of these administered with injection equipment reused in the absence of sterilization, by subregion, $2000^{\text {a }}$

[^87]
## Proportion of the population exposed to contaminated injections

The proportion of the population exposed to contaminated injections reflected the frequency of injections received, the frequency of reuse of injection equipment and the prevalence of active infection with HBV, HCV and HIV (Table 22.6). This estimate varied from $0.03 \%$ (AMR-B) to $13.33 \%$ (EMR-D) in the case of HBV, from less than $0.03 \%$ (AMRB) to $16.73 \%$ (EMR-D) in the case of HCV, and from $0.00 \%$ (EUR-B) to $2.05 \%$ (AFR-E) in the case of HIV.

### 2.8 Estimates for the relative risks of infection for RECEIVING CONTAMINATED INJECTIONS

In the case of HIV, contaminated injections did not account for most new infections (i.e. $I_{u}$ was not close to $I_{t}$ ). Thus, model-based estimates of relative risk were used for all subregions (Table 22.7[c]). In the case

of HCV, contaminated injections did not account for most of new infections in all subregions apart from EUR-C, SEAR-D and EMR-D. For EUR-C and SEAR-D, model-based relative risks for EUR-B and WPRB, which had similar prevalence patterns, were used. In EMR-D, the available study-based relative risk was used (Table 22.7[b]) (El-Sakka 1997). In the case of HBV, contaminated injections did not account for most of new infections in all subregions apart from SEAR-D and EMRD. In EMR-D, the available study-based relative risk was used (Anonymous 1998). For SEAR-D, the study-based relative risk for EMR-D was used as this subregion had HBV prevalence patterns and injection practices close to those of EMR-D (Table 22.7[a]).

### 2.9 Progression of HBV, HCV and HIV infection to disability and death

## TIME INTERVAL BETWEEN INFECTION AND THE OCCURRENCE OF DISABILITY AND DEATH

The majority of the burden of disease associated with infections with HBV, HCV and HIV is delayed in time. For HBV infection, a small proportion of acute infections lead to death through fulminant liver failure. However, most of the burden of disease is secondary to the long-term consequences of chronic HBV infection, including end-stage liver disease and hepatocellular carcinoma. For HCV infection, the death to case ratio for acute infections is negligible and all the burden of disease is secondary to the long-term consequences of chronic infection, including end-stage liver disease and hepatocellular carcinoma. For HIV infection, the burden of disease is secondary to the progression to AIDS and to death following AIDS.

To take into account the time interval between infection and the progression towards death and disability, two measures need to be distinguished. First, the attributable burden in 2000 includes the current burden in the year 2000 that is secondary to past and present unsafe injection practices. Second, the future burden due to current unsafe injection practices in 2000 includes the future long-term consequences in terms of end-stage liver disease, hepatocellular carcinoma and AIDS of the HBV, HCV and HIV infections acquired in 2000 because of contaminated injections.

## CUrrent burden due to past and present unsafe injection practices

In the absence of information regarding injection practices in the past, we were unable to model the fraction of HBV, HCV and HIV infection that was attributable to contaminated injections before the year 2000. Thus, we made the assumption that the fraction of HBV, HCV and HIV infections attributable to contaminated injections in the past was identical to the one modelled for the year 2000. We then applied these attributable fractions to the current burden in 2000 in terms of DALYs and
deaths that were associated with the consequences of HBV, HCV and infection (i.e. acute infections, hepatocellular carcinoma, end-stage liver diseases and HIV infection/AIDS).

## Future burden due to current unsafe injection practices

To reflect the delay between infection and disease outcomes, the fraction of new infections with HBV, HCV and HIV attributable to contaminated injections was converted into years of life lost (YLL) using synthetic cohorts of infected individuals followed for mortality associated with HBV, HCV or HIV infection (AIDS or chronic liver disease) and background mortality. Background mortality was taken into account using age, sex and subregion-specific Global Burden of Disease (GBD) life tables. ${ }^{2}$ To estimate the years of life lost secondary to HBV infections, the model parameters included:

- a rate of progression to chronic infection of $30 \%$ among persons infected under the age of 5 years and of $6 \%$ for persons infected at the age of 5 years or older (McMahon et al. 1985);
- an annual rate of clearance of infection (i.e. sero-reversion) of $1 \%$ following chronic infection (Alward et al. 1985); and
- an age-dependent yearly mortality rate associated with chronic liver disease among persons chronically infected with HBV (Figure 22.3) that was modelled on the basis of African and Asian studies (Gay et al. 2001).

To estimate the years of life lost from HCV infections, two sets of assumptions were used according to the age of the individual at infection (Figure 22.4). For persons infected before the age of 40, the model parameters included:

- a rate of progression to chronic infection of $63 \%$, the average of rates observed in two large studies conducted in this age group (Alter and Seeff 2000);
- a cumulated incidence rate of cirrhosis of $5 \%$ at 20 years among patients with chronic infection (Alter and Seeff 2000; Freeman et al. 2001); and
- a yearly mortality rate associated with hepatocellular carcinoma and chronic liver disease of $3.7 \%$ after the onset of cirrhosis, the average of two large studies (Alter and Seeff 2000).

For persons infected at the age of 40 years or older, the model parameters included:

- a rate of progression to chronic infection of $80 \%$ (Alter and Seeff 2000);
Figure 22.3 Decision tree for the theoretical cohort used for the calculation of the years of life lost (YLL) secondary to hepatitis $B$ virus infection

| Year 0 |  |  |  |  |  |  |

* GBD life tables prepared for World health report 2001 (WHO 2001)
Figure 22.4 Decision tree for the theoretical cohort used for the calculation of the years of life lost (YLL) secondary to hepatitis C virus infection

* GBD life tables prepared for World health report 2001 (WHO 2001).
- a cumulated incidence rate of cirrhosis of $20 \%$ at 20 years (Alter and Seeff 2000; Freeman et al. 2001); and
- a yearly mortality rate associated with chronic liver disease of $3.7 \%$ after the onset of cirrhosis, as in the younger age group.

Disability and death attributable to acute viral hepatitis were considered negligible for HBV and HCV in comparison with the disability and death secondary to chronic infection. In the case of HIV, parameters of progression of HIV infection to AIDS and death developed by WHO and UNAIDS were used (N. Walker, personal communication, 2002).

## Uncertainty analysis

Standard errors were calculated for selected key input parameters, including the annual number of injections per person and the proportion of reuse. Standard formulae for the calculation of confidence intervals for means and proportions were used. In the specific case of the proportion of reuse estimated on the basis of measures of association, total sample size was assumed to be the total number of study participants included in the study.

For subregions for which good quality data were available on injection frequency (injection frequency surveys) or injection safety (standardized or non-standardized injection safety surveys), a $95 \%$ confidence interval was calculated for the input parameter on the basis of the standard error ( $\pm 2 \mathrm{SE}$ ). For subregions for which only lower quality data were available for injection frequency (other population-based injection frequency data) or injection safety (back-calculated estimates), an arbitrary larger interval was used to account for added uncertainty ( $\pm 4 \mathrm{SE}$ ). For subregions for which no data were available and inferences were made using other subregions, an even larger interval was arbitrarily used to account for added uncertainty ( $\pm 6$ SE).

Lower and upper bounds of the $95 \%$ confidence intervals for the proportion of the population exposed and for relative risk estimates were obtained by including the values for lower and upper bounds of the input parameters in the model equations. Confidence intervals for the relative risks that were study-based rather than model-based were calculated on the basis of the confidence interval of the relative risk in the original epidemiological studies. See section 4 for further discussion of sources of uncertainty.

## 3. Results

### 3.1 Fraction of infections attributable to contaminated INJECTIONS IN 2000

Globally, the fractions of incident HBV, HCV and HIV infections attributable to contaminated injections in the subregions where reuse of injec-
tions was reported were $31.9 \%$, $39.9 \%$ and $5.4 \%$, respectively (Table 22.8). For HBV, this proportion was highest in EMR-D (58.3\%) and lowest in EUR-B ( $0.9 \%$ ). For HCV, this proportion was highest in EMRD $(81.7 \%)$ and lowest in EUR-B ( $0.9 \%)$. For HIV, this proportion was highest in SEAR-D ( $24.3 \%$ ) and lowest in AMR-B $(0.00 \%)$. In absolute numbers of infections, our analysis indicated that globally, in 2000, contaminated injections may have caused 20.6 million cases of new HBV infections, 2.0 million cases of HCV infections and 260000 cases of HIV infections.

### 3.2 Current burden due to past and present unsafe INJECTION PRACTICES

The current burden in 2000 due to past and present unsafe injection practices reached 501000 deaths, with the majority of deaths occurring in Asia ( $39 \%$ and $31 \%$ in WPR-B and SEAR-D, respectively) (Table 22.9 ) and among persons aged $\geq 15$ years ( $n=444000,88 \%)$. When death and disability were combined, the burden reached 10461000 DALYs, with a similar predominance in Asia ( $27 \%$ and $39 \%$ in WPRB and SEAR-D, respectively) and adults ( $n=8419000,81 \%$ of DALYs among persons aged $\geq 15$ years). Taken together, viral hepatitis $B$ and $C$ and their chronic consequences accounted for $74 \%$ and $61 \%$ of the deaths and DALYs, respectively, and HIV accounted for the remainder. There were no substantial differences in the distribution of death and disability by sex.

### 3.3 Future burden due to current unsafe INJECTION PRACTICES

Models of natural history and background mortality allowed estimation of the burden of disease attributable to contaminated injections received in 2000. This analysis suggested that the 20.6 million HBV infections in the year 2000 would lead to 26492 deaths in 2000 from fulminant hepatitis and an additional 49000 early deaths from the consequences of chronic infection between 2000 and 2030. With respect to HCV infection, we estimated that the two million infections in 2000 would lead to 24000 early deaths between 2000 and 2030. Finally, 210000 of the 260000 persons infected with HIV through contaminated injections in 2000 are expected to die prematurely from AIDS between 2000 and 2030. While our analytic horizon did not go beyond year 2030, it is anticipated that persons infected with HBV and HCV because of contaminated injections in 2000 would continue to develop long-term complications leading to death beyond this date.

## 4. Discussion

While the consequences of poor injection practices have been recognized for many decades (Anonymous 1945; Wyatt 1984), the safe and

appropriate use of injections remains a target that has not been reached in most developing and transitional countries. Since the early 1990s, epidemiological studies of new HBV, HCV and HIV infections have indicated that unsafe injections are a risk factor for each disease (Simonsen et al. 1999). In most transitional and developing countries where HBV and HCV lead to a high burden of chronic liver disease, unsafe injections account for a high proportion of these infections (Hutin et al. 1999; Khan et al. 2000; Luby et al. 1997; Narendranathan and Philip 1993).

This chapter made use of the best available evidence regarding the rates of injection use, the frequency of reuse and the association between injections and infections. Use of a mass action model was needed for the communicable nature of outcomes and lack of transferability of hazard from across populations. The results indicate that in 2000, four decades after the widespread availability of disposable injection equipment and two decades into the HIV pandemic, contaminated injections accounted for close to a third of new HBV infections, $40 \%$ of new HCV infections and $5 \%$ of new HIV infections globally. The burden of disease in 2000 due to past and current infections reached 501000 deaths and 10461000 DALYs, with the majority of deaths occurring among adults, mostly in Asia.

Using available studies, we described injection practices worldwide in terms of safety and frequency. Our analysis indicated high rates of injection worldwide, with marked subregional variations, for a total exceeding 16 thousand million injections in the 10 (of 14) subregions that were included in our study. This order of magnitude is validated by the market analysis suggesting that in Japan, the United States of America and western Europe, 17.5 thousand million syringes are sold annually (Kaninda 2001).
Four subregions stood out with particularly high estimates. The crude annual number of injections per person was the highest in the former socialist economies of Europe and central Asia, reaching 11.3 and 5.2 in EUR-B and EUR-C, respectively. Most injections in these countries are administered in public health care facilities by physicians or nurses, with a high number of injections per prescription (CDC 1999; WHO 1999). While patients' demand is commonly quoted by health care providers as a major driver of injection overuse, knowledge, attitude and practice (KAP) surveys find that health care providers have a tendency to overestimate patients' preference for injections and that the population is open to alternatives to injected medications (CDC 1999; Vong et al. 2002). In fact, KAP surveys conducted among physicians indicate that prescribers have false preconceptions about the effectiveness of injectable medications and that these preconceptions are sometimes supported by non-evidence-based official treatment protocols. Thus, prescribers' attitudes also contribute to injection overuse (Stoica et al. 1999).

Injection use was also high in the Middle East and in south Asia where the annual number of injections per person reached 4.3 and 4.0 in EMR-

D and SEAR-D, respectively. In these countries, a high proportion of injections are administered by private providers who, in some cases, are not medically qualified (Khan et al. 2000; Kosen 1999; Talaat et al. 2001). In such settings, health care providers' attitudes also drive injection overuse (Khan et al. 2000; Luby et al. 1997). However, practices are different. The reference to any guideline is uncommon. Injections are frequently used on an ad hoc basis to administer mixtures of antibiotics, analgesics, vitamins or antihistamines in the desire to meet what is believed to be the demand of the user (Khan et al. 2000).

Reducing injection overuse would only be a matter of promoting rational drug use if injections were administered safely. Unfortunately, our analysis indicated that injections are given in a way that may harm the injection recipient. Determinants of these unsafe injection practices include the lack of supplies of new, sterile, single-use, disposable injection equipment (Dicko et al. 2000), the lack of awareness among patients and providers regarding the risks associated with unsafe practices (Anand et al. 2001; Khan et al. 2000), and the absence of an efficient sharps waste management system to prevent recycling of contaminated equipment (Hofmann 2001). Of interest, our analysis suggests that injection practices are safer in sub-Saharan Africa ( $19 \%$ and $17 \%$ of reuse in AFR-D and AFR-E, respectively) than in the Middle East and south Asia ( $70 \%$ and $75 \%$ reuse in EMR-D and SEAR-D, respectively). The proportion of the population aware of the potential risk of HIV infection through unsafe injections was $24 \%$ in Pakistan in 1998 (Luby et al. forthcoming), $19 \%$ in India in 1999 (Anand et al. 2001) and $52 \%$ in Burkina Faso in 2001 (Logez 2001). In addition, the social and economic consequences of the HIV pandemic have been perceived more acutely on the African continent than in Asia. Thus, a higher awareness regarding the risks of HIV infection associated with unsafe injections in subSaharan Africa (Birungi 1998) may partly explain this difference observed in the proportion of reuse.

HBV infection was the most common consequence of unsafe injection practices in the world, with more than 20 million cases of infection annually. Among the three pathogens that we examined, HBV is the most prevalent globally (Maynard et al. 1989) and the one most easily transmitted through unsafe injections (Seeff et al. 1978). The subregionspecific fractions of new HBV infections attributable to contaminated injections were compatible with those reported in analytical studies, including $2 \%$ (Thuring et al. 1993) to $73.9 \%$ (Ko et al. 1991a) in WPRB (compared with $33.6 \%$ in our model), $49.7 \%$ (Singh et al. 2000) to $53.3 \%$ (Narendranathan and Philip 1993) in SEAR-D (compared with $53.6 \%$ in our model) and $27.7 \%$ (Anonymous 1998) to $52 \%$ (Hussain 2001) in EMR-D (compared with $58.3 \%$ in our model). Because attributable fractions were also high among children aged $<5$ years, a substantial proportion of unexplained transmission of HBV among preschool children may thus be attributed to unsafe injections
(Davis et al. 1989). Such infections would entail a substantial burden of disease and death in the future since the long-term consequences of HBV infections are most severe among persons infected during childhood (McMahon et al. 1985). The natural history of the infection is well described for HBV and there was relatively little uncertainty around the disease progression parameters that we used.

The burden of disability and death secondary to injection-associated HBV infections was estimated to be low in comparison to the number of infections because of the low proportion of progression to chronic infections and the delay between infection and death. This delay between initial infection and death reduced the burden because of the 30 -year horizon of this work and because background mortality would lead infected persons to die from other causes during this time interval. In addition, the burden of disease avoidable through the control of contaminated injections as a risk factor is limited because universal childhood immunization against hepatitis B is being increasingly introduced in resource-poor countries with the support of the Global Alliance for Vaccines and Immunization (GAVI). If high vaccination rates are indeed reached in the future, as in our assumptions for 2030, herd immunity will progressively reduce the incidence of injection-associated infections through a high prevalence of immunity and a low prevalence of active infection (Wittet 2001).

HCV infection was estimated to be the second most common consequence of contaminated injections worldwide, with more than two million infections each year. Injection-associated HCV infection was less common than injection-associated HBV infection because of the lower prevalence of HCV infection (WHO 2000a) and the lower percutaneous transmission potential of HCV (CDC 1997). However, the fraction of new HCV infection attributable to contaminated injections was high among all age groups, including adults, and was higher than for HBV infection. These high attributable fractions are compatible with those reported in analytical studies, including $20.1 \%$ (Chen et al. 1995) to $90.6 \%$ (Thuring et al. 1993) in WPR-B (compared with $37.6 \%$ in our model), and 9.9\% (Mohamed et al. 1996) to 87.9\% (El-Sakka 1997) in EMR-D (compared with $81.7 \%$ in our model).

HCV is primarily transmitted through percutaneous or permucosal exposure to blood (Alter 1995). Transmission among sexual partners occurs but is not efficient (Alter 1995), occurring mostly among individuals engaging in high-risk sexual behaviour that may expose them to blood, or body fluids contaminated with blood (Williams et al. 1999). Sexual transmission may account for a higher proportion of HCV infections in industrialized countries, where contaminated health care injections and other unsafe percutaneous procedures are uncommon (Alter et al. 1999). However, in developing and transitional countries, the exposures most likely to transmit HCV include unsafe injections, transfusion of blood, blood components and blood products, and other unsafe
percutaneous exposures conducted in medically-related and other settings (e.g. dental care, surgery, circumcision, shaving).

The risk of HCV infection following transfusion of contaminated blood—about $92 \%$ (Aach et al. 1991)—greatly exceeds the risk of HCV infection following a contaminated injection. However, transfusion of blood, blood components and blood products is an infrequent exposure in comparison with injections. Annually, worldwide, it is estimated that over 75 million blood donations occur (WHO 2000b). Our analysis suggested that for developing and transitional countries alone, more than 16 thousand million injections might occur annually. Thus, despite a lower risk associated with each unsafe event, the higher frequency of injections explains why, globally, our analysis suggested that a high proportion of HCV infection was attributable to contaminated injections. While percutaneous exposures other than injections have been associated with HCV infection in epidemiological studies, they rarely explain a high proportion of infections (Wasley and Alter 2000).

HCV infection is currently not preventable through immunization and, in contrast to HBV infection, its long-term consequences may be more severe among persons infected during adulthood than among persons infected during childhood (Alter and Seeff 2000; Vogt et al. 1999). To estimate the burden of disease secondary to current injectionassociated HCV infections, we used conservative estimates for the parameters describing the progression of HCV infection towards chronic liver disease and its consequences. However, there is substantial uncertainty as to whether these estimates obtained from studies conducted in industrialized countries are representative of the natural history of HCV infection in developing and transitional countries as environmental factors could influence the risk of progression to chronic liver diseases and its consequences. In addition, because the parameters that we selected assume that infected patients only die after 20 years, the 30 -year analytic horizon of this work only captured a small proportion of the future early deaths. Nevertheless, if the parameters used in our model were indeed representative, our analysis would suggest that injection-associated HCV infections would not constitute a major avoidable burden of disease between 2000 and 2030. If we underestimated the severity of the natural history of HCV infection, then the burden of chronic liver disease and death secondary to injection-associated HCV infection that could be avoided in the future, particularly in countries highly endemic for HCV, would be estimated as substantial.

Historically, health care injections have not been viewed as a major vehicle of HIV infection and the promotion of safe injection practices has not held a high priority in HIV prevention programmes. However, most nosocomial outbreaks of HIV infection have been reported from countries with low prevalence of HIV infection, including Colombia (Shaldon 1995), the Libyan Arab Jamahiriya (Yerly et al. 2001), Romania (Hersh et al. 1993) and Ukraine (Simonsen et al. 1999). In
other countries where HIV infection and poor injection practices are more common and where sexual transmission accounts for the majority of infections, injection-associated HIV infections are likely to occur but they have rarely been reported or suspected.

Our analysis suggests that contaminated injections may cause $5.4 \%$ of new cases of HIV infection worldwide, representing the largest burden of disease that could be avoided through safe and appropriate use of injection policies. Few epidemiological studies are available with which to validate our estimates, either because transmission through injections was not examined or because these studies were not based upon recent, incident HIV infections. This lack of information represents a substantial source of uncertainty. In AFR-E where several studies were available (Bultreys et al. 1994; N'Galy et al. 1988; Quigley et al. 2000; Wawer et al. 1994), the lowest attributable fraction (8\%) calculated on the basis of the data provided by Wawer et al. (1994) largely exceeded our estimate of $2.5 \%$. In EMR-D and SEAR-D, the model suggests that the attributable fraction could reach $7.1 \%$ and $24.3 \%$, respectively. These estimates are not validated by epidemiological studies and may be overestimated because the epidemic is still concentrated, violating the assumptions made in the mass action model about the distribution of contaminated injections. Despite large uncertainty in attributable fractions in these two subregions, the high frequency of unsafe injection practices coinciding with emerging HIV epidemics must lead to urgent preventive measures.

In the future, studies of the risk factors for HIV infection should ensure that data are collected in a way that allows examination of the association between HIV infection and injections. In the meantime, HIV prevention programmes should communicate the risk of HIV infection associated with health care injections since safe and appropriate use of injection policies constitute effective interventions against HIV infection (CDC 2001; Logez 2001; Prawitasari Hadiyono et al. 1996).

While much emphasis was put on gathering the best available data from published and unpublished sources, this analysis has a number of limitations due to data scarcity.

- Our model was constrained by the limited number of studies with adequately described injection practices. Moreover, some of these studies employed non-standardized methodologies, which could not be used. The high frequency of injections reported in developing and transitional countries contrasts with the paucity of data available to describe practices. Until recently, few standardized tools for assessment or evaluation were available to routinely collect information on injection frequency or safety. However, WHO has recently developed new assessment tools that utilize standardized methods, which will prospectively generate information of appropriate quality. This should
allow future revisions of these burden of disease estimates to be based upon data of better quality.
- The transmission potential of HBV, HCV and HIV through percutaneous exposure was obtained on the basis of epidemiological studies that estimated the risk of infection with bloodborne pathogens among health care workers following a needle-stick injury. Although these figures are based upon many well-conducted studies that included a large number of study participants, they estimated a different risk: infection associated with a needle-stick injury. Factors that could cause the risk from contaminated injections to be higher than the risk from needle-stick injuries include the liquid flow rinsing the needle that occurs during an injection and the potential survival of HBV and HCV in the pots of tepid water often used to rinse injection equipment between injections. Factors that could cause the risk from contaminated injections to be lower than the risk from needle-stick injuries include a longer time interval between injections that could cause inactivation of some virus particles and a dilution effect in the pots of tepid water when injection equipment is reused.
- Our model only estimated the incidence of infections with HBV, HCV and HIV secondary to the reuse of injection equipment on one patient. It did not take into account the transmission secondary to the reuse of equipment on multiple patients, the transmission associated with unhygienic use of multi-dose medication vials and the transmission that may occur through cross-contamination while preparing injections. Failure to address these specific unsafe practices may have led to an underestimation in our results.
- Our analysis did not take into account any transmission networks by which injection frequencies, background prevalence of infection or probability of exposure to unsafe practices, were assessed. As a result, exposure to contaminated injections would not be distributed independently, thus creating various population subgroups with different bloodborne pathogen transmission dynamics. This would be particularly important in settings with concentrated groups of infected persons (e.g. persons with HIV in SEAR-D). However, we excluded persons presenting with very high injection frequencies to calculate the subregional injection frequency input parameters and adjusted the model for the possibility that persons receiving a high number of injections could already have immunity against infection with bloodborne pathogens. Further a potential network effect could involve percutaneous and sexual transmission (e.g. use of injected antibiotics among commercial sex workers), thereby transforming a dendritic transmission network into a more effective cyclic one (Potterat et al. 1999; Rothenberg et al. 1998).

Safe and appropriate use of injection policies aims to eliminate unnecessary injections and achieve safe injection practices. Such initiatives should not constitute separate programmes but should be integrated with other activities (WHO 2000c) to provide more effective interventions including:

- communication of risks associated with unsafe injections to patients and health care workers through disease prevention programmes such as HIV prevention;
- ensuring access to sufficient quantities of single-use, disposable injection equipment in health care facilities; and
- management of sharps waste to prevent reuse of dirty equipment and needle-stick injuries.

This study generated initial estimates of the burden of disease that could be avoided through the implementation of such policies. Further studies will address sources of uncertainty that remain in the natural history of HCV infection and in the proportion of HIV infections attributable to contaminated injections.

## 5. Projections of future Levels of exposure

The future prevalence of exposure to contaminated injections and the future relative risk of HBV, HCV or HIV infection associated with contaminated injections were calculated by including different input parameters into the same model. Assumptions regarding the injection practice parameters in 2030, including the annual number of injections per person and proportion of reuse, were generated through a survey of nine experts from four of the six WHO regions. These projections took into account the high effectiveness of planned or implemented interventions aimed at improving the safety of injections, the moderate effectiveness of interventions aimed at decreasing injection overuse, the prospective for future increased access to health care in sub-Saharan Africa (which could lead to an increase in injection use), and the potential for health care reform in the former socialist countries of eastern Europe and central Asia (which could lead to a decrease in injection overuse). Assumptions regarding the expected number of injections per person and the proportion of reuse were compatible with a slight decrease of injection frequency and a marked improvement of injection safety, although subregions were expected to remain heterogeneous (Table 22.10).

Epidemiological parameters of HBV infection were modified to account for the expected increased use of hepatitis B vaccine secondary to the accelerated introduction of this vaccine into immunization programmes supported by GAVI: the three-dose vaccine coverage was assumed to be $90 \%$ among persons aged $<15$ years and $50 \%$ among persons aged 15-29 years. The prevalence of active infection in the pop-

Table 22.10 Assumptions regarding projected injection practices in 2030

| :--- | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Proportion <br> of reuse <br> (\%) | 8 | 7 | 0 | 4 | 25 | 0 | 4 | 8 | 17 | 9 |
| Annual <br> no. of <br> injections <br> per <br> person | 2.3 | 2.2 | 1.2 | 1.9 | 3.0 | 1.6 | 2.2 | 1.7 | 2.4 | 1.8 |

ulation was assumed to be $2 \%$ in all subregions, except for AMR-B and AMR-D, where it was assumed to be $0.5 \%$. The annual incidence among susceptible individuals was assumed to be $0.1 \%$ in all subregions, except for AMR-B and AMR-D where it was assumed to be $0.01 \%$. In the absence of available epidemiological projections, the incidence and the prevalence of HCV and HIV were assumed to remain constant. Changes in parameters were assumed to be linear between 2000 and 2030.

Our projections into the future of the risk of infection with bloodborne pathogens associated with exposure to contaminated injections did not take into account the dynamic effect of new injection-associated infections on the prevalence of infection with bloodborne pathogens. Our model, a Bernoulli risk projection model, is more adapted to the estimation of the current and past incidence of injection-associated infections. In the case of HIV, where contaminated injections account for only a small proportion of new infections and the pandemic continues to be largely driven by sexual transmission, this limitation is unlikely to substantially affect our results. In the case of HBV, contaminated injections account for a substantial proportion of new infections. The impact of prevention policies on the future burden of disease is likely to be underestimated because prevented cases of HBV infection will reduce the pool of chronically infected persons who constitute sources of infection. However, in countries of intermediate or high HBV endemicity, agespecific prevalence of infection and historical data suggest that the endemicity level has not substantially changed over the past decades, and there is no evidence of injection practices playing a major role in the introduction of HBV in a community.

In contrast, in the case of HCV, where the proportion of infections attributable to injections is high, the effect of this limitation is likely to be considerable. In addition, there is evidence that in some countries, including China (Province of Taiwan) (Sun et al. 1999), Egypt (Frank et al. 2000) and Pakistan (Luby et al. 1997), HCV was recently introduced,
largely through contaminated injections, and rapidly reached high prevalence levels. In fact, in some of these countries, the prevalence is heterogeneous and areas persist where the virus has not been widely introduced (Mujeeb et al. 2000; Sun et al. 1999). In subregions where reuse of injection equipment is common but the prevalence of HCV infection is not yet high (e.g. SEAR-D), there is an opportunity at present to prevent future community-wide outbreaks of HCV infections. Our model does not reflect this opportunity.

## Acknowledgements

We are grateful to Steve Luby for critical comments on the methodology and on the manuscript; to David Gisselquist for assistance with the review of epidemiological studies that examined the association between injections and HIV infection; and to John Potterat for assistance in addressing the network effect issue.

## Chapter 23

# Child sexual abuse 

Gavin Andrews, Justine Corry, Tim Slade, Cathy Issakidis and Heather Swanston

## Summary

This chapter summarizes the evidence of a relationship between child sexual abuse and subsequent mental disorder. Child sexual abuse (CSA) typically includes unwanted and inappropriate sexual solicitation of, or exposure to, a child by an older person; genital touching or fondling; or penetration in terms of oral, anal or vaginal intercourse or attempted intercourse. CSA can vary along a number of dimensions including frequency, duration, age at onset, and relationship of victim to perpetrator. However, the most common dimension used to define CSA is type of abuse. Three categories are commonly reported in the literature. Noncontact abuse encompasses a range of acts and includes inappropriate sexual solicitation or indecent exposure. The two other categories are contact abuse, which includes touching or fondling, and intercourse, which includes oral, anal or vaginal intercourse. In this chapter the upper age limit used to define childhood was 18 years. The theoretical minimum exposure was defined as no abuse.

The disease outcomes chosen for the current analysis were depression, panic disorder, post-traumatic stress disorder (PTSD), alcohol abuse/ dependence, drug abuse/dependence and suicide attempts. Evidence for causality came from twin studies, prospective studies and representative community studies. In particular, the three twin studies available provided strong evidence of a causal relationship as they inherently controlled for the genetic and family environment factors that are also associated with mental disorders (Dinwiddie et al. 2000; Kendler et al. 2000; Nelson et al. 2002). These studies provide evidence of significant associations between CSA and depression, panic disorder, alcohol abuse/dependence, drug abuse/dependence and suicide attempts. While PTSD was not considered as an outcome in the twin studies, data from a prospective study (Silverman et al. 1996) and three representative community studies (Davidson et al. 1991; Molnar et al. 2001; Saunders
et al. 1999) provided consistent evidence that a strong association exists. There was insufficient evidence to support the relationship with obsessive-compulsive disorder (OCD) and so it was excluded. A number of other mental disorder outcomes that were not considered here have been linked to child sexual abuse. Eating disorders have long been conceptualized as a response to a dysfunctional family environment, of which child sexual abuse can be a part. A number of studies have also looked at the association between child sexual abuse and personality disorders, particularly antisocial and borderline personality disorder. Additionally, child sexual abuse does not only produce an increased risk of mental disorder. There has been anecdotal and experimental evidence suggesting that CSA increases the probability of negative psychological outcomes such as poor self-esteem, lack of a sense of control or agency, difficulties with intimacy and continuing sexual difficulties.

Review articles on the prevalence of child sexual abuse have commonly reported a range of prevalence anywhere from $2 \%$ to $62 \%$. Previous studies have demonstrated a significant difference in the prevalence of CSA, depending on a number of methodological factors, including method of data collection, number of questions used to assess CSA, definition of childhood and the type of sample assessed. Therefore, multiple linear regression analyses were employed separately for males and females to identify the methodological characteristics that significantly contribute to the variation in prevalence. Any unwanted variation was removed by adjusting individual prevalence estimates accordingly. These "adjusted" prevalence estimates were then broken down into the three levels of abuse (non-contact, contact and intercourse) and the eight age groups. Meta-analysis was then used to combine the estimates within each country. These country estimates were weighted by the population of the country and combined to provide the final subregional ${ }^{1}$ estimates. Prevalence estimates were higher in females than in males and varied across subregions with the highest prevalence estimates found in AFR-E and SEAR-D.

Relative risk estimates were derived from studies examining the relationship between CSA and psychiatric outcomes. Where relative risks were reported only for overall exposure to CSA, these were extrapolated into the three levels of abuse. Few studies adjusted for the confounding effects of family dysfunction. An external method of adjustment was applied to the relative risks from those studies that did not control for family dysfunction. The small number of studies available for analysis meant that separate relative risks for different age, sex and subregional groups could not be obtained. Relative risks were stratified by psychiatric outcome before being combined using meta-analysis. Results showed that the relative risks are not significantly different across types of mental disorder suggesting that CSA is not particularly associated with any one disorder. Additionally, across types of abuse there was a general trend for increased risk to be associated with "increased" exposure to CSA.

That is, as more severe forms of CSA were experienced the risks for developing a mental disorder increased. After external adjustment the contact and intercourse categories of abuse remained significant across most disorders but non-contact abuse became non-significant.

Across the world CSA contributed to between $4 \%$ and $5 \%$ of the burden of disease in males and between $7 \%$ and $8 \%$ of the burden of disease in females, for each of the conditions depression, alcohol abuse/dependence and drug abuse/dependence. The attributable fractions were higher for panic disorder ( $7 \%$ for males and $13 \%$ for females) and higher still for PTSD ( $21 \%$ for males and $33 \%$ for females). For suicide attempts attributable fractions were $6 \%$ for males and $11 \%$ for females. There were slight regional variations in the amount of burden that could be attributed to CSA, with AFR-E and SEAR-D having higher attributable fractions. Prevalence was estimated to be higher in these subregions. However, data for these subregions came from a few studies that were methodologically poor. The burden of disease attributed to CSA was greater in the younger age groups and declined in the older age groups. Since risk was assumed to be constant across age, this merely reflected the age distribution of the mental disorder disease burden, which impacts largely on the younger age groups due to its early onset and chronic nature. Avoidable burden would be the same as attributable since it was assumed that the prevalence of CSA does not change over time under a "business-as-usual" scenario.

## 1. Introduction

### 1.1 DEFINITIONS OF RISK FACTOR

Definitions of exposure to child sexual abuse vary. Patterns of interpersonal behaviour are being described, not the results of measuring a physical attribute like body mass index, hypertension or blood lead levels. In physical inactivity we accept the report of a person's habitual behaviour and calculate the health consequences of that behaviour to that person. In CSA we quantify one person's behaviour with a child, and usually have to rely on the retrospective report of that child when adult. We then estimate the health consequences of that occurrence. It is important to point out that, even in prospective studies, data on CSA are gathered retrospectively. It is unethical, and in many countries illegal, to prospectively identify CSA and not intervene. The problems of measurement have proven to be difficult but not insurmountable.

In its broadest sense CSA includes unwanted and inappropriate sexual solicitation of, or exposure to, a child by an older person (non-contact abuse), genital touching or fondling (contact abuse), and penetration in terms of oral, anal or vaginal intercourse or attempted intercourse (intercourse). Many studies have used a narrow definition of CSA to include contact abuse and intercourse only. Definitions of CSA also differ
depending on the cut-off age used to define childhood. While in most countries 18 years of age is the legal cut-off used to define childhood, in many countries the age of consent, especially for sexual activity, is lower. However, the most widely-reported definition of childhood in large population surveys of CSA is 18 years or less. Very few studies provided estimates of prevalence by different age groups and none provided estimates of mental disorder risk by different age groups. Furthermore, as described below, it has been shown that the first onset of CSA is less likely to occur between the ages of 15 and 18 years than in younger children. For these reasons the cut-off age used to define childhood in this chapter was set at 18 years.

### 1.2 Choice of exposure variable, reasons and implications

The causes of adult mental disorders have proven difficult to define. There is considerable evidence from longitudinal and twin studies that both genetic and environmental factors are implicated in different proportions in different disorders. Because we are dealing with human behaviour there is also evidence of substantial gene-environment interaction (Kendler et al. 2000; Rutter 1999). Advances in medicine generally have been simplified by the availability of animal models of the condition, which allow the biology to be explicated. Animal models of mental disorders just do not exist, and progress in understanding has to be made by association and inference and does not come from experimental paradigms.

It is simplistic to assume that genetic contributions are immutable. Few would claim that the genetic factors are, except in the case of Huntington chorea and some dementias, a full and sufficient explanation. Genetic factors act to enhance vulnerability. For example, the indicated prevention programmes in anxiety disorders almost certainly work by inhibiting the expression of that genetic vulnerability. Nevertheless, it is inherently more plausible to identify a risk factor that is purely environmental, as CSA is, when looking for a risk factor that might be avertible.

In broad terms, the risk factors for mental disorders can be grouped into vulnerability produced by temperament, by adversity and by deprivation. Trauma and CSA are examples of adversity; family dysfunction and neglect are examples of deprivation (Bryant and Range 1995; Kessler et al. 1997). Temperament, adversity and deprivation co-occur more often than is predicted by chance and, as these impact throughout childhood and adolescence in complex ways, their influence in adult functioning is not likely to be simple or linear (Mullen et al. 1996, 2000; Rutter 1999).

CSA is no exception to this rule. It is more frequent in situations in which the other factors are present. Fortunately, it is possible to estimate the independent contribution of CSA to adult mental disorders from both
twin studies on twin pairs discordant for CSA (where both genetics and family environment like deprivation and other adversity are controlled by virtue of the twin method), and longitudinal studies of young people growing up (where data were prospectively gathered on temperament, non-CSA adversity and deprivation) (Borowsky et al. 1999; Kendler et al. 2000; Molnar et al. 2001; Mullen et al. 1993, 1996; Yama et al. 1995; Zuravin and Fontanella 1999). The link between CSA and adult mental disorders has been established, even after controlling for these other determinants of adult mental disorders.

Two other issues make CSA an appropriate exposure variable to choose. First, it is not rare-most reviews have concluded that close to one child in six experiences an episode of CSA as defined using the broad definition above (Fergusson and Mullen 1999). Second, there is an extensive literature on CSA, much of it recent and much using the definitions presented above, which made a systematic review possible. The literature on deprivation or other adversity is nowhere near as extensive, coherent or accessible.

### 1.3 Choice of theoretical minimum

Given the nature of CSA and the way it is defined in this chapter, the only acceptable theoretical minimum is zero.

## 2. Estimating risk factor levels

### 2.1 Methods

The methods used to identify sources and studies for estimation of both risk factor levels and risk factor-disease relationships are presented in the following section.

### 2.2 Criteria for considering sources and studies

The following inclusion criteria were used:

- any study which determined the prevalence of childhood sexual abuse in any sample;
- any study which determined both the presence and absence of CSA and the subsequent presence and absence of our chosen outcomes;
- any review chapters or reports published in the last 10 years where the topic was CSA (books where the central topic was CSA were included regardless of year of publication);
- methodological papers to assist with the interpretation of the results; and
- meta-analyses of original research results.

The following exclusion criteria were then applied before collection of the articles:

- prevalence studies with total sample sizes of less than 100 (unless data was from an underrepresented country); and
- studies where the population was sampled on the basis of the presence of one of our chosen outcomes.

The first exclusion criterion was applied on the basis of the recommendation of Fergusson and Mullen (1999) and because samples of less than 100 may not provide accurate prevalence estimates for CSA. The second exclusion criterion was applied because studies that sampled on the basis of the presence or absence of an outcome could not be used to calculate a relative risk for that outcome (Streiner 1998). In epidemiological terms this means we could not determine the number of CSAexposed individuals who developed the outcome of interest. Instead, we determined the number of people with outcome A who were exposed to CSA, thus answering a different question. Case-control studies were therefore only included where "cases" were individuals exposed to CSA and "controls" were those who were not exposed.

### 2.3 Search strategy for identification of studies

Several strategies were used to locate studies for this chapter. First, computer searches of 16 databases were conducted. Databases searched were the following: Medline; Embase; Psychinfo; E-psych; Healthstar; Cinahl; Cochrane; Social Work Abstracts; Health \& Society; Family \& Society; General Science Abstracts; Cambridge Life Sciences; Family Studies; Dissertation Abstracts; Child Abuse; Child Welfare \& Adoption; Social Sciences Citation Index.

Subject heading (SH) and key word (KW) searches were carried out in two stages and were defined as follows:

Stage 1
SH: Child Sexual Abuse
OR
KW: "child*" (child, childhood, children) AND KW: ["sexual abuse", "sexual assault", "molestation", "incest"]

AND
Stage 2 (RISK FACTOR LEVELS)
SH: Epidemiology OR KW: ["epidemiology", "prevalence", "incidence"]

STAGE 2 (RISK FACTOR-DISEASE RELATIONSHIPS)
SH: Depression, OR KW: "depress"" (depression, depressive)
SH: Anxiety Disorders, OR SH: [Panic Disorder, Agoraphobia, Obsessive Compulsive Disorder, post-traumatic stress disorder] OR KW: ["panic disorder", "agoraphobia", "obsessive compulsive disorder", "OCD", "post-traumatic stress disorder", "PTSD"]

SH: [Substance Related Disorders, Alcoholism] OR KW: ["alcohol abuse", "alcohol dependence", "alcohol use", "substance abuse", "substance dependence", "substance use", "drug abuse", "drug dependence", "drug use"]

SH: [Suicide, Suicide Attempted], OR KW: ["suicid" " (suicide, suicidal)]
These searches generated a list of over 12000 studies, of which approximately 4000 were duplicates. The abstracts of the remaining 8000 were examined to isolate potentially appropriate studies. The inclusion criteria were applied and the number of potentially relevant articles was reduced to approximately 1000. Many of the articles excluded at this step were those that either did not measure CSA separately from other types of abuse, or did not include a non-exposed control group.

After the exclusion criteria were applied to the 1000 articles, an initial sample of 460 articles was identified for collection. As the articles were reviewed the reference lists were examined in an attempt to uncover additional studies. The tables of contents of Child Abuse and Neglect, the leading journal in the area of child sexual abuse, were searched to locate any articles missed in searches. Experts in the area were contacted for information on unpublished data or for data from countries underrepresented in the usual databases and journals. These experts were located through the membership directory of the International Society for Prevention of Child Abuse and Neglect (ISPCAN), an organization sponsored by UNICEF-NY, Child Protection Division. The Society has over 300 members. All members were contacted via email or fax, with the exception of those from countries where we had adequate published data. A request for data was also put out on a "child maltreatment researchers" list on the Internet which yielded further information. The researchers had access to translation services so articles were not excluded on the basis of language.

The final database consisted of 604 articles. Of these, a further 91 were excluded after collection on the basis of the exclusion criteria defined above (CSA not reported separately from other types of abuse or from abuse as an adult $n=33$; subjects sampled on the basis of outcome $n=33$; no non-exposed control group $n=11$; sample size too small $n=11$; individual case study data only $n=3$ ). In these cases it was not possible to determine from the abstract alone whether the study
should be included. This produced a final set of 513 articles or reports. They were as follows:

- 103 reviews or meta-analyses;
- 55 methodological papers;
- 179 coded studies;
- 48 studies not coded as data had been collected from another paper or report;
- 52 prevalence studies not coded as data on CSA were derived from a secondary source such as official reports or records;
- 13 studies not coded as subjects were gathered from a special sample;
- 48 studies not coded as the outcome data were either not adequately measured or outcome was measured using a continuous as opposed to a categorical measure; and
- 15 studies not coded, as we were unable to obtain copies of the relevant papers or reports.

The 179 coded studies were coded for risk factor levels, risk factor-disease relationships or both.

### 2.4 Methods for obtaining estimates where more than one data source exists

More than one estimate was available for each subregion. Therefore a meta-analysis was conducted to combine estimates. However, before this was carried out the prevalence estimates were adjusted to remove any differences that can be explained by variations in methodology employed in the studies.

## Coding of studies

Prevalence of CSA was obtained from each study included in this analysis. Where possible, an overall prevalence of any CSA was coded as well as a breakdown into the mutually exclusive groups of non-contact, contact and intercourse. A number of methodological characteristics were also coded from each study. These included the type of sample, the representativeness of the sample, age and sex distributions, the method of data collection employed, how childhood was defined, survey response rate, how many questions were used to elicit the presence of CSA and whether restrictions were placed on the definition of abuse.

## Correcting for methodological variability within studies

Previous studies have noted that the prevalence of CSA differs depending on a number of methodological factors, including method of data collection, number of questions used to assess CSA, definition of child-
hood and the type of sample assessed (Bolen and Scannapieco 1999; Gorey and Leslie 1997; Haugaard and Emery 1989; Wynkoop et al. 1995). In order to examine the methodological characteristics that influence the variability in prevalence, multiple linear regression analyses were conducted. As it was assumed that the impact of these factors may differ for males and females, separate regression models were fitted for all estimates of prevalence for males ( $N=93$ estimates) and all estimates of prevalence for females ( $N=143$ estimates). Too few data points existed to carry out the regression analyses in each of the levels of exposure. Thus, the independent variable was prevalence of any CSA (coded as either broad or narrow definition).

## Model-building steps

1. Each independent variable was screened for adequate cell sizes as well as its relationship with all other independent variables. Cells were collapsed where necessary and choices were made between two variables when they were significantly related (Table 23.1 displays the variables chosen for the regression analysis and their categories).
2. The distribution of the dependent variable was tested for skewness, kurtosis and univariate outliers. Three outliers were removed from the analysis.
3. All variables were tested univariately and then entered together into a single model. A process of backward elimination was employed to remove the least significant variable at each step until all variables left in the final model were statistically significant at the 0.05 level. As shown in Table 23.1 two of the dependent variables entered into the model were "subregion" and "CSA definition". Variability in prevalence across different World Health Organization (WHO) regions and across the broad and narrow definitions of CSA was considered to be important. Thus, these variables were left in the multivariate model even if they were non-significant.

## Results

The final model examining the multivariate effects of methodological factors accounted for $27 \%$ of the variance in prevalence of CSA in males and $22 \%$ of the variance in prevalence of CSA in females (beta weights and significance levels for the statistically significant variables in the multivariate model are shown in Table 23.1). The variables remaining in the "males" model were "subregion" $(F=0.68, d f=3, P=0.5688)$, "CSA definition" $(F=1.98, d f=1, P=0.1637)$ and "sample type" $(F=6.13$, $d f=4, P=0.0002$ ). These results indicate that studies of male college samples and general practitioner (GP) attendees report a significantly higher overall prevalence of CSA than studies of community samples ( $12 \%$ and $12 \%$ vs $6 \%$ ). The variables remaining in the "females" model

were "subregion" $(F=7.18, d f=3, P=0.0002)$, "CSA definition" $(F=$ 5.17, $d f=1, P=0.0247$ ) and "Number of questions" $(F=13.65, d f=$ $1, P=0.0003$ ). These results indicate reported prevalence is lower among women in some European countries compared to North America (15\% vs $22 \%$ ), among studies that employed a narrow definition of CSA
(19\%) than those that employed a broad CSA definition (23\%), and those which used only one question to assess the presence of CSA ( $14 \%$ ) than those with more than one question ( $23 \%$ ).

The finding that CSA definition independently contributed to variance in prevalence for females but not males is unusual. The difference between the broad and narrow prevalence estimates is wholly explained by whether or not non-contact forms of abuse are included in the definition. Therefore, if non-contact abuse is rare as the only form of abuse experienced in males then it is likely that including non-contact abuse in a definition of CSA in males would not substantially alter the overall prevalence. However, the pattern across types of abuse for males does not indicate this to be the case ( $40 \%$ of all CSA in males is non-contact CSA). A more plausible explanation is that the low overall prevalence in males coupled with the smaller number of estimates and their substantial variance contributed to the lack of effect observed for different CSA definitions in males. One might expect that had more estimates been available in males a significant difference may have emerged.

The finding that studies that included more than one question about abuse yielded higher prevalence rates is widely supported in the CSA literature (Fergusson and Mullen 1999; Mullen et al. 2000; Peters et al. 1986; Plunkett and Oates 1990); it is also reported that the higher rates observed in such studies are likely to be more accurate (Bolen and Scannapieco 1999). Within this context, adjusting the prevalence estimates from studies that used only one question to more closely reflect those that used multiple questions (rather than the other way around) is likely to be a more accurate reflection of true prevalence in the population. Once again, the lack of effect in male estimates may be a function of the smaller number of estimates, especially given that the number of questions did significantly predict prevalence in males in the univariate analyses.

More intriguing is the finding that the prevalence in females was lower in EUR-A countries than in North America, from where the majority of the world's prevalence estimates come. Finkelhor (1994) reported on the international epidemiology of CSA and concluded that between-country differences were more likely to be due to methodological differences than reflective of true differences in prevalence. However, the fact that the effect in the present analysis remains after controlling for methodological factors may reflect true differences between these cultural groups. Moreover, in light of the larger number of studies available for the present analysis, it does appear to be true that international differences in prevalence exist. Within this context, it is important to note that there were substantial variations in CSA prevalence within subregions even when controlling for methodological variations, and this is reflected in the modest proportion of explained variance for the final model $(22 \%)$. Therefore, the lower observed prevalence may, in fact, be a function of a non-examined explanatory variable. Moreover, a substantial number
of subregions were either underrepresented or not represented at all in this analysis, and it is therefore difficult to interpret these findings in a broader international context.

## Weighting of prevalence estimates

The results of the above regression analyses were used to weight the overall CSA prevalence estimates for both males and females. Specifically, the unstandardized regression coefficients from the two final models were used to adjust the raw prevalence estimates. This was achieved by subtracting the coefficients from the prevalence for all levels of a variable that were statistically significant (e.g. if the prevalence in males was derived from a college sample the adjusted prevalence would be the raw prevalence minus 4.52 percentage points). The variables of "subregion" and "CSA definition" did not contribute to this adjustment because they do not reflect differences in methodological quality. This produced the desired effect of controlling for any influence these factors had on other variables while at the same time keeping any variance in prevalence due to these factors.

It is worth noting that implicit in this process of adjustment was the assumption that estimates from the group used as the reference group more closely reflected the true population prevalence. Thus, estimates for males from college and GP samples were adjusted to more closely reflect the prevalence observed in community samples. For females, prevalence estimates were adjusted to more closely reflect those observed in studies where more than one question to define CSA was asked.

## EXTrapolation across LEVELS OF EXPOSURE

Once weighted prevalence estimates were obtained for each study they were divided into the mutually exclusive groups of non-contact, contact and intercourse using the following method. The relationship between each level of exposure, expressed as a proportion of the overall prevalence, was calculated for all studies that reported prevalence of CSA by type of exposure. When a study reported prevalence based on a broad definition, this was apportioned into non-contact CSA, contact CSA and intercourse (eight studies for males, 12 studies for females). When a study reported prevalence based on a narrow definition this was apportioned into contact CSA and intercourse ( 12 studies for males, 20 studies for females). These proportions were then applied to those studies only reporting an overall prevalence to obtain an estimate of prevalence for each level of exposure in each study. A small number of studies reported proportions in the three levels of exposure that were opposite in direction to all other studies, and these were excluded from the present calculations. Sensitivity analyses were carried out to assess the impact of these two apportioning fractions (e.g. including all studies, excluding studies where the proportion was opposite to all other studies) on the prevalence in each of the three levels of exposure. The results of these

Table 23.2 The impact of different apportioning fractions on the prevalence of CSA in the three levels of exposure

|  | Method 1 |  |  | Method 2 |  |
| :--- | :---: | :---: | :---: | :---: | :---: |
|  | Apportioning fraction | Prevalence |  | Apportioning fraction | Prevalence |
| Males |  |  |  |  |  |
| Non-contact CSA | 0.297 | 2.6 |  | 0.387 | 3.1 |
| Contact CSA | 0.448 | 4.0 |  | 0.378 | 3.7 |
| Intercourse | 0.255 | 2.0 |  | 0.235 | 1.9 |
| Females |  |  |  |  |  |
| $\quad$ Non-contact CSA | 0.279 | 6.7 | 0.291 | 6.8 |  |
| Contact CSA | 0.500 | 12.7 | 0.512 | 13.2 |  |
| Intercourse | 0.221 | 5.8 | 0.197 | 5.3 |  |

Method I: Proportions derived from all studies ( $n=12$ for males, $n=20$ for females).
Method 2: Proportions derived from all studies ( $n=10$ for males, $n=17$ for females) except those in opposite direction to expected proportions (this method was used in the final calculations).
analyses are shown in Table 23.2. The overall impact of these excluded studies on each level of exposure was minimal. They were therefore not included in the calculation of this apportioning fraction.

The observed relationship between non-contact, contact and intercourse for both males and females indicated that intercourse was the least common form of abuse, a finding that has been widely reported (Fergusson and Mullen 1999; Mullen et al. 2000).

## Extrapolation of combined estimates across age

Exposure to CSA, by definition, occurs in childhood. Thus, during childhood the prevalence of CSA represents current exposure, and reflects cumulative exposure to CSA from birth until current age. The prevalence of CSA in persons aged $\geq 18$ years necessarily represents past exposure and reflects cumulative exposure from birth until the age of 18 years. Therefore prevalence of CSA will vary across age groups from $0-17$ years dependent on both the age at which exposure to CSA usually begins (age at onset) and the duration of CSA throughout childhood. Because exposure is fixed at the age of 18 years, the prevalence of CSA across age groups after 18 years will vary only if the prevalence of CSA is changing over time. For example, if birth cohorts between 1956 and 1970 (current age 30-44 years) were more likely to be exposed to CSA in childhood than birth cohorts before 1956 (current age $\geq 45$ years) then the prevalence of CSA for these age groups would differ.

The age groups required for reporting by WHO therefore necessitated three separate steps for calculation of exposure across age groups. The first step estimated prevalence in the $0-4-$, $5-14-$, and $15-17$-year age groups. The second step estimated prevalence in the 18-29-, 30-44-, $45-59-, 60-69-, 70-79$ - and $\geq 80$-year age groups. The third step esti-
mated a combined prevalence in the 15-17- and 18-29-year age groups to obtain prevalence for the age group 15-29 years.

## Step 1: Estimating prevalence in persons aged 0-17 years

No data exist on the prevalence of CSA in different childhood age categories. Age is usually examined in terms of the age at first onset of the abuse or the duration of abuse. In order to estimate prevalence of CSA across different childhood age categories, all studies that contained information about onset or duration were examined. The main difficulty arose from the use of disparate age categories that did not always conform to those required for the WHO estimates. The following steps were carried out to examine this issue.

Age at onset of abuse. A total of 22 studies presented data on age at onset of abuse. Although categorization of age varied considerably across studies, onset was consistently more prevalent in the $5-14$-year age group. This pattern was the same for both males and females. It is noted that the validity of self-reported abuse with an onset before the age of 5 years should be considered, at best, speculative. Age at onset for different levels of exposure and between different subregions could not be examined with the available data. Therefore, the following procedures were applied equally to males and females, across all levels of exposure and across all subregions.

- Two studies presented data in the $0-4$-year age group. These studies indicate that approximately $6.5 \%$ of abuse begins in this age group. If the age band is extended to include $0-5$ year olds (six studies in total) then the equivalent estimate is $9.7 \%$. The midpoint of these two values indicates that approximately $8.1 \%$ of all cases of CSA have their onset before the age of 5 years.
- Three studies presented data for those aged $\geq 15$ years. These studies show that approximately $19.7 \%$ of abuse begins in this age group. If the age band is restricted to those aged $\geq 16$ years (six studies in total) then the equivalent estimate is $18.8 \%$. The midpoint of these two values indicates that approximately $19.3 \%$ of all cases of CSA have their onset after the age of 14 years.
- The middle age group was derived from the above calculations to give a value of $72.6 \%(100 \%-8.1 \%-19.3 \%)$, which is consistent with the overall pattern observed.

Duration of abuse. If prevalence of CSA in different childhood age groups is based only on the age at onset, then abuse that begins in one age group and continues into the next will not be counted. One way to account for this is to adjust for duration, that is, to include a proportion of cases with long duration in more than one age category.

Finkelhor (1979) estimated that $16 \%$ of those who experience CSA experience it on more than one occasion and for a duration of more than one week. Bagley and Mallick (2000) estimated this figure at approximately $20 \%$. However, of most interest to the current analysis were the studies that reported the number of CSA cases where duration was at least one year. Two studies with such estimates were found (Collings 1997; Risin and Koss 1987), and they placed the prevalence of CSA cases with a duration of more than one year at $6.3 \%$ and $12 \%$ of all CSA cases. The midpoint of these values indicated that approximately $9.2 \%$ or one in ten cases of CSA would continue for more than one year (Risin and Koss 1987). Finkelhor (1979) further examined duration by level of exposure and indicated that non-contact abuse was the least likely to continue for more than one year while intercourse was the most likely ( $4.3 \%$ for noncontact, $5.8 \%$ for contact and $8.8 \%$ for intercourse, representing respective proportions of $0.68,0.92$ and 1.40 , compared to the overall figure of $6.3 \%$ ).

Combining onset and duration. Weights derived from age at abuse ( $0.081,0.726$ and 0.193 ) were combined with information about duration in the following way: $9.2 \%$ of cases in the $0-4$-year age group were carried over to the $5-14$-year age group using the above proportions for each level of abuse $(0.68,0.92$ and 1.40). The same calculations were made in carrying over cases from the 5-14-year age group to the 15-18year age group.

Step 2: Estimating prevalence in persons aged $>18$ years
For the reasons outlined earlier, prevalence of CSA in adults will only vary if the prevalence of CSA is changing over time. Several reviews have attempted to examine cohort effects in order to address this issue (Bagley 1990, 1995; Bagley and Ramsay 1985; Bickerton et al. 1991; Feldman et al. 1991; Fergusson et al. 2000). Three of these reviews concluded that the prevalence of CSA could be increasing over time while three reviews also concluded that there is no evidence to support a change in prevalence over time. This pattern is not explained by the publication dates of these reviews and many of the authors also pointed out that it is difficult to interpret these results without reference to a potential reporting phenomenon. That is, women in older age groups may be less willing or less able to report experiences of sexual abuse in childhood.

This issue was also examined empirically in the current data set. Each estimate for males and females was assigned a year of birth, calculated by subtracting the mean age of the sample from the year of publication (or where available the year the survey was conducted). This variable was then examined in a linear regression to determine whether year of birth explained any of the variance in prevalence. The continuous year of birth variable was also converted to a categorical variable with birth cohort defined according to the current age categories provided by

WHO. Birth cohort did not explain any variance in prevalence estimates for either males or females.

Given both these findings indicated no clear trend in prevalence of CSA over time, it was decided that estimates of prevalence would be combined across adult age groups. This had the effect of providing more stable estimates, particularly from underrepresented subregions.

Step 3: Combining estimates for 15-17 and 18-29 year olds
In order to combine estimates of prevalence in these two groups, it was necessary to determine the proportion of the population that fell into these two age groups for each subregion. This was calculated for each subregion represented in the data and was done separately for males and females. The data were obtained from the estimates provided by WHO and were based on population figures for the year 2000. As these data were only available for 15-19 year olds, as opposed to 15-17 year olds, population proportions were calculated using this age group.

## Combining estimates within countries

Once estimates of prevalence were apportioned into the three levels of exposure and across the eight separate age groups (yielding 24 separate prevalence estimates for each study), prevalences were combined within countries. The prevalence estimates were combined using meta-analysis with STATA Intercooled 7. For ease of calculation the "meta" macro was used (Sharp and Sterne 1997). Heterogeneity between studies within each country was tested using the chi-squared statistic. When only two or three studies were available for combination, the between-study variance was estimated with poor precision (Cooper and Hedges 1994). Countries with less than five estimates were combined using a fixed-effects model, and countries with five or more estimates, and statistical heterogeneity, were combined using a random-effects model.

## Combining estimates within subregions

In order to combine prevalence estimates between countries within each subregion, each country estimate was weighted for the population of that country. This meant that prevalence estimates from countries with large populations were given more weight in the final estimates. A combined estimate was obtained for each subregion by calculating a mean for each level of exposure in each age group for males and females.

### 2.5 Methods for obtaining estimates where no data existed

Extrapolation across subregions was one of the most difficult issues encountered in the construction of the prevalence estimates and arguably represents one of the greatest threats to the validity of the estimates in subregions where no data were available. For two out of the 14 subregions no prevalence data were found (EMR-B and EMR-D). These sub-
regions represent vastly different cultural, socioeconomic and geographic populations. In the absence of data it is impossible to speculate on how these differences might have impacted on the prevalence of CSA. No estimates were obtained for any countries in the Middle East. Therefore the estimate that was used comes from Turkey (EUR-B), which was considered the most appropriate in the absence of any other data. This extrapolation should be considered conjectural and the resultant estimates of prevalence in these subregions should be quoted with caution. It should also be noted that there was an uneven distribution of estimates in the remaining 12 subregions with a small number of countries making up a large proportion of the total number of estimates.

### 2.6 DESCRIPTION OF STUDIES, INCLUDING METHODOLOGICAL QUALITIES

Prevalence studies included in the analysis are presented in Table 23.3. They are presented in three levels according to the type of sample used and the representativeness of this sample. The levels are defined as follows.

Level A: Representative community samples-samples of adolescents or adults where the article explicitly stated that the sample was representative of the population from which it was drawn. In general this was achieved through the use of complex sampling procedures or weighting.

Level B: Other community samples (representativeness not known)samples of adolescents or adults where it was not known whether the samples were truly representative of the population from which they were drawn.

Level C: Community subgroups and convenience samples-samples of adolescents or adults drawn from a subgroup within the community based on factors such as ethnicity, educational or socioeconomic status.

### 2.7 Characteristics of excluded studies

There were 48 studies that were not coded due to their outcome measurement methods. Where the outcome was measured using a continuous measure for which there were established diagnostic cut-off points, authors were contacted and $2 \times 2$ tables were requested. The majority of authors responded and supplied data and these studies were included in the 179 coded studies. The 48 remaining were either not coded because authors could not supply data or authors were not contacted because the measure used could not be mapped to diagnostic criteria.

The characteristics of the 15 studies that could not be obtained are presented in Table 23.4. Inter-library loans were requested where items were only available interstate or overseas but several articles had not arrived at the time this chapter was being compiled.

Table 23.3 Characteristics of studies included in prevalence analysis

| Study authors | Sample |  |  |  | CSA data collection |  |  |

### 2.8 Estimates by age, sex and subregion

Table 23.5 presents the final estimates of CSA prevalence by age, sex, level of exposure and subregion. It is presented in the format required for the WHO estimates. Table 23.6 presents the same data with level of abuse and age categories collapsed. This allows an easier comparison across subregions for both males and females. From Table 23.6 a number of interesting findings emerge. First, it can be seen that, on average, the prevalence of CSA is higher in females than in males. This is a commonly reported phenomenon. As demonstrated in the regression analysis, differences in prevalence also exist between subregions. Due to the paucity of prevalence estimates in subregions other than AMR-A, EUR-A and WPR-A it is not possible to look at differences between all subregions. However, the pattern of results does suggest that a high prevalence of CSA is found in AFR-E and SEAR-D. It should be noted that the

Table 23.5 CSA prevalence estimates (\%) by subregion, sex, level of exposure and age group

| Subregion | Sex | Level | Age group (years) |  |  |  |  |  |  |  |

a Subregions for which no data were available. Estimates were used from EUR-C.
estimates from AFR-E and SEAR-D come from very few studies that were relatively poor methodologically. This makes the estimates for these subregions at best highly uncertain. More studies are obviously needed to confirm whether or not the prevalence is higher in these subregions of the world. Some of these subregional differences appear dependent on sex. For example, in AMR-B, AMR-D and WPR-B the studies reported a higher prevalence in males than females. Only a few studies contributed to the estimates in these subregions and without measures of variability around the estimates it was difficult to draw firm conclusions.

### 2.9 Quantitative and qualitative sources of uncertainty

Uncertainty in the current analysis came from several sources. Studies of the prevalence of CSA varied in terms of methodological characteristics. Regression analyses demonstrated that several methodological factors contributed to the variability in prevalence estimates. This was the major quantitative source of uncertainty and was reduced by adjusting the prevalence estimates to more closely reflect ideal methodology. Metaanalysis was used as a method of quantifying the uncertainty around the final prevalence estimates, taking into account sample size or variability between studies, whichever is appropriate given the homogeneity of the estimates being combined. Other sources of uncertainty arose from
decisions made regarding inclusion and exclusion criteria, and methods of extrapolation across age, sex and subregion. These decisions and their rationale have been documented in the relevant sections. It should also be noted that the estimates of uncertainty will necessarily be underestimated, as data do not exist for every country in all subregions.

## 3. Estimating risk factor-Disease RELATIONSHIPS

### 3.1 Outcomes to be assessed: including evidence FOR CAUSALITY AND REASONS FOR EXCLUSION OF RELATED OUTCOMES

## OUTCOMES INCLUDED AND EXCLUDED

The choice of outcomes to be assessed was guided by two principles. First, choice of outcomes was limited to those diseases or outcomes that were included in the Global Burden of Disease (GBD) study. Second, outcomes were limited to those for which there was sufficient evidence of a causal relationship with CSA, the exposure variable. Section 3.4 presents a detailed assessment of the evidence for causality between CSA and six mental disorders (depression, panic disorder, agoraphobia, PTSD, and alcohol and drug abuse or dependence) and suicide attempts.

Child sexual abuse has also been linked to other mental disorders, including OCD, eating disorders and personality disorders. Three studies examined the relationship between CSA and OCD (Arata 1999; Saunders et al. 1992; Stein et al. 1988), however the evidence was equivocal and further research is required to confirm any association or lack thereof. Eating disorders have long been conceptualized as a response to a dysfunctional family environment. While it was originally thought that CSA played a pivotal role in the development of eating disorders, recent community studies have reported only a modest association between CSA and subsequent development of eating disorders after controlling for confounding influences of the family and social environment (Mullen et al. 1996; Wonderlich et al. 1997). CSA has also been linked to personality disorders, with a couple of studies finding positive associations between CSA and antisocial personality disorder (Scott 1992) and borderline personality disorder (Johnson et al. 1999). These disorders are currently not included in the GBD project and therefore were not examined here.

CSA does not only produce an increased risk of mental disorder. There is anecdotal and epidemiological evidence that CSA increases the probability of negative psychological outcomes such as poor self-esteem (Romans et al. 1997), lack of a sense of control or agency (Mullen and Fleming 1998), difficulties with intimacy and continuing sexual difficul-
ties that demonstrate the far reaching damage that occurs in some individuals (Mullen et al. 1996). These outcomes were outside the scope of this analysis and several meta-analyses examining the relationship between CSA and aspects of psychological adjustment offer a more comprehensive review of these psychological correlates (Jumper 1995; Paolucci et al. 2001; Rind et al. 1998). But this does not infer that they are in any way less harmful or less important to the person than the mental disorders identified in this report. The impact of CSA on adult life has also been studied in terms of non-mental health consequences. These include the increased risk of developing sexually transmitted diseases, teenage pregnancies, multiple sexual partnerships and sexual revictimization (Gorcey et al. 1986; Nagy et al. 1995). It has been suggested that a history of CSA, particularly of the more intrusive types, interrupts the child's development of sexuality and normal sexual relationships (Fleming et al. 1999). However, these were also outside the scope of this analysis.

## GENERAL ASSESSMENT OF CAUSALITY

Below, Hill's (1965) criteria for causality were applied to the case of CSA and adult mental disorders. The remainder of this section outlines each of these criteria as they relate to research in the area of child sexual abuse. A more detailed assessment of causality for each outcome is included in section 3.4.

## Temporality

To satisfy the requirement of temporality, exposure to child sexual abuse must occur prior to the onset of adult mental disorder. By definition, some mental disorders are neither present nor easy to diagnose in children; therefore the time of onset of these disorders relative to child sexual abuse is a moot point. However, it is generally acknowledged that preexisting vulnerabilities or predisposition to adult mental disorder exist even in childhood (Caspi et al. 1996). Long-term prospective studies that follow children from a young age and control for these vulnerabilities therefore provide the best evidence regarding temporality. While a number of research projects have been prospective in design, the majority of studies of child sexual abuse have been cross-sectional and retrospective. Traditionally, cross-sectional studies are not considered sources of evidence for temporality. However, by definition, exposure to child sexual abuse occurs during childhood and therefore prior to onset of an adult psychiatric disorder. It is for this reason that cross-sectional studies that indicate a relationship between child sexual abuse and adult mental disorder can still be indicators of temporality.

It is important to point out that even in prospective studies, data on CSA are gathered retrospectively. It is unethical, and in many countries illegal, to prospectively identify CSA and not intervene. However, retrospective studies rely on recall of memories and can therefore suffer from
unreliable data. Moreover, reports of CSA are often ascertained contemporaneously with assessment of disorder, which leaves recall open to bias in which those with disorder are more prone to recall CSA (Mullen et al. 2000). The issue of potentially unreliable recall represents one of the central threats to the validity of the published literature on CSA. Unfortunately, given that very few cases of CSA are reported to other adults, and even fewer to authorities, the validity of retrospective of CSA is very difficult to establish. Fergusson and Mullen (1999) recommended that one way of approaching this issue was to question the same individuals on multiple occasions to examine the consistency of their reports. Although this issue has rarely been examined, evidence suggests moder-ate-to-good consistency of CSA reports over time (Fergusson and Mullen 1999). Moreover, evidence also indicates that unreliability commonly arises from false negative reports (Fergusson et al. 2000) rather than false positive reports. Presumably greater validity would also be achieved if the presence of disorder were not determined at the same time as reports of CSA were obtained. As almost none of the prospective studies of CSA separated the ascertainment of disorder and reports of CSA, it is difficult to comment on what effect, if any, this may have had on results published to date. In summary, given that retrospective reports of CSA are virtually the only measure of CSA available in the literature, they must be accepted within the context of the caveats stated.

## Strength

Several prospective studies (Fergusson et al. 1996b; Silverman et al. 1996) and several large studies with representative samples (Molnar et al. 2001; Saunders et al. 1999; Stein et al. 1988; Wilsnack et al. 1997) have found an association between CSA and mental disorders. These studies have reported odds ratios (ORs) of between 1.1 for depression (Kendler et al. 2000) and 10.2 for PTSD (Molnar et al. 2001). Despite this variability, CSA has been found to have at least a moderate effect on the outcomes studied (see Table 23.7 for a summary of the evidence). The strength of the relationship between CSA and mental disorders or suicide attempts is generally reduced when the effects of mediating variables are taken into account. This is particularly evident for non-contact forms of abuse.

## Elimination of other possible causes

Child sexual abuse often co-occurs within the context of other family dysfunction, social deprivation, emotional and physical abuse and other environmental stressors that are also associated with mental disorders (Fergusson and Mullen 1999). The interaction between these additional stressors, CSA and adult mental disorders is not likely to be simple or linear (Mullen et al. 1996, 2000; Rutter 1999). Furthermore, it has been argued that the apparent association between CSA and mental disorders can in fact be attributed to family dysfunction rather than to CSA (Rind
et al. 1998). It is therefore important to establish that the effect of CSA on adult functioning remains after controlling for some of these cooccurring factors. The following section contains a discussion of the mediating factors that are commonly reported in studies of the effects of CSA on adult functioning.

Sociodemographic characteristics. CSA is not evenly distributed across sex and socioeconomic groups (Mullen et al. 2000), factors that have been found to be independently associated with mental disorders in adulthood (Andrews et al. 2001; Kessler et al. 1994). However, after controlling for these factors, several studies have demonstrated an independent association between CSA and mental disorders (see Table 23.7). Additionally, a recent meta-analysis found that sex or socioeconomic status did not mediate the relationship between CSA and depressive symptoms, PTSD or suicide attempts (Paolucci et al. 2001).

Family environment. Family environment is one of the most commonly reported mediating factors in the CSA literature. Aspects of family environment studied are myriad but include parental functioning and relationships, domestic violence, parental separation during childhood, growing up away from parents, poor parental health—both physical and emotional-and parental drug and alcohol use (Conte and Schuerman 1987; Fergusson and Mullen 1999; Fromuth 1986; Jumper 1995; Kendall-Tackett et al. 1993; Martin 1996; Mullen et al. 2000; Neumann et al. 1996; Rind et al. 1998; Wyatt and Newcomb 1990). Although measures of adverse family environment vary substantially, it is generally considered to be one of the most important mediators of the effect of CSA on adult functioning (Chandler and Jackson 1997; Fergusson and Mullen 1999; Rind et al. 1998). Moreover, most studies have found that although the independent effect of CSA on adult functioning is substantially reduced once family environment is controlled for CSA, particularly abuse involving penetration is significantly and independently associated with negative outcome (Mullen et al. 2000).

Other abuse. Children who have experienced CSA are at considerably greater risk of experiencing other types of abuse such as physical abuse and neglect (Bifulco et al. 1991; Briere and Runtz 1990; Fergusson and Mullen 1999; Fergusson et al. 1996a; Hibbard et al. 1990; Mullen et al. 1996, 2000; Paradise et al. 1994). There is also some evidence that psychopathology increases with the number of abuse types experienced. In a retrospective study of adult women in New Zealand, the chances of being assigned a clinical diagnosis increased to $24 \%$ for a single type of abuse (sexual, physical or emotional), $41 \%$ for two types of abuse and to $60 \%$ for three types of abuse (Mullen et al. 1996). As such it is difficult to isolate the independent contribution of each of these types of abuse to adult psychopathology. Nonetheless, of the studies included in
the present report that controlled for other types of abuse the majority supported an independent effect of CSA on outcome (Molnar et al. 2001; Mullen et al. 1993, 1996; Yama et al. 1995; Zuravin and Fontanella 1999).

Temperament. The area of CSA deals specifically with human behaviour and therefore with substantial gene environment interaction (Kendler et al. 2000; Rutter 1999). Genetic factors act to enhance vulnerability to mental disorders in general, and may also act to enhance or reduce the risk of developing mental disorders following CSA. Twin studies provide one of the best ways to examine the interplay between genetic and environmental influences. There have been three studies examining the effects of CSA on mental disorders in twins (Dinwiddie et al. 2000; Kendler et al. 2000; Nelson et al. 2002). All three studies concluded that CSA is independently associated with most mental disorders and suicide attempts; two reported that the effect was found, even in twins discordant for CSA, when genetic vulnerabilities and many family factors were controlled for. Unfortunately small numbers of CSA-discordant twins in these analyses meant that, although these studies were included in the final estimates for this report, we could not include a separate genetic adjustment factor.

Protective factors. Much of the discussion around variables that mediate the effects of CSA on adult mental disorder focuses on negative or destructive environmental influences rather than protective ones. However, a recent prospective study examined external protective factors that can modify a child's psychiatric trajectory. Lynskey and Fergusson (1997) developed a regression model that demonstrated factors that protected against the development of psychiatric disorders. These were higher levels of paternal care during childhood and having fewer affiliations with delinquent or substance abusing peers. Once the model adjusted for both of these factors, severity of the sexual abuse (ranging from none, non-contact, contact through to intercourse) was not a significant predictor of outcome. Similarly, having a warm and supportive relationship with the non-offending parent and lower levels of abuserelated stress have been shown to predict resilience in sexually abused girls (Spaccarelli and Kim 1995). In essence, while the majority of research has shown that other negative factors contribute to the risk of developing adult mental disorder having experienced sexual abuse as a child, the converse is also likely to be true. That is, certain positive mediating variables are likely to reduce the risk of negative outcomes following CSA. This concept is often referred to as resilience (Fergusson and Mullen 1999). Unfortunately very few studies have measured protective factors in a systematic way and as such they could not be quantified for the present report.

## Covariation or biologic gradient

For biological risk factors such as blood pressure levels this criterion is typically established by the presence of a dose-response relationship between risk factor and outcome. In the area of child sexual abuse, it is difficult to determine the presence of a dose-response relationship because it is difficult to define a "dose". A dose most closely relates to the severity of abuse to which an individual is subjected. The literature generally defines severity of abuse in five ways: type, frequency, duration, age of onset of abuse, and relationship of victim to offender. Regardless of how it is defined, there is broadly supportive evidence relating the severity of the abuse to the degree of psychiatric or psychological disturbance.

Type of abuse. Using this definition, severity of abuse is generally taken to express the spectrum that ranges from non-contact forms of sexual abuse (e.g. verbal sexual invitations, showing pornography), to contact forms of abuse (touching), through to intercourse. In those studies that have presented risk for disorder according to exposure to different types of abuse, risk for disorder increases as exposure to more severe types of abuse occurs (Baynard 1999; Fergusson et al. 1996b; Kendler et al. 2000; Saunders et al. 1992). In general the literature supports the notion that CSA involving contact or intercourse is associated with a more negative outcome in adulthood than non-contact CSA. It is also the most widely reported definition of the severity of exposure to CSA and is therefore used to obtain estimates for the current report.

Frequency of abuse. It has been demonstrated that experiencing one episode of child sexual abuse is often associated with further sexual victimization. In one study, for example, $16.8 \%$ of children were reabused in the 61-72 months prior to follow-up, with the greatest risk period occurring in the two years immediately after the initial abuse (Levy et al. 1995). In another study of 24507 children with substantiated abuse/ neglect who were monitored up to four years after the initial maltreatment incident, $9.3 \%$ of the children experienced abuse or neglect in the follow-up period (Fryer and Miyoshi 1994). For these children, the risk of reabuse continued to be greater than the risk of abuse in the general population and was greatest immediately following the first notified abuse/neglect incident. For example, 24\% of abused/neglected children were revictimized in the first month following the index event. Bentovim et al. (1987) followed up families who were referred to a treatment programme for sexual abuse and found that $16 \%$ of children had experienced revictimization; in $15 \%$ of children it was unclear whether children had been reabused or not. In a sample of children and adolescents, Boney-McCoy and Finkelhor (1995) found that $39 \%$ of children who had histories of prior sexual victimization had been sexually abused in
the last year. Similar outcomes can occur in adults. Women with a history of CSA were significantly more likely to experience rape as an adult and to be victims of domestic violence (Fleming et al. 1999), which raises the question as to whether child sexual abuse is a vulnerability factor to further sexual abuse in and of itself.

Several studies have reported that not only is reabuse common, it is also associated with poorer outcome. In their meta-analysis, KendallTackett et al. (1993) observed that poor psychological and behavioural outcomes in children were related to a variety of abuse-related variables, including greater abuse frequency. Increases in frequency of abuse have also been shown to be significantly associated with greater severity of psychological disorder, such as making more numerous suicide attempts (Bagley et al. 1995). While it is generally acknowledged that frequency of abuse is associated with more negative outcome, very few studies report outcome for varying abuse frequencies.

Duration of abuse. Duration of CSA has been shown to significantly affect psychological outcome, both in meta-analyses (Kendall-Tackett et al. 1993) and other research. Peters (1988) found that the greater the duration of the abuse, the more mental disorders and suicide attempts in adulthood. This is consistent with the notion that cumulative trauma has a more substantial effect than a single or less frequent abusive event. Once again, outcome of CSA is rarely reported for varying duration of abuse.

Age at onset of the abuse. At first glance, the evidence of the effect of age at abuse onset on mental disorder appears to be conflicting in terms of its direction. Peters (1988) found that women aged 18-36 years who had been older at the time they were sexually abused were diagnosed with more mental disorders or had made more suicide attempts. In contrast, Lynskey and Fergusson (1997) found a significant relationship between being younger at the time of the sexual abuse and increasing rates of mental disorders in a sample of 18 year olds. In both of these analyses, once adjusted for confounders, the relationship between age at abuse onset and mental disorders was no longer significant. Consistent with the conclusion of Browne and Finkelhor (1986) there appears to be no solid evidence for a relationship between age at onset and mental disorders after controlling for other aspects of the abuse and relationship variables.

Relationship of the offender to the child. A meta-analysis of the child sexual abuse research found no significant association between the relationship of the offender to the child, and mental disorders (Paolucci et al. 2001). This relationship is surprising given that intrafamilial abuse may occur over a longer period of time and with greater frequency than extrafamilial abuse (Fergusson and Mullen 1999). Browne and

Finkelhor (1986) suggest two reasons why the relationship of the child to the offender may not be a consistent predictor of negative outcomes. First, that lack of a consistent association may reflect variations in the degree of betrayal, rather than whether the victim and perpetrator are related. Second, while abuse by someone who is trusted may involve betrayal, abuse by a stranger may involve more fear and therefore be more aversive to the victim.

## Consistency

The literature has consistently reported that psychiatric disorders are frequently found to be more common among those subjected to CSA compared to their non-abused peers. This finding persists across a range of populations that have included college students, community samples, school students, children, adolescents and adults, and cohorts in a number of different developed countries. Few studies, however, have been conducted in developing countries. Further research is required to confirm that the deleterious consequences associated with CSA reported in the literature so far also applies to the rest of the world and is not mediated by cultural and social factors.

## Plausibility

It is acknowledged that psychiatric disorder arises from an interaction between adverse environmental influences and an individual's genetic make-up (Rutter 1999). Genetic influences aside, it is accepted that childhood adversity is a potent influence on psychiatric outcome (Brown and Moran 1994; Kessler and Magee 1993). This milieu of adversity has been described as a matrix of disadvantage (Mullen et al. 2000) and includes a variety of socioeconomic, familial and other environmental factors, as outlined earlier. Child sexual abuse falls at the more severe end of the spectrum of this adversity.

In terms of the effect that child sexual abuse has on the individual, it is logical that a child exposed to a traumatic event such as sexual assault may function less well psychologically and may develop phobic responses and anxiety-related symptoms, including PTSD (Green 1988). It has been proposed that the sexual abuse, regardless of type, involves four traumagenic dynamics (Finkelhor and Browne 1988). These are betrayal, powerlessness, traumatic sexualization and stigmatization. Synthesizing the child sexual abuse literature, Polusny and Follette (1995) placed the various outcomes associated with child sexual abuse in the context of emotional avoidance, suggesting that these outcomes are the result of maladaptive coping behaviour. Within this framework, a spectrum of avoidance, anxiety, despair and attempts to control becomes evident. When that fails, it produces anxiety disorders, alcohol and substance abuse, depression and other psychopathology, and suicide at the extreme. Within this context, despite the lack of a biological link between CSA and mental disorders, a causal relationship would certainly be plausible.

### 3.2 DESCRIPTION OF STUDIES INCLUDING METHODOLOGICAL QUALITIES

Table 23.7 presents the characteristics of the studies that contributed to the risk factor-disease relationship grouped by psychiatric outcome. Also reported in Table 23.7 are the range of odds ratios and significance for each study.

### 3.3 Overview of methods

The criteria for identifying relevant studies and the characteristics of excluded studies have been reported on previously. All articles that met the inclusion criteria were coded against each outcome measured. The majority of studies measured more than one of our chosen outcomes. Where possible both unadjusted and adjusted measures of risk (RRs and ORs) were coded from articles. The majority of studies did not present estimates of risk adjusted for relevant confounders. Moreover, many presented proportions only. Regardless of which estimates of risk or association were quoted in articles, $2 \times 2$ tables were coded from every article included in the analysis. Where possible $2 \times 2$ tables were coded for each exposure level and where these data were not available 2 x 2 tables were coded for overall exposure. Where studies presented risks or proportions for both lifetime and current levels of outcome, both were coded. Many articles presented outcome as a continuous rather than a categorical variable. In these cases and where studies had used a measure of outcome that could be mapped to diagnostic criteria via a validated cut-off point, authors were contacted and asked to supply 2 x 2 tables. Unadjusted RRs and ORs and corresponding $95 \%$ confidence intervals were calculated from each $2 \times 2$ table using conventional formulae (Gardner and Altman 1989; Streiner 1998).

EXtrapolations Across SEX, DIAGNOSTIC TIME FRAME AND LEVELS of EXPOSURE

Given the requirements for data presentation (relative risk by age and sex for each level of exposure for each subregion) the biggest source of error in the data arose from having a small number of studies from which to derive estimates. The following sections detail the decisions that were made for each of these extrapolations. However, several general rules applied.

- Consider any theoretical implications of the extrapolation (e.g. is there any reason to expect relative risk will vary with age or sex or that confounding factors will differ for different mental disorder outcomes? Is there a plausible hypothesis or explanation?).
- Assume that no difference exists between the groups of interest (e.g. across sex, age or diagnostic time frame) unless there is clear evidence of a consistent pattern.
Table 23.7 Characteristics of studies included in the risk factor-disease relationship analysis

- In the absence of a large number of estimates assume that reporting data from fewer sources is likely to be a greater source of error than extrapolation of data to fit the categories required for reporting (e.g. risk by type of exposure or by sex).

## Sex

Within the literature, a large proportion of the research has examined the sequelae of CSA in females, leaving males underrepresented. This trend was reflected in the data set with many estimates for females and relatively few for males. Additionally, for males, there were no estimates in the severity categories of non-contact, contact and intercourse. Those studies that did examine sequelae in males only gave estimates for the categories of narrow or broad CSA. Therefore, no data were available in the categories required for analysis for males. Given the assumption that more error would be introduced if no estimates were available for males, a decision was made to extrapolate from data for females. To examine the validity of this decision a comparison between males and females was made between those studies that measured outcome in both (restricted to the narrow and broad categories since males only had data for these).

Comparisons were available across all disorder categories and $95 \%$ CIs were compared between male and female estimates within studies to determine if male and female estimates differed significantly. Confidence intervals for the RRs overlapped for depression, agoraphobia, panic, drug and alcohol abuse/dependence for all the studies available for comparison. For PTSD there were significant differences for both of the studies, but as the relative risk was higher for males in one study, and this effect was reversed in the other, no difference between males and females was assumed. For suicide attempts two studies found differences between males and females with the relative risk for males being higher in both. However, in the other six studies available for comparison for suicide attempts no significant differences were observed. Additionally, reviewers have implied that no difference exists between males and females in terms of consequences of CSA (Urquiza and Capra 1990; Watkins and Bentovim 1992). Overall, given that no significant differences were found between the sexes and no theoretical reason presents, no difference between the sexes for the relationship between CSA and mental disorders was assumed.

In light of this decision and in order to maximize the number of estimates available for analysis a hierarchy for selection of studies based on sex was constructed. Where estimates for males and females combined were available from a study these were selected first. Female estimates were then chosen followed by male estimates. This ensured that one estimate was available for each outcome that each study reported.

## Diagnostic time frame

There was considerable variation in the time frame used to measure outcome across studies. While some studies determined the presence of mental disorders over an individual's lifetime, others determined the presence of disorder over the past 12 months, six months or one month. While current or one month estimates might be considered the most accurate measure of current risk, these were only presented for a small number of studies (see Table 23.7). In order to examine the differences between lifetime and current estimates the following analysis was undertaken.

Lifetime and current estimates of risk were compared in the six studies that presented both. All six samples were in the $30-44$-year age group. There were five sets of estimates for depression, two for panic disorder, two for drug dependence, three for alcohol dependence and two for PTSD. Only one study presented estimates for males. Ratios of current to lifetime relative risk ranged from 0.57 to 3.21 with a trend for current risks to be greater than lifetime (ratios of $>1$ ). However, when confidence intervals around RRs were examined very few comparisons were significant.

A second set of comparisons was also undertaken. Relative risks across all studies were grouped according to diagnostic time frame and averaged within age groups and outcomes. Again no clear pattern emerged. On the basis of these analyses and in order to maximize the number of estimates it was decided to include all estimates of relative risk regardless of whether the diagnostic time frame used was lifetime, current or 12 months. Where studies presented both, current risk was used.

## Levels of exposure

Many studies presented relative risk for exposure vs non-exposure only, rather than by levels of exposure. Moreover these studies varied in terms of whether they presented relative risk for broad CSA (non-contact, contact or intercourse) or for narrow CSA (contact or intercourse only). There is strong evidence in the literature to suggest that outcome varies with level of exposure, risk being the highest for those who have experienced abuse involving intercourse (Fergusson and Mullen 1999). In order to examine the relationship between relative risks for each level of exposure the following analysis was undertaken.

Relative risks for overall exposure to CSA were calculated for all studies $(N=5)$ that presented risk by level of exposure. Relative risks for each level of exposure were then expressed as a ratio of the overall risk. Estimates and ratios are presented in Table 23.8.

The ratios in Table 23.8 were then applied to those studies that only reported risk for exposed vs non-exposed. More specifically, the ratios derived from those studies reporting risk estimates for the contact and intercourse categories of abuse were applied to those studies reporting

risk estimates for the narrow category of abuse. Ratios from studies reporting risk estimates in the non-contact, contact and intercourse categories were applied to the risk estimates for the broad category of abuse. This process generated relative risks for the three categories of abuse required for analysis in relation to the single estimate reported by each study. In this way, the extrapolated relative risks reflect an approximation of what the risk may have been if each study had reported risks for levels of exposure, rather than only risks for exposure vs non-exposure. This ensured that data from studies reporting risk in terms of exposed vs non-exposed, rather than risk by levels of exposure, could still be included in the analysis.

The accuracy of the extrapolated relative risks relies on the premise that risk increases with level of exposure to the same degree across
studies. It was decided, however, that the error introduced by the extrapolation process was less than the error introduced by pooling relative risk estimates from a small number of studies. After the extrapolation process each study that reported an estimate only for the broad category of abuse now had relative risks for the non-contact, contact and intercourse categories of abuse. Accordingly, each study that reported an estimate for the narrow category of abuse now had a relative risk for the contact and intercourse categories of abuse.

In order to calculate confidence intervals for those relative risks that had been extrapolated, standard errors had to be estimated. In this instance, the standard errors derived for the relative risks for the broad and narrow categories of abuse were used. This may not accurately reflect-indeed may underestimate-the true variance around the extrapolated estimates, but for the purposes of this analysis it was assumed to be a reasonable approximation.

## ADJUSTMENT FOR CONFOUNDERS

There is strong evidence within the literature that child sexual abuse is often comorbid with other forms of child abuse and also that child abuse occurs within the context of other family dysfunction (Fergusson and Mullen 1999). Given this, any studies that do not control for these other childhood adversities may inflate the contribution child sexual abuse makes to the onset of our chosen outcomes. Only 13 studies in the data set controlled for confounders. In order to adjust uncontrolled estimates for the potential contribution of confounders a method proposed by Rothman and Greenland (1998) was utilized.

Each of the 13 studies varied in terms of outcomes measured and confounders controlled for. For each study the confounders were recorded and grouped into four categories: sociodemographic, other psychopathology, other abuse and family dysfunction. The studies varied according to the types of confounders controlled for and the measures used. In particular, the category of family dysfunction represented a wide variety of factors. The measures used varied from questionnaires concerning parental attachment and parent/child bonding through to those measuring markers of dysfunction, such as whether the subject grew up in a nuclear family or whether there was parental psychopathology. While the measures varied greatly it was assumed that a common underlying dimension was being measured, that is, the degree to which the family environment was impoverished or dysfunctional and so they were grouped together.

At this stage five studies were excluded from the analysis, as they were not consistent with the pattern of confounders measured by the other seven studies. Saunders et al. (1999), Molnar et al. (1998) and Wilsnack et al. (1997) were excluded since they only controlled for sociodemographic variables and might dilute the adjustment factor if they contributed to the average estimate. Stein et al. (1988) was excluded since
it did not control for any childhood adversity, instead only controlling for subsequent adult sexual abuse. Spak et al. (1998) controlled for childhood behavioural difficulties and childhood psychopathology. These may be important factors confounding the relationship between CSA and alcohol dependence, but, it is unclear to what extent childhood behavioural difficulties and childhood psychopathology are additive to the effects of other confounders. It was therefore excluded.

The eight studies left in the analysis controlled for family dysfunction or other types of abuse, including physical and emotional abuse. Therefore the adjustment factor derived from these studies reflects an adjustment for childhood adversity stemming from dysfunctional home and family environments and is the confound identified as being most important in the literature (Chandler and Jackson 1997; Fergusson and Mullen 1999).

For each of the eight studies adjusted odds ratios and unadjusted odds ratios could be derived. Using the odds ratios an adjustment factor was calculated using the following formula:

$$
U=O R_{u} / O R_{a}
$$

$O R_{u}$ represents the unadjusted odds ratio, $O R_{a}$ represents the odds ratio adjusted for confounders and U is the bias produced from failure to control for the confounders. Since there were only eight studies some assumptions about the commonality of effect across sex, disorder categories and abuse categories had to be made. Table 23.9 presents the final adjustment factors by study and disorder averaged across abuse category and sex.

## Extrapolation across sex

Of the eight studies, seven provided estimates for females but only two provided estimates for males. One study provided estimates for males and females combined. Of the two studies that presented data for both males and females there was no clear pattern of differences between the sexes. Additionally, there is no theoretical reason to expect that the confounders in question would differentially affect the relationship between exposure to CSA and disorder; and due to the paucity of data for males we assumed no difference.

## Extrapolation across levels of exposure

With the exception of three studies, all of the studies provided estimates for only the narrow or broad categories of abuse. In the absence of any data it was assumed that the effects of confounders would be the same across abuse categories.

## Extrapolation across outcomes

Most of the eight studies in the analysis only provided estimates for one or two disorders. There were three studies that gave estimates for most of the disorders, excluding suicide attempts; and within these studies there was no definitive variation across disorder. This conclusion is again limited by paucity of data, but there is no theoretical reason for the confounders to act differentially according to disorder. Suicide attempts appear to be an exception since when the means across disorder and study are compared the adjustment factor for suicide is higher. This may indicate that the confounding variables are more predictive of suicide attempts than the other disorders considered and hence, to be conservative, a different adjustment factor is applied to the suicide estimates.

## Generalizability of the adjustment factor

The validity of adjusting estimates from uncontrolled studies using an adjustment factor derived from studies that do control for confounders will be accurate only to the extent that the confounding effects of the covariates are similar across both the controlled and uncontrolled studies (Greenland 1987). While there is no way to assess this issue quantitatively, we can consider the samples from which our adjustment factors were derived. If the samples from controlled studies are drawn from significantly different groups within the community then generalizability to the uncontrolled studies may be limited. In the current analysis the controlled samples included four community and one college sample that were representative of the samples from uncontrolled studies. Moreover, the two samples from community subgroups, low-income mothers, and American Indian and Alaska Native youth, provided estimates that are comparable to the community estimates.

## Application of adjustment factors

Adjustment factors were applied differentially across the risk estimates according to several criteria. For those eight studies reporting both adjusted and unadjusted risk estimates from which an adjustment factor could be calculated, its own individual adjustment factor was applied to each. For those studies that reported no adjusted estimates and from which an adjustment factor could not be derived, the average of the adjustment factors was applied. The exception was where the unadjusted relative risks were non-significant, and in this instance the relative risks were not adjusted for the presence of confounders. This ensured that a significant protective relationship between CSA and psychiatric outcome was not created artificially.

## META-ANALYSIS

The relative risks were combined using meta-analysis with STATA Intercooled 7. For ease of calculation the macro "meta" was utilized (Sharp and Sterne 1997). Estimates were grouped according to psychiatric outcome and then combined. In most cases the studies combined within each group were significantly heterogeneous according to Cochrane's Q statistic, indicating that moderator variables other than psychiatric outcome were still accounting for significant variation. However the small number of studies prevented further partitioning according to other hypothesized moderator variables.

The presence of significant, unexplained heterogeneity generally indicates preference for a random-effects model to take into account the between-study heterogeneity (Cooper and Hedges 1994; Rothman and Greenland 1998). However, when only two or three studies are available for combination, the between-study variance is estimated with poor precision (Cooper and Hedges 1994). In this instance it was decided that

Table 23.10 Number of studies contributing to each estimate within disorder category

|  | No. of studies |  |  |
| :--- | :---: | :---: | :---: |
| Outcome | Non-contact | Contact | Intercourse |
| Depression | 14 | 23 | 25 |
| Panic disorder | 5 | 8 | 8 |
| Alcohol abuse/dependence | 7 | 13 | 15 |
| Drug abuse/dependence | 4 | 7 | 7 |
| PTSD | 5 | 6 | 8 |
| Suicide attempts | 13 | 29 | 29 |

groups with five or more studies would be combined using a randomeffects model and those with less than five would use a fixed-effects model.

### 3.4 Assessment of causality for each outcome

The following summarizes the evidence of a causal relationship between CSA and each of the seven outcomes examined. A schema or hierarchy was developed to organize this evidence and is outlined below. All of the studies that reported relevant data on proportions of persons in the clinical ranges for each outcome have been tabulated by level of evidence. For some, the $\chi^{2}$ statistic was calculated to test for significance of the odds ratios where these were not available from the studies themselves. Where research on a given psychiatric outcome focused on a subsample of a study group that has been described previously, the findings of the main sample are reported.

Level 1: Studies controlling for both genetic background and family environment.

Level 2: Prospective studies where family environment measured prospectively was used to control confounding of deprivation and CSA.

Level 3: Retrospective cross-sectional studies in which the occurrence of CSA was determined at the time illness was ascertained. Family environment measured reliably was used to control confounding of deprivation and CSA.

Level 3a: Representative community samples: samples of adolescents or adults where either sampling strategy or weighting procedures ensured representativeness of sample.

Level 3b: Non-representative community samples: samples of adolescents or adults where methodology did not necessarily ensure representativeness of sample.

Level 3c: Community subgroup samples: samples of college students, general practice attendees or other community subgroups.

Level 4: Prospective case-control studies in which a CSA group was compared with controls matched for family environment (actually or statistically) and followed over time to measure the onset of mental disorders.

Level 5: Single wave case-control studies in which a CSA group was compared with controls matched for family environment (actually or statistically).

Level 6: Studies of special groups such as foster care children, street youth and juvenile detainees.

## DEPRESSION

The most convincing evidence for a relationship between child sexual abuse and adult depression is from three level 1 studies of adult twins. Dinwiddie et al. (2000) adjusted for demographic factors and found significant relationships between contact or intercourse CSA and depression for female ( $O R=2.20$ ) and male twins $(O R=3.93)$. Restricting the sample to twin pairs discordant for CSA (and thereby substantially reducing the power of the analysis), the relationship between CSA and depression was no longer statistically significant for either males or females even though both were at increased risk for depression.

Kendler et al. (2000) adjusted for family functioning and parental psychopathology in a sample of female twins. They found that odds ratios for the risk of depression in abused twins compared to non-abused twins were modest but not significant for non-genital abuse ( $\mathrm{OR}=1.08$ ), but increased with the severity of the abuse. For abuse involving genital contact $(\mathrm{OR}=1.58)$ and intercourse $(\mathrm{OR}=2.79)$, odds ratios were significant. When analyses were restricted to twins discordant for CSA, odds ratios were of similar magnitude to the previous analysis but only risk in the intercourse category of abuse remained statistically significant (Kendler et al. 2000). It was noted by the author that the discordant twin analyses were limited by small sample size.

In a sample consisting of monozygotic and dizygotic twins who were discordant for CSA, the risk of developing major depression was 1.68 for women and 1.25 in men; however, this relationship was significant only for women (Nelson et al. 2002). Of note was the non-significant trend for non-abused co-twins to also be at greater risk of having a history of depression in comparison to twin pairs with no history of abuse, providing evidence for the contribution of familial factors to the onset of disorder. Therefore, the finding that abused co-twins have a higher risk of depression than their non-abused co-twins demonstrates the increased risk that CSA contributes over and above family background.

Across the three twin studies a significant relationship between CSA and depression has been found. Particularly, abuse involving contact and penetration has been found to significantly increase the risk of a depressive disorder. Discordant twin analyses were conducted for three studies and have the advantage of controlling more tightly for familial and genetic factors. These analyses also found CSA to contribute significantly to onset of depression, but in the case of Dinwiddie et al. (2000) and Kendler et al. (2000) only when the abuse involved intercourse. While the small sample sizes of the discordant twins restricted the power of the analyses they do provide strong support for a causal relationship between depression and CSA involving intercourse.

To conclude, there have been three level 1, and 19 level 2 and 3 studies examining the relationship between CSA and depression; 19 of them supported a significant relationship. There is strong, consistent evidence that, after adjustment for confounders, there is a significant relationship between CSA and depression in adults, particularly for women who experienced more severe forms of abuse.

## PANIC DISORDER

There is evidence from level 1 twin studies for a relationship between CSA and panic disorder. Defining sexual abuse as contact or intercourse, Dinwiddie et al. (2000) adjusted for demographic factors and found significant relationships between CSA and panic disorder for female (OR = 3.54 ) and male twins ( $\mathrm{OR}=5.02$ ). In the twin pairs discordant for CSA, the relationship between CSA and panic disorder was no longer significant for women even though they were at increased risk for the disorder ( $\mathrm{OR}=2.00$ ). Similar analyses were unable to be conducted for men because of sample size.

In their analyses of panic disorder, Kendler et al. (2000) adjusted for family functioning (but not parental psychopathology) and found that odds ratios in abused twins compared to non-abused twins were modest but not significant for either non-genital abuse ( $O R=1.25$ ) or for abuse involving genital contact ( $\mathrm{OR}=1.92$ ). Odds ratios for intercourse (OR $=2.62$ ) were significant. Discordant co-twin analyses were not performed due to small sample sizes. Prospective studies have found equivocal evidence of a relationship (Brown and Harris 1993; Ernst et al. 1993) and studies using community samples have found significant associations between some forms of CSA but not others (Molnar et al. 2001; Saunders et al. 1992; Stein et al. 1988). Although few studies have examined panic disorder as an outcome of CSA, there is evidence from two level 1 studies, one level 2 study and three level 3 studies that the rates of panic disorder are increased in sexually abused adults and are more strongly predicted by abuse involving penetration.

## ObSESSIVE-COMPULSIVE DISORDER (OCD)

Only three studies explored the relationship between CSA and OCD and only one of these controlled for confounders. This representative community sample (level 3a) adjusted for demographics and other abuse but found no significant relationships between CSA and lifetime or 6-month history of OCD (Stein et al. 1988). Results from the two samples that did not adjust for confounders were mixed. In a sample of female college students (level 3c) (Arata 1999), no significant relationships were reported between CSA and lifetime or 1-month history of OCD. However, childhood was defined as aged $<14$ years and was therefore quite restrictive. Saunders et al. (1992) (level 3b) defined childhood more broadly, as aged $<18$ years. While results for non-contact abuse were not significant, women were 4.5 times more likely to have a lifetime history of OCD if they had experienced CSA in the form of contact abuse and over six times more likely if they had experienced intercourse; and these findings were significant. This pattern of significant results was also the case for the relationship between CSA and women who met the diagnostic criteria for OCD at interview. In summary, only one study supported a relationship between CSA and OCD. Further research is required in order to confirm this association. For this reason the risk for OCD will not be calculated in this report.

## Post-traumatic stress disorder (PTSD)

There was one study of PTSD that provided level 2 evidence (Silverman et al. 1996). This was a 17-year follow-up of a community sample of children in a working class area. There was no adjustment for confounders; however, a significant relationship was found between CSA and lifetime history of PTSD for females at age 21 years.

Of the remaining studies of PTSD, all were from level 3 evidence and only two of these adjusted for confounders. These studies were representative community samples (level 3a). One study restricted CSA to intercourse only, and only adjusted for age, but found that CSA significantly increased the risk of lifetime $(\mathrm{OR}=3.42)$ and recent $(\mathrm{OR}=3.17)$ PTSD (Saunders et al. 1999). The other study adjusted for demographic and family variables such as parental substance abuse and psychopathology, and the presence of physical abuse (Molnar et al. 2001). Child sexual abuse was defined as contact sexual abuse or intercourse and was found to be significantly related to lifetime history of PTSD in women ( $\mathrm{OR}=10.2$ ) and men ( $\mathrm{OR}=5.3$ ). A notable finding was that the risk of PTSD was significantly higher for penetrative abuse than contact abuse.

In summary, there were eight level 2 and 3 studies; all showed a significant relationship between child sexual abuse and adult PTSD. There is strong, consistent evidence that, after adjustment for confounders, there is a significant relationship between CSA and PTSD in adults, particularly for those who have experienced more severe forms of abuse.

## AlCOHOL ABUSE OR DEPENDENCE

The evidence for a relationship between childhood sexual abuse and adult alcohol abuse/dependence is from the three level 1 studies of adult twins. Dinwiddie et al. (2000) adjusted for demographic factors and found significant relationships between contact or intercourse CSA and alcohol abuse/dependence for female ( $\mathrm{OR}=2.81$ ) and male twins (OR $=1.91)$. Restricting the sample to twin pairs discordant for CSA, the relationship between CSA and alcohol abuse/dependence was no longer significant for either males or females; however females remained at increased risk ( $\mathrm{OR}=2.50$ ).

Kendler et al. (2000) adjusted for family functioning and parental psychopathology in a sample of female twins. The odds ratios for the risk of alcohol abuse/dependence in abused twins compared to non-abused twins were modest but not significant for genital contact abuse ( $\mathrm{OR}=$ 1.91). For non-genital abuse ( $\mathrm{OR}=3.20$ ) and intercourse ( $\mathrm{OR}=6.48$ ), odds ratios were significant. Analyses for twins discordant for CSA, or where the co-twin had experienced a less severe form of abuse, showed that intercourse significantly increased the risk of alcohol abuse/dependence. In another sample that also presented results for CSA among discordant twins the risk of developing alcohol abuse/dependence was 1.73 for women and 1.25 in men; however this relationship was significant only for women (Nelson et al. 2002). In particular, the findings from the discordant twin analyses suggest a causal relationship between CSA and alcohol abuse/dependence, and indicate that CSA increases the risk over and above that arising from family background. Low sample size of the discordant twin analyses may have produced the non-significant results for contact forms of abuse but the significant finding for intercourse in spite of low power makes this finding notable. Other prospective and community studies also provide evidence for a relationship between CSA and alcohol abuse/dependence with two out of three level 2 studies and seven out of nine level 3 studies presenting significant odds ratios.

## DRUG ABUSE OR DEPENDENCE

There was only one level 1 study that explored drug abuse or dependence. In their study of female twins, Kendler et al. (2000) adjusted for family functioning and parental psychopathology. They found that odds ratios for the risk of drug abuse/dependence in abused twins compared to non-abused twins were modest but not significant for genital contact abuse ( $\mathrm{OR}=1.21$ ). For non-genital abuse ( $\mathrm{OR}=3.57$ ) and intercourse ( $\mathrm{OR}=6.55$ ), odds ratios were significant. Analyses of twins discordant for CSA, or where the co-twin had experienced a less severe form of abuse, showed a similar pattern of results with non-genital CSA and CSA involving intercourse placing subjects at increased risk (ORs 4.29 and 2.85 , respectively). However, these results were not significant, and this is likely to be a function of small sample sizes.

Of the three level 2 studies, only one showed a significant association and was significant only for the intercourse category of abuse ( $\mathrm{OR}=5.1$ ) (Fergusson et al. 1996b). The two other prospective studies failed to show a relationship (Silverman et al. 1996; Widom and White 1997). Of the four level 3 studies using community samples, three demonstrated a significant association but not across all three levels of abuse. In summary, there is evidence to suggest a relationship between CSA and drug dependence but only for the more severe forms of abuse. However, the evidence is more equivocal compared to other outcomes and more research is required to confirm this relationship.

## Suicide attempts

There were two level 1 studies of adult twins that addressed suicide attempts. In the first, Dinwiddie et al. (2000) adjusted for demographic factors and found significant relationships between contact or intercourse CSA and serious suicide attempts for female ( $\mathrm{OR}=7.74$ ) and male twins $(\mathrm{OR}=7.07)$. Restricting the sample to twin pairs discordant for CSA, the relationship between CSA and suicide attempts was no longer significant for females; however they were still at increased risk ( $\mathrm{OR}=2.33$ ). Risk estimates could not be computed for males in the discordant twin analysis due to small numbers. In the second study of twins who were discordant for CSA (Nelson et al. 2002) the risk of suicide attempts was 2.33 for women and 4.50 in men. This relationship was significant for women, and almost reached significance in men (95\% CI 0.97-20.83), even after adjustment for demographic and family factors. Furthermore, three of four prospective studies (level 2) and 16 of 18 level 3 studies also found significant associations between CSA and suicide attempts. There is strong evidence for a relationship between CSA and suicide attempts.

## Completed suicide

Completed suicide, by definition, can only be studied prospectively. Only one study to date has examined the relationship between completed suicide and child sexual abuse. This Australian study was based on a relatively small sample of sexually abused young people, the majority of them female, who presented to hospitals for the abuse, and a control group of non-abused young people from the community (Plunkett et al. 2001). Without controlling for confounders, CSA was found to increase the risk of completed suicide; and the rate was found to be very high, 179.5 per 100000 person-years, or $1.8 \%$, but this relationship was not significant. It should be noted that the number of completed suicides was 3 out of a sample of 259 , and none of the controls had committed suicide, so analyses were somewhat limited. The national suicide death rates for 15-24 year olds during the same time period ranged from 13.8 to 16.7 , so the observed rate in the study was 10.7 to 13.0 times that of the Australian national suicide death rate (Dudley et al. 1998).

## RELATIONSHIP BETWEEN ATTEMPTED AND COMPLETED SUICIDE

Attempted suicide has consistently been shown to be a strong predictor of completed suicide (see Graham et al. 2000 for review). Estimates of the magnitude of this risk however, vary considerably. The prevalence of completed suicides among those who have attempted has been estimated at $1 \%$ to $19 \%$ in the 12 months after the attempt (Diekstra 1992; Graham et al. 2000), $2.8 \%$ after 8 years (Hawton and Fagg 1988) and $10 \%$ after 10 years (Tejedor et al. 1999). Lifetime prevalence of completed suicide in those who have ever been hospitalized for suicidality has been estimated at $8.6 \%$ (Bostwick and Pankratz 2000). Although difficult to quantify on the basis of available data, the evidence suggests that approximately 1 in 10 individuals who attempt suicide will die by suicide at some point following the attempt. These reviews also pointed out, however, that the majority of completed suicides are not preceded by a suicide attempt (Graham et al. 2000). Estimates of risk for completed suicide that are derived only from estimates of previous attempts are therefore likely to underestimate the risk of completed suicide.

The issue is further complicated in that mental disorders have also been shown to be strong and consistent predictors of both suicide attempts and completed suicide (Brent et al. 1999; Graham et al. 2000; Harris and Barraclough 1997; Hawton and Fagg 1988; Kessler et al. 1999). Within this context, the exact nature of the relationship between CSA, mental disorder, suicide attempts and completed suicide is likely to be complex (Beautrais 2000). Unfortunately, none of the studies in the present report that examined the relationship between CSA and suicide attempts controlled for concurrent psychopathology.

From the above it is concluded that there is evidence of a relationship between attempted suicide and completed suicide. However, for the purposes of the current analysis it is necessary to determine whether a person who has been subject to CSA has any higher or lower chance of completing suicide conditional on having attempted it. To our knowledge these data do not exist. In the absence of these data the relative risk for suicide attempts will be used as proxies for the relative risk for completed suicide. This assumes a constant relationship between attempted and completed suicide given exposure to CSA. The extent to which this underestimates or overestimates the relative risk is unknown.

### 3.5 Estimates of risk factor-disease relationships by age, SEX AND SUbREGION

## Estimates of RISK

Table 23.11 summarizes the results of the meta-analysis and reports the relative risks for the psychiatric outcomes examined. No estimates are available for different age and sex groups. All studies were from AMR-A, WPR-A or EUR-A. No studies were available from other subregions that may have different cultural norms and socioeconomic
Table 23.1I Unadjusted and adjusted relative risks across disorder and abuse categories

|  | Non-contact abuse |  |  |  | Contact abuse |  |  |  | Intercourse |  |  |  |

| These relative risks have been adjusted for family dysfunction and other types of abuse. The RRs for suicide attempts have been divided by 2.66 and have been adjusted by I.39. |  |  |  |  |  |  |  |  |  |  |  |  |
| b Fixed-effects model used to combine estimates due to small number of studies available. |  |  |  |  |  |  |  |  |  |  |  |  |

circumstances. No differences in risk were assumed across sex and age breakdowns since numbers were few and many studies used lifetime diagnoses.

On the whole several conclusions can be drawn from these results. First, the relative risks were not significantly different across types of mental disorder, suggesting that CSA is not particularly associated with any one disorder. Rather the risk appears to be pervasive across the whole spectrum of mental disorders examined. This lack of specificity makes CSA particularly damaging, putting individuals at risk for a wide range of mental disorders.

Second, with the exception of suicide attempts, risks did not vary significantly across categories of abuse. This may reflect the small number of studies available for analysis, as there is a general trend for increased risk to be associated with "increased" exposure to CSA. That is, as more severe forms of CSA are experienced the risks for developing a mental disorder increase. This may indicate that those exposed to CSA do not represent a homogeneous group but instead reflect a group that varies in terms of exposure and subsequent risk for psychiatric disorder (Fergusson and Mullen 1999). However, this finding is largely an artefact of the extrapolation process. Further research will enable this "dose-response relationship" to be confirmed.

Non-contact abuse was not a significant predictor of risk after external adjustment for confounders. Non-contact abuse may constitute a more heterogeneous category of abuse compared to the contact and intercourse categories. Certainly, in the studies that contributed to this analysis the category of non-contact abuse encompassed a variety of acts. Such heterogeneity may make the results of the analysis hard to interpret. The question is whether non-contact does not place individuals at increased risk for disorders or whether some non-contact forms of abuse are more or less harmful than others. Cultural factors are likely to play a role in this and further investigation is required. Across the majority of disorders (excluding drug abuse/dependence) the relative risks for contact and intercourse forms of abuse remained significant after external adjustment. These results are more easily interpreted as the two categories are a more homogeneous group of acts and can be more tightly defined.

Results of the current meta-analysis were consistent with the only other review to look systematically at psychiatric diagnosis as an outcome of CSA. Fergusson and Mullen (1999) collated and reanalysed data from 12 studies reporting on the relationship between CSA and psychiatric dysfunction. While Fergusson and Mullen (1999) did not statistically combine the estimates, consistent and pervasive relationships between CSA and adult psychopathology were apparent. Other metaanalyses have been conducted in this area (Jumper 1995; Paolucci et al. 2001; Rind 1997; Rind et al. 1998) but have focused on continuous measures of adjustment. Jumper (1995) and Paolucci et al. (2001) have com-
mented on the difficulty in quantifying the impact that confounders have since many large-scale community studies do not measure them. Rind et al. (1998) was the only meta-analysis to control for the confounding effect of family environment using college samples since confounds are more likely to be measured in studies using these samples. Results of their analysis showed that the relationship between CSA and adjustment in adulthood disappeared after controlling for family environment. Adjustment in their analysis refers to the various psychological correlates of CSA measured in the studies that contributed to their analysis. Eighteen categories of psychological correlates were coded from the studies and included anxiety and depressive symptoms, plus broader areas of adjustment such as sexual adjustment and social adjustment. When commenting on Rind et al. (1998) results, Kendler et al. (2000) stated that CSA appears to be more related to lifetime psychiatric disorder rather than cross-sectional measures of adjustment which focus solely on current well-being. Certainly, the results of the current metaanalysis do suggest a significant relationship between CSA and psychiatric disorder after adjustment for important confounders.

Several caveats should be mentioned in regard to the current analysis. The external method of adjustment used was limited by the methodology of the studies from which the adjustment factors were derived. Across the studies family dysfunction was not defined or measured consistently and the measures that were used may not be reliable. It should also be noted that current research methodologies make it impossible to determine whether any antecedent signs or symptoms of psychiatric disorders mean that the child is more vulnerable to abuse, thus inflating the risk factor-disease relationship. Additionally, the majority of studies contributing to this analysis were conducted during a time when CSA was ignored and the victims were stigmatized. While no cohort effects were found for reporting episodes of CSA the stigmatization could possibly have had an impact on the degree to which people were affected.

To conclude, it appears that CSA is particularly damaging with effects evident over and above other forms of childhood adversity. Contact and intercourse categories of abuse remained significant after controlling for confounders but the category of non-contact was non-significant. Further research is required to understand the effects of various forms of noncontact abuse.

## RISK REVERSIBILITY

By definition, exposure to CSA stops at the age of 17 years. The reversibility of risk therefore refers simply to decline in the risk of developing mental disorder given exposure to CSA over the lifespan. Problems in quantifying the decline arise from both paucity of data and competing theoretical arguments. There are two arguments. Either assume that risk remains constant throughout the lifespan or assume that
risk subsides over time and eventually becomes that of people who were never abused. One can argue that risk remains constant over time as there is evidence to suggest that CSA alters your life trajectory such that you are more likely to experience problems with relationships, selfesteem and sexual adjustment (Mullen et al. 2000). These problems in themselves are associated with mental disorder and so potentially mediate the relationship between CSA and disorder in later life. Therefore, those exposed to CSA remain at increased risk for mental disorder compared to those who have not been exposed. Alternatively one can argue that risk decreases over the lifespan. As a person moves away from a traumatic life event, its power to inflict psychological harm is lessened and so those exposed to CSA eventually have the same risk for mental disorders as those not exposed.

The data collected for this report do not inform either argument further. Preliminary analyses divided the relative risks into two age groups, 15-29 and 30-44 years. Confidence intervals overlapped suggesting no significant difference between the two age groups. Two explanations can be given. First, the numbers in the groups were small limiting the robustness of the estimates. Second, most studies reported estimates of risk for lifetime mental disorders thereby preventing any clear distinction in onset of mental disorders between the two age groups from being made. In the absence of data we have assumed that risk remains constant over the lifespan, as it becomes mere speculation if one tries to estimate the amount risk reduces over time. In order to better inform this decision, data on risk for current disorder are required, broken down into appropriate age groups. Further analyses of the large community and prospective samples are required to address this.

### 3.6 Reasons and implications for extrapolation of risk FACTOR-DISEASE RELATIONSHIPS FROM ONE SUBREGION TO ANOTHER

This represents perhaps the biggest threat to validity to the present study. The studies in the risk analysis were overrepresented by samples from Australia, Canada, New Zealand, some European countries and the United States of America. The prevalence of psychiatric disorders varies from country to country and this variability represents the myriad social, economic and cultural factors that interplay with the development of disorder. The degree to which these same factors mediate the relationship between CSA and mental disorder cannot be quantified and is difficult to even speculate on. The answer to this is not likely to be reached in the near future as extensive research is required before sound conclusions can be drawn. The paucity of data and theoretical complexity necessitated the assumption that the relative risks remain constant across subregions.

### 3.7 Quantitative and Qualitative sources of uncertainty

Uncertainty in the current analysis came from several sources. Metaanalysis was used as a method of quantifying the quantitative uncertainty around the final prevalence estimates taking into account sample size or variability between studies, whichever is appropriate given the homogeneity of the estimates being combined.

The methods of extrapolation also introduce uncertainty into the analysis. In particular, the extrapolation conducted to get relative risks for the three levels of exposure will have introduced error. The ratios used for extrapolation came from only five studies and the relationship between the relative risks for each level of exposure may vary according to the population studied.

The external method employed to adjust for confounders introduces three sources of uncertainty. First, the instruments used to measure the confounders may have variable reliability. Second, the 12 studies that contributed to the adjustment factor all measured family dysfunction differently thereby creating another source of uncertainty. Third, the ability of the adjustment factor to be generalized to other studies conducted on different populations can be questioned. It is possible that confounders may mediate the relationship between CSA and outcomes differentially depending upon the population studied. Not enough studies that controlled for confounds were available to see if the adjustment factor varied in any systematic way.

Additionally, while all estimates came from AMR-A, WPR-A and EUR-A not all countries from those subregions were represented. Inter-country variations within subregions are possible and may affect the generalizability of our relative risk estimates. Even greater uncertainty is introduced when estimates from one subregion are extrapolated to another, a decision necessitated by the paucity of data from other subregions.

## 4. <br> Results and discussion

The discussion of the estimates of the burden in mental disorder outcome that is attributable to CSA will focus on differences between mental disorders, followed by an examination of sex, age and subregional differences. Across the world, CSA contributed to between $4 \%$ and $5 \%$ of the disability-adjusted life years (DALYs) in males and between $7 \%$ and $8 \%$ of the DALYs in females for each of depression, alcohol abuse/dependence and drug abuse/dependence. The attributable fractions were higher for panic disorder ( $7 \%$ for males and $13 \%$ for females) and higher still for PTSD ( $21 \%$ for males and $33 \%$ for females). For suicide attempts the attributable fractions were $6 \%$ for males and $11 \%$ for females. As discussed above, the confidence intervals around the relative risks of each of the mental disorders overlap and thus the apparent differences may not be real. The same applies to the attributable fractions.

On the whole CSA contributes to a higher percentage of DALYs for females than for males. This difference is driven by the difference in the prevalence of CSA for females and males. There are slight subregional variations in the attributable fractions. In particular, AFR-E and SEARD have higher attributable fractions than the other subregions. This is a function of the higher prevalence rates for these subregions. However, data for these subregions came from a few studies that were poor methodologically.

The number of DALYs attributable to CSA varies as this is a function of both the attributable fractions and the amount of burden of disease accounted for by psychiatric disorders in the various subregional groups. One pattern is evident, however: the number of DALYs are greater in the younger age groups and decline in the older age groups. Since risk was assumed to be constant across age, this merely reflected the distribution of DALYs for mental disorders, which impact largely in the younger age groups due to their early onset and chronic nature.

## 5. METHODS FOR PROJECTION OF EXPOSURE FORWARD

Estimates of avoidable burden, the amount of burden that could be prevented if exposure to CSA was curtailed, are dependent upon the expected prevalence of CSA in the future. As outlined above, we have assumed that CSA will not vary over time. The reviews conducted on cohort effects have provided equivocal evidence (Bagley 1990, 1995; Bagley and Ramsay 1985; Bickerton et al. 1991; Feldman et al. 1991; Fergusson et al. 2000). Three reviews concluded that the prevalence of CSA could increase over time while three reviews also conclude that there is no evidence to support a change in prevalence over time. Analysis of this phenomenon in our own data set also provided no evidence of a change in prevalence over time. Additionally, it is difficult to speculate on what future factors may arise to influence prevalence. Therefore, the estimates of avoidable burden should be the same as those for attributable burden.

## Chapter 24

# Distribution of risk factors BY POVERTY 

Tony Blakely, Simon Hales, Charlotte Kieft, Nick Wilson and Alistair Woodward

## Summary

Socioeconomic position is an important distal risk determinant for many health outcomes. While it was not possible (owing to limitations of data and other factors) to directly map socioeconomic position to the burden of disease, it was considered possible to map some risk factors by absolute poverty, which is one measure of socioeconomic position.

The proportions of the population living on $<$ US $\$ 1$, on US\$ 1-2 and on $>$ US $\$ 2$ per day were estimated for each of the 14 subregions ${ }^{1}$ using World Bank estimates of poverty by country. The counterfactual scenario was no absolute poverty in the world (no one living on $<$ US $\$ 2$ per day). The prevalences of risk factors for each subregion were obtained from the relevant risk factor chapters in this publication.

The associations of absolute poverty with eight risk factors (child and maternal underweight, unsafe water and sanitation, unsafe sex, indoor air pollution, outdoor air pollution, tobacco use, alcohol use and overweight [women only]) were determined by an indirect method, using asset scores calculated from demographic and health survey (DHS) data and income from living standards measurement surveys (LSMS) data. First, the joint association of the asset score or income variable with the risk factor was determined for each subregion. Second, the percentage estimates of poverty by subregion were overlaid on the ranked asset scores and income variables (e.g. if $20 \%$ of people in a subregion were estimated to be living on $<$ US $\$ 1$ per day, then the prevalence of each factor among these poor people was assumed to be that observed for the $20 \%$ of people with lowest asset scores). Third, the crude relative risks of each risk factor by level of poverty were estimated based on this overlay. We also undertook selective literature reviews for some risk factors.

Approximately one fifth of the world's population live on $<$ US\$ 1 per day and almost half on $<\mathrm{US} \$ 2$ per day. Of the 14 subregions, three
(EUR-A, AMR-A and WPR-A) had negligible levels of absolute poverty and were excluded from all subsequent analyses. We estimate that $9 \%$ of people in EMR-B were living on $<$ US $\$ 2$ per day ( $2 \%$ on $<$ US $\$ 1$ per day), but the estimates for this subregion were based on sparse data. The estimates for the remaining 10 subregions ranged from $18 \%$ ( $3 \%$ ) for EUR-B to $85 \%(42 \%)$ for SEAR-D and $78 \%$ ( $56 \%$ ) for AFR-D.

Childhood malnutrition, unimproved water and sanitation and indoor air pollution were strongly associated with absolute poverty. The associations of poverty with one indicator of unsafe sex (unprotected sex with a non-marital partner) and tobacco and alcohol consumption were weaker and variable across subregions. Our analyses and literature reviews were consistent with the proposition that tobacco and alcohol consumption, adverse lipid profiles, hypertension and overweight initially affect the non-poor in developing countries.

If the worldwide prevalence of childhood malnutrition among all children living on $<$ US $\$ 2$ per day were changed to that of children living on $>$ US $\$ 2$ per day (i.e. counterfactual scenario 1 ), $37 \%$ of the cases worldwide of underweight would be prevented (assuming a causal relationship). The equivalent percentage reduction from shifting all poor children to exactly US\$ 2 per day (counterfactual scenario 2 ) was $23 \%$. For inadequate water and sanitation these percentage reductions were $51 \%$ and $36 \%$, respectively.

Both poverty and risk factor data were available or were used for only some countries within each subregion, and thus extrapolations had to be made from those countries with data. Second, some subregions had no data at all for some risk factors (e.g. unsafe sex), thus limiting the number of subregions for which we could conduct analyses. Third, all results were based on survey data with their associated errors. Another notable limitation with our analyses was the assumption that the ranking by asset score was comparable to the unobserved ranking by income poverty. Nevertheless, our findings confirm that there are currently severe inequalities in the distribution of childhood malnutrition, inadequate water and sanitation and indoor air pollution by income poverty worldwide, with these risks concentrated among the poorest sectors of society.

## 1. Introduction

Income may affect health outcomes directly or through exposure to other risk factors (Figure 24.1). In this work, we mapped the crude associations of poverty with some of the health risk factors detailed elsewhere in this book. The risk factors included were childhood underweight, unsafe water and sanitation, unsafe sex, alcohol use, tobacco use, overweight (women only), indoor air pollution and outdoor air pollution.

There were insufficient data at the time to present analyses for the other risk factors. Also, some of the analyses for the risk factors men-

Figure 24.I Diagrammatic representation of poverty in relation to other risk factors and the global burden of disease

tioned above were more prone to bias because of unavailability of data, data being available or used for only a few countries within a given subregion, or proxy data being used (e.g. expenditure on tobacco and alcohol used as a proxy for actual consumption). Literature reviews were therefore conducted for both (i) the risk factors for which we conducted quantitative analyses but had concerns about the accuracy of our results; and (ii) those remaining risk factors for which there was published literature on the association with poverty or socioeconomic position. These reviews are presented for tobacco use, alcohol use, hypertension/blood pressure, cholesterol level, physical inactivity, overweight, lead and illicit drugs.

This chapter includes neither quantitative nor literature review findings for the following risk factors: child sexual abuse, contaminated injections in health care settings, fruit and vegetable consumption, injuries, micronutrient (vitamin A, iron and zinc) deficiencies, climate change, mental health risk factors and occupational risks.

### 1.1 SOCIOECONOMIC POSITION, RISK FACTORS AND HEALTH STATUS

Socioeconomic position is a multifaceted construct that includes both resource-based and prestige-based measures:

Resource-based measures refer to material and social resources and assets, including income, wealth and educational credentials; terms used to describe inadequate resources include "poverty" and "deprivation". Prestige-based measures refer to individuals' rank or status in
a social hierarchy, typically evaluated with reference to people's access to and consumption of goods, services and knowledge, as linked to their occupational prestige, income and educational level (Krieger 2001).

Health status is strongly determined by socioeconomic position. A burgeoning research literature from developed countries demonstrates that all-cause mortality and most causes of death occur at greater rates among groups with lower socioeconomic position (Blakely 2002; Drever and Whitehead 1997; Howden-Chapman and Tobias 2000; Mackenbach et al. 1997; Pamuk et al. 1998; Sorlie et al. 1995). Emerging research in the developing world points to similar associations within countries (Evans et al. 2001; Leon and Walt 2001; Wagstaff 2000; Wagstaff and Watanabe 2001), although data are still limited for individual-level (as opposed to ecological-level) analyses. However, it is unlikely that the relationship of personal socioeconomic position with health is of similar magnitude in all countries. For example, the association of lung cancer with lower socioeconomic position in developed countries is (mainly) due to the greater prevalence of tobacco smoking among groups with a lower socioeconomic position. However, this picture has arisen over time as tobacco consumption has moved from a pattern of behaviour associated with the more advantaged groups to one associated with those of lower socioeconomic positions in the developed world. As the tobacco epidemic moves through the developing world, we would first expect to see higher tobacco consumption among groups with higher socioeconomic position, and correspondingly higher lung cancer rates among groups with higher socioeconomic position. Thus we would expect to see varying associations of socioeconomic position with health status by subregion, and variation over time. This means that caution should be applied when generalizing the association of socioeconomic position with health status from one country to another, and from one time period to another.

### 1.2 Poverty as a measure of socioeconomic position

The definition of socioeconomic position given above makes it clear that poverty is only one component of the broader construct of socioeconomic position. As with socioeconomic position, poverty too is a multifaceted construct.

> A complex construct, poverty is inherently a normative concept that can be defined-in both absolute and relative terms-in relation to: "need", "standard of living","limited resources", "lack of basic security", "lack of entitlement", "multiple deprivation", "exclusion", "inequality", "class", "dependency" and "unacceptable hardship" (Krieger 2001).

The United Nations has identified two forms of poverty: "human poverty" and "income poverty" (UNDP 2000). Income poverty refers to
deprivation in a single construct-income. While income poverty is only one dimension of poverty, it is undoubtedly a core element. Human poverty, on the other hand, is characterized by impoverishment in multiple dimensions such as health, knowledge, standard of living and participation in society. The World Bank also accepts this view of poverty, which covers not only material deprivation but also low achievement in health and education (World Bank 2001a).

Sen (1999) views income poverty as one component of "capability deprivation", whereby the latter includes health and educational status that may offset income poverty, lead to income poverty, or be affected by income poverty. Also, the instrumental relationship between income and capability deprivation varies by circumstance. For example, someone in poor health may lose his or her source of income and incur extra expenditure.

A World Health Organization (WHO)-sponsored commission has recently underlined the importance at a macroeconomic level of investing in health care and public health services to enhance economic development (Commission on Macroeconomics and Health 2001). Such an approach is in contrast to the assumption that improved health status follows economic development. Thus, at both the individual and the country level, we are forced to think of a bi-directional association between poverty and health.

The advantages of income poverty as the indicator of socioeconomic status (SES) include:

- income poverty is more readily measured in a standardized way across countries and subregions than a more general and multifaceted measure of poverty;
- there has recently been a concerted attempt to measure the prevalence of absolute poverty by country (sponsored by the World Bank) in which the percentages of people in each country living on $<$ US $\$ 1$ and <US\$2 per day have been estimated (Chen and Ravallion 2000; World Bank 2001a);
- while we fully recognize that a broader concept of poverty encompasses health and other capabilities, in mapping health risk factors by poverty we wanted to avoid the endogeneity that would be incurred by directly incorporating health status in our measure of poverty (put another way, we wanted to avoid "self-correlation" whereby we map health risk behaviour by a poverty variable that incorporates health status as one component);
- income poverty might be considered more directly amenable to policy intervention than measures of socioeconomic position incorporating status and prestige; and
- it is not implausible to imagine a world in which people do not live on $<\mathrm{US} \$ 1$ or $<\mathrm{US} \$ 2$ per day-it would take only a relatively small amount of the income of populations in developed countries to be redistributed to poor people to lift everyone out of absolute poverty.
Nevertheless, there are disadvantages in using absolute poverty as the measure of socioeconomic position. First, the use of the absolute limits of US\$ 1 and US\$ 2 per day means that the affluent regions of the world (Western Europe, North America and the Western Pacific) are not included in analyses, since only a negligible proportion of the population in these regions live in such depths of absolute income poverty. Poverty still exists in these regions, but given the higher standards of living and average income it is of a more "relative" than "absolute" nature. One solution to this problem is to use relative poverty cut-offs, e.g. $60 \%$ of the median income in each country. We did not pursue this alternative, although our methods could be adapted to do so and there are World Bank estimates of relative poverty that are consistent with the absolute poverty estimates used in this chapter (Chen and Ravallion 2000). Second, poverty is only one aspect of socioeconomic position; we could, for example, have mapped health risk factors by educational status. Difficulties with such an approach include data limitations and a lack of standardized measures of education between countries and subregions.

Studies in developing countries were examined in order to give an approximation of the degree of concordance between the different socioeconomic measures, e.g. education, income and occupation. Of the 79 papers retrieved, 29 reported on the prevalence of a risk factor by more than one socioeconomic measure. Table 24.1 shows the papers that included more than one socioeconomic measure and the number that then revealed similar trends between the measures used. Some risk factors and socioeconomic measures have distinctive gender or cultural patterns that may affect these results.

Based on these papers, the distribution of risk factors showed similar trends by education and by income. Indeed, 10 of the 13 papers that used both income and education as independent measures of socioeconomic position showed similar relationships with the risk factor in question during analysis. By contrast, four out of the six papers that used both occupation and income independently as measures of socioeconomic position and only five out of 10 papers with occupation and education showed similar trends.

### 1.3 Poverty-Risk association

In addition to the advantages and disadvantages of our choice of absolute poverty as the measure of socioeconomic position, there are other limitations that must be borne in mind when interpreting the findings of this analysis.

Table 24.I Overview of papers from the literature review that used more than one measure of socioeconomic position

| Socioeconomic variable | Reference | Proportion showing similar association |
| :---: | :---: | :---: |
| Occupation, socioeconomic status | Agarwal et al. (1994) | 1/I |
| Education, occupation, income | al-Mannai et al. (1996); Ekpo et al. (I992); Grol et al. (1997a) | 2/3 |
| Education, income | al-Nuaim et al. (1996, 1997); Delpeuch et al. (2000); Kikafunda et al. (1998); Monteiro et al. (1995); Obot (1990); Rossouw et al. (1990); Sakamoto et al. (200I) | 6/8 ${ }^{\text {a }}$ |
| Education, occupation | Chaturvedi et al. (1998); Hodge et al. (1994); Hu and Tsai (2000); Jarallah et al. (1999); Narayan et al. (1996) | 2/5 |
| Water supply type, income, education | Chen (1996) | 0/1 |
| Education, insurance premium level | Chung et al. (1992) | 0/1 |

## Causal inference

There are two major problems with determining causality for poverty-risk factor relationships: endogeneity (i.e. the inseparability of poverty and health owing to dynamic, synergistic and bi-directional causal associations, as described above) and confounding (since poverty may be correlated with other determinants of health such as education) (Kaufman and Cooper 1999). We have taken the approach of simply
reporting ("mapping") crude associations of poverty and health risk factors. While this approach is limited by problems of endogeneity and confounding, it also avoids tenuous assumptions about controlling for confounders that are part of the constellation of factors that accompany poverty.

## Time-Lags

Any changes in health status or health risk factors caused by poverty will take time to occur. Some effects may be relatively rapid, such as an improvement in income that may immediately lead to the ability to buy food and avoid malnutrition. Other effects may take a long time. For example, it may take many years before political decisions utilize the collective wealth of the community to invest in a supply of clean water and adequate sewage disposal.

We do not account for time-lags, so that current distributions of risk factors may be a consequence of poverty levels in the past. This is consistent with the "mapping" nature of our project that determines the crude associations of poverty and risk factors.

## Heterogeneity of income within poverty levels

People living on $<\mathrm{US} \$ 1$ per day in one part of the world will differ in many ways from those living on $<$ US $\$ 1$ per day in other parts of the world. Some of this variation will be due to the accompanying (and possibly confounding) factors. For example, two countries may differ greatly in average educational level, despite having similar levels of income poverty.

However, there is likely to be variation in the depth of income poverty between countries and subregions. Most of the people living on $<$ US $\$ 1$ per day in one country may be living on an amount just less than US\$ 1 per day, whereas in another country the depth of poverty may be much greater. Having determined the prevalence of poverty by cut-offs such as US\$ 1 and US\$ 2 per day, economists then go on to characterize variation in depth of poverty by measures such as the poverty gap (and the squared poverty gap), which take account of the absolute shortfall (squared) in income beneath the poverty cut-off.

We have not accounted directly for varying levels of depth of poverty by subregion. However, by conducting analysis of people ranked by value of socioeconomic position (e.g. asset scores calculated at a subregional level), and using both a <US\$ 1 and <US\$ 2 per day cut-off, we have captured some of this variation.

Heterogeneity of the association of poverty with risk factors
In addition to the varying depths of poverty, there will be a range of reasons for heterogeneity in the association between poverty and health or health risk factors across the world, including:

- macroeconomic policies may mitigate against the expected health consequences of income poverty (for example, welfare system development and infrastructure may reduce the impact on risk factors of being poor);
- health care and public health services, if well organized and effective, should alter socioeconomic gradients in risk factors; and
- the effect of one socioeconomic factor (e.g. education and cultural factors) may interact with another (e.g. poverty), which if their joint distribution between countries/regions varies (as would the joint distribution of education and poverty), would manifest as heterogeneity of effect for either education or poverty considered in isolation.

For example, the cross-national comparison studies by Kunst and Mackenbach and colleagues demonstrate that the all-cause mortality differentials are surprisingly similar across European countries. However, the cause-specific gradients vary notably (Kunst et al. 1998a, 1998b; Mackenbach et al. 1997). For example, there are stronger cancer gradients in the south of Europe, and stronger cardiovascular disease gradients in the north. This variation by cause of death points to underlying variations between the north and south in the distribution of traditional lifestyle risk factors by socioeconomic position.

## 2. Methods

### 2.1 ESTIMATING ABSOLUTE POVERTY AND RISK FACTOR LEVELS

The proportion of total population in each country in absolute poverty was taken from the World Development Indicators 2001 CD-ROM (World Bank 2001b). These estimates were made by Chen and Ravallion (2000) using 265 national sample surveys for 83 countries, allowing for purchasing power parity (1993 base). In brief, these estimates of absolute poverty:

- extended previous work by Ravillion et al. (1991) for 1985 that found US\$1 a day to be representative of poverty lines found among lowincome countries;
- were based on consumption data where possible, although income data (with adjustment) were used when consumption data were missing;
- considered local as well as global estimates of poverty lines in order to arrive at one poverty level applicable to all countries;
- used data from different time periods, but adjusted all dollar estimates to one point in time (1993) and adjusted for purchasing power parity; and
- applied to consumption per person per day (i.e. not household consumption).

Chen and Ravallion set the main poverty line at US\$ 1.08 per person per day, using 1993 as the base year. These authors and the World Bank simply referred to this cut-off as US\$ 1 per day, and we followed this method. We also included an additional income range of US\$ 1-2 per day.

To allow comprehensiveness, we used 1993 estimates of poverty as provided on the World Development Indicators 2001 CD-ROM (World Bank 2001b) and extracted data on the percentage of the population with a daily income of $<\mathrm{US} \$ 1$ and $<\mathrm{US} \$ 2$ per day for all available countries. We used the estimates of country populations provided on the CDROM to calculate the distribution of the population by subregion within the trichotomous absolute poverty variable.

To estimate the percentage of people living in absolute poverty by subregion, we simply extrapolated the estimated percentages of people living in absolute poverty based on countries with data to the countries without data. Figure 24.2 shows the variation in the percentages of the total population of each subregion living in countries with World Bank estimates

Figure 24.2 Percentages of the population in each subregion living in countries with available World Bank income poverty estimates

Subregion

[^91]of absolute poverty. For example, in AFR-D the countries for which there were poverty data comprised $79.7 \%$ of the total population of that subregion.

The three subregions with $<5 \%$ of their populations represented by countries with absolute poverty estimates were the three most affluent subregions: AMR-A, EUR-A and WPR-A. As these three subregions contain no (or very few) people living in absolute poverty, they were not included in the analyses.

Ten of the remaining 11 subregions had country-level poverty data covering $>70 \%$ of the total population in the subregion. The subregion with the least data was EMR-B. For this subregion only $11 \%$ of the total population lived in countries for which there were absolute poverty estimates from the World Bank. Accordingly, all estimates presented in this chapter of an association between absolute poverty and risk factors in EMR-B, should be treated with considerable caution.

The country-level (World Bank) and subregional-level estimates (our extrapolations) of the percentages of people in absolute poverty are shown in Table 24.2. We estimated that $9.1 \%$ of people in EMR-B were living on $<$ US $\$ 2$ per day ( $2.1 \%$ on $<$ US\$ 1 per day), although the estimates for this subregion were based on sparse data, as described above. The poverty estimates for the remaining 10 subregions ranged from $17.6 \%$ of people living on $<$ US\$ 2 per day ( $3.0 \%$ on $<$ US $\$ 1$ per day) for EUR-B to $85.2 \%$ ( $42.4 \%$ ) for SEAR-D and $77.9 \%$ ( $55.5 \%$ ) for AFR-D.

Table 24.3 presents estimates of absolute poverty for the whole world and for developing countries. The first panel of estimates is that provided by Chen and Ravallion (2000) for the member 2 (i.e. developing, nondonor) countries of the World Bank. These estimates, covering the period 1987-1998, generally indicate that a quarter of the population of the developing world live on $<$ US $\$ 1$ per day, that over half live on $<$ US $\$ 2$ per day, and that there was some reduction in the prevalence of absolute poverty between 1993 and 1996. However, the estimates for 1998 were provisional.

The second panel of results in Table 24.3 shows our estimates of absolute poverty for the 11 "non-A" subregions, i.e. the pooled estimates based on the data in Table 24.2. The World Bank data used in Table 24.2 were mostly for the late 1990 s. We have therefore placed our estimates under 1996-1998 and they can be seen to be very close to those for a similar time period for the non-donor countries of the World Bank.

The third panel of results in Table 24.3 shows our estimates of absolute poverty for the whole world, assuming nil absolute poverty in EUR-A, AMR-A and WPR-A. We estimated that $20.2 \%$ of the world's population live on $<\mathrm{US} \$ 1$ per day and $48.6 \%$ live on $<\mathrm{US} \$ 2$ per day, representing 1.2 billion and 2.9 billion people, respectively. These estimates agree well with those of 1.2 and 2.8 billion, respectively, reported in the World development report 2000/2001 (World Bank 2001a).

| <US\$ I per day |  |  |  |  |  |
| <US\$ 2 per day | - | - | - | 20.2 |  |
| - No data. | - | - | - | 48.6 |  |

The country-level poverty estimates from the World Bank were not disaggregated by sex and age. We assumed a uniform distribution of absolute poverty by sex and age. (We also estimated the crude joint distribution of poverty and risk factors without considering variation by sex and age.) A future improvement to the analyses presented here, therefore, would be to conduct sensitivity analyses on the variation in the poverty distribution by sex and age. This improvement, however, would also require estimating sex- and age-specific joint associations of poverty and each risk factor, for which there are currently very few data.

We obtained the prevalence (or distribution) of risk factors by subregion from the respective chapters in this publication. Wherever possible we used a dichotomous specification of the risk factor for the age and sex strata combined (i.e. crude prevalence estimates by subregion for each risk factor) except for unsafe sex, for which the different sexes were analysed separately. Using a dichotomous variable resulted in the loss of information included in distributions or multiple exposure categories.

### 2.2 Estimating Joint distribution of absolute poverty and RISK FACTOR RELATIONSHIP

Table 24.4 represents a stylized version of the data collection sheets required for each subregion. The marginal totals (in bold) show absolute poverty and risk factor prevalence. Our task was to estimate the cell values, $a, b, c$, $d$, e and $f$. If each of the values " $a$ " to " $f$ " represents the absolute percentage of the population of the total subregion in each cell, then:

$$
a+b+c+d+e+f=100 \% .
$$

Table 24.4 Data collection sheets by subregion: 2 by 3 tables of percentage risk factor by poverty

|  | Exposed to risk factor | Not exposed to risk factor |  |
| :--- | :---: | :---: | :---: |
| <US\$ I per day | a | b | $\mathbf{M}_{\mathbf{1}}$ |
| US\$ I-2 per day | c | d | $\mathbf{M}_{\mathbf{2}}$ |
| Non-poverty | e | f | $\mathbf{M}_{\mathbf{3}}$ |
|  | $\mathbf{P}$ | $\mathbf{Q}$ | $\mathbf{1 0 0 \%}$ |

It was possible to approximate the values for " a " to " f " via the results of the regression analyses and indirect method described above. However, these estimates would have been consistent with the prevalence of the risk factor in the survey data sets used (i.e. DHS or LSMS), but not necessarily consistent with the prevalence of the risk factors determined in the relevant chapters in this publication. Likewise, the fixed poverty percentages came from an external source, and thus all the marginal percentages ( $\mathrm{M}_{1}, \mathrm{M}_{2}, \mathrm{M}_{3}, \mathrm{P}$ and Q ) were fixed. To solve the joint distribution within the table, we used prevalence ratios (referred to as "relative risks" hereafter) estimated using the regression and indirect method, such that:

$$
\begin{align*}
\mathrm{RR}_{1} & =\text { relative risk of risk factor for <US\$1 compared to }>\text { US } \$ 2 \\
& =\left(\mathrm{a} / \mathrm{M}_{1}\right) /\left(\mathrm{e} / \mathrm{M}_{3}\right) \tag{1}
\end{align*}
$$

$\mathrm{RR}_{2}=$ relative risk of risk factor for $>$ US \$ 1 but $<$ US $\$ 2$

$$
\begin{equation*}
\text { compared to >US\$ } 2 \tag{2}
\end{equation*}
$$

$$
=\left(\mathrm{c} / \mathrm{M}_{2}\right) /\left(\mathrm{e} / \mathrm{M}_{3}\right)
$$

Given that $\mathrm{c}=(\mathrm{P}-\mathrm{a}-\mathrm{e})$, then Equation 2 can be rearranged to give:

$$
\begin{align*}
\mathrm{RR}_{2} & =\left((\mathrm{P}-\mathrm{a}-\mathrm{e}) / \mathrm{M}_{2}\right) /\left(\mathrm{e} / \mathrm{M}_{3}\right) \\
& =\frac{(\mathrm{P}-\mathrm{a}-\mathrm{e}) \mathrm{M}_{3}}{\mathrm{eM}} \\
\rightarrow \mathrm{eRR}_{2} \mathrm{eM}_{2} & =\mathrm{PM}_{3}-\mathrm{aM}_{3}-\mathrm{eM}_{3}  \tag{3}\\
\rightarrow \mathrm{e}\left(\mathrm{RR}_{2} \mathrm{M}_{2}+\mathrm{M}_{3}\right) & =\mathrm{PM}_{3}-\mathrm{aM}_{3} \\
\rightarrow \mathrm{e} & =\frac{\mathrm{M}_{3}(\mathrm{P}-\mathrm{a})}{\mathrm{RR}_{2} \mathrm{M}_{2}+\mathrm{M}_{3}}
\end{align*}
$$

Rearranging Equation 1 to solve for "e", and substituting in Equation 3 allows a solution in terms of " a ":

Figure 24.3 Flow diagram of how the distribution of poverty and risk factors might be estimated

$$
\begin{align*}
a M_{3} / R_{1} M_{1} & =M_{3}(\mathrm{P}-\mathrm{a}) /\left(\mathrm{RR}_{2} \mathrm{M}_{2}+\mathrm{M}_{3}\right) \\
\rightarrow \mathrm{a} & =\left(\mathrm{RR}_{1} \mathrm{M}_{1} \mathrm{P}-\mathrm{RR}_{1} \mathrm{M}_{1} \mathrm{a}\right) / \mathrm{RR}_{2} \mathrm{M}_{2}+\mathrm{M}_{3} \\
\rightarrow \mathrm{a}\left(\mathrm{RR}_{2} \mathrm{M}_{2}+\mathrm{M}_{3}\right) & =\mathrm{RR}_{1} \mathrm{M}_{1} \mathrm{P}-\mathrm{RR}_{1} \mathrm{M}_{1} \mathrm{a}  \tag{1}\\
\rightarrow \mathrm{a}\left(\left(\mathrm{RR}_{2} \mathrm{M}_{2}+\mathrm{M}_{3}\right)+\mathrm{RR}_{1} \mathrm{M}_{1}\right) & =\mathrm{RR}_{1} \mathrm{M}_{1} \mathrm{P} \\
\rightarrow \mathrm{a} & =\mathrm{RR}_{1} \mathrm{M}_{1} \mathrm{P} /\left(\left(\mathrm{RR}_{2} \mathrm{M}_{2}+\mathrm{M}_{3}\right)+\mathrm{RR}_{1} \mathrm{M}_{1}\right)
\end{align*}
$$

Having calculated "a" the remaining within-cell percentages in Table 24.4 are easily solved.

Figure 24.3 shows a flow diagram of three methods that might be used to estimate this joint distribution.

Ideally the direct method would have been used, but there were no appropriate survey data using a poverty definition equivalent to that of Chen and Ravallion (2000). We therefore had to employ an indirect estimation procedure, using survey data on the joint distribution of other socioeconomic and risk factors. A necessary and key assumption of this indirect method was that the association of risk factors with various
ranked socioeconomic factors was similar. Put another way, we had to assume that one socioeconomic factor could be substituted for another when measuring socioeconomic gradients in health-related behaviour. This was a strong assumption, but one with some support. We did not use the last option of extrapolation from other subregions or expert opinion.

### 2.3 Data sources and analysis

Table 24.5 provides a summary of the risk factors reported elsewhere in this book, and the extent of inclusion of risk factors in this work.

Indirect estimation of the joint distribution of poverty by risk factor required individual-level data from countries within all subregions. Selected DHS were the main source of these data. We also used LSMS data and survey data specific to China.

## DEmographic and health survey (DHS) data

DHS are nationally representative household surveys with large sample sizes of about 5000 households (see http://www.measuredhs.com). The DHS programme is conducted by Macro International, with support from the US Agency for International Development. A standard set of questionnaires, similar in all countries, is used to collect data at individual, household and community levels. Four rounds of surveys have been conducted in the past two decades, in which several thousand households were sampled at intervals in some 50 countries across Asia, Africa, the Middle East, Latin America and the area covered by the former Soviet Union.

The core DHS consists of questionnaires for the household and for women specifically. A sample of women aged 15-49 years are interviewed on the following topics: household characteristics, lifetime reproduction, contraceptive knowledge and use, maternity and breastfeeding, immunization, children's health, marriage and fertility preferences, husband's background and the woman's work status. In addition, other country-specific questions may be asked. The DHS contains data for five of the comparative risk assessment (CRA) risk factors:

- underweight in children (weight-for-age $z$-score, DHS variable code hw8);
- improved water and sanitation (DHS variable codes v113 and v116);
- unsafe sex (DHS variable codes v502, 525, 531, 761, 851, 852, 853, 872);
- mother's body mass index (DHS variable code v445); and
- cooking fuel (country-specific variables).

We constructed these variables, in some cases by using several of the original DHS variables. We obtained unit-level data for 53 countries,
Table 24.5 Summary of the CRA risk factors

| Risk factor | Continuous/categorical | Survey data available for socioeconomic position by risk factor | Inclusion in data analysis | Inclusion in systematic literature review |
| :---: | :---: | :---: | :---: | :---: |
| Air pollution, indoor | Prevalence of solid fuel exposure | Yes-LSMS | Yes | No |
| Air pollution, urban | PM $10\left(\mu \mathrm{~g} / \mathrm{m}^{3} ; 1-10,11-50,5 \mathrm{l}-100, \geq 100\right)$ | Partial | Yes | No |
| Alcohol use | Amount weighted by pattern of drinking | Yes ${ }^{\text {a }}$ | Yes | Yes |
| Child sexual abuse |  | No | No | No |
| Contaminated injections in health care settings | Proportion receiving injection contaminated with HIV, HCV, HBV | Insufficient | No | No |
| Global climate change |  | Insufficient | No | No |
| High blood pressure |  | Insufficient | No | Yes |
| High cholesterol |  | Insufficient | No | Yes |
| Illicit drug use |  | Insufficient | No | Yes |
| Lead exposure | Mean (SD), prevalence $>0.016 \mu \mathrm{~g} / \mathrm{dl}$ | Insufficient | No | Yes |
| Low fruit and vegetable consumption | Mean (g/day), prevalence could be derived | Insufficient | No | No |
| Malnutrition: protein-energy (0-4 years) | Prevalence underweight (weight-for-age z-score <-2) | Yes-DHS | Yes | No |
| Micronutrient deficiencies | (Vitamin A, haemoglobin, iodine) | Insufficient-UNICEF MICS2 not yet available | No | No |
| Occupational risks (selected) | Prevalence chemical, physical, biological, human factors, safety risk | Insufficient | No | No |
| Overweight and obesity | Prevalence of overweight and obesity | Yes (women only)—DHS | Yes (women only) | Yes |
| Physical inactivity |  | No | No | Yes |
| Tobacco use | Used indirect method | Yes ${ }^{\text {a }}$ | Yes | Yes |
| Unsafe sex | United Nations variables | Yes-DHS | Yes | No |
| Unsafe water, sanitation and hygiene | Prevalence of five exposure scenarios | Yes-DHS | Yes | No |

a Alcohol and tobacco data on LSMS were household expenditure data only. Further, it was not possible to "weight" alcohol data by pattern of drinking as in chapter 12.
taking the most recent survey if the country had been surveyed more than once in the period 1986-2000. Of these, an asset score could be calculated for 51 countries, as listed in Table 24.2.

## Calculation of asset score

Income was not directly elicited by the standard DHS. However, the World Bank has undertaken extensive work to create asset scores using DHS data (Filmer and Pritchett 1988). Data from the first round of surveys were re-coded to ensure comparability with the subsequent three rounds of surveys. Core questions from all surveys were combined into a single data set. Four categorical variables were constructed as component variables for a DHS asset score: urban-rural status, housing construction material (usually floor material), educational status and availability of electricity. If these variables were missing for a particular country a substitute variable was used where possible, as follows:

- wall material was substituted for floor material in Pakistan;
- number of rooms was substituted for floor material in India; and
- possession of a radio was substituted for electricity supply in Burundi, the Dominican Republic, Liberia and Tunisia.

For two countries (Sri Lanka and Turkey) it was not possible to find suitable substitute variables and asset scores could not be calculated. We considered including more variables in the factor analysis in order to increase the resolution of the asset scores. However, no further variables were available for all countries; thus the addition of further variables would have meant that fewer countries could be included in the subsequent analyses. We considered it important that the asset score be applicable to as many countries as possible. Also, unlike some other asset scores, ours did not include access to safe water to avoid self-correlation in the analyses of water and sanitation by asset score.

Figures 24.4-24.7 show the distribution of DHS observations by the four variables used to calculate the asset scores. (The actual numbers of observations are shown in Appendix A, Table A.1.) There was a predominance of rural people in the DHS data sets (Figure 24.4). There was notable variation between subregions in floor type (Figure 24.5), but there was also some possible variation in coding patterns between countries with regard to the use of the intermediate "rudimentary" floor type. The education variable had four levels, with reasonable spread across respondents and variation in patterns between subregions (Figure 24.6). There was marked variation between subregions in the dichotomous variable for access to electricity.

The distributions of these variables varied markedly between different countries, even within subregions (Appendix A, Table A.1).

A global ${ }^{2}$ asset score was calculated using factor analysis. The four variables used to make up the asset scores were coded within the DHS

Table 24.7 Loadings for factor I (from Table 24.6)

| Variable | Factor loading | Uniqueness |
| :--- | :---: | :---: |
| Education | 0.60216 | 0.63740 |
| Urban-rural | -0.58536 | 0.65735 |
| Floor type | 0.59736 | 0.64316 |
| Electricity | 0.68570 | 0.52982 |

Table 24.8 Scoring coefficients for factor I (from Table 24.6)

| Variable | Scoring coefficient |
| :--- | :---: |
| Education | 0.25759 |
| Urban-rural | -0.24446 |
| Floor type | 0.25310 |
| Electricity | 0.34373 |

data sets with numeric values corresponding to different categories or variable values:

- urban-rural status: $0=$ large city, $1=$ small city, $2=$ town, $3=$ rural area
- floor type: 1 = natural, 2 = rudimentary, 3 = finished
- highest education level achieved: $0=$ none, $1=$ primary, $2=$ secondary
- access to electricity: $0=$ no, $1=$ yes.

Principal factor analysis was performed in Stata (an interactive data analysis program) for these four variables. The results are shown in Tables 24.6 and 24.7.

Given that only four variables (each with relatively few values) were available for the factor analysis, only 96 discrete asset score values were generated, ranging from -1.12 (more poor) to 1.60 (least poor). The scoring coefficients are shown in Table 24.8.

A full account of the resulting asset score values, and the number of DHS observations with each score by subregion, is given in Appendix A, Table A.2.

Figure 24.8 shows the number of DHS observations by asset score by subregion. The size of the circles represents the number of observations at that asset score value. The number of DHS observations with asset scores is fewer for EMR-B $(n=4184)$ and EUR-C $(n=4704)$ than for subregions such as AFR-D $(n=94811)$ and SEAR-D $(n=107044)$. For AFR-D and AFR-E the asset scores are skewed towards the lower end (as expected) and for AMR-B and AMR-D are skewed to the higher end.

We did not calculate subregional-level asset scores. As the eventual use of asset scores was to rank individuals by socioeconomic position, based on the assumption that this ranking was comparable to that by absolute poverty (also a global construct), we did not consider the construction of subregional-level asset scores justified. Moreover, the range of discrete values of the asset score and sample sizes within some subregions would have introduced instability in asset score indices between subregions that may not have been a function of genuinely varying "asset score constructs" but rather introduced greater random error.

## Weighting of the DHS data sets

The objective of the weighting was to ensure that the analyses represented as closely as possible the distribution of the whole population in each subregion. A two-step weighting procedure was thus required.

Figure 24.8 Distribution of asset scores by subregion

Table 24.9 Examples of weights for DHS analyses

| Country in given subregion | Number of people <br> in DHS sample ( $n$ ) | Number of people <br> in country (N) | Weight (N/n) |
| :--- | :---: | :---: | :---: |
| Country A | 1000 | 500000 | 500 |
| Country B | 5000 | 5000000 | 1000 |
| Country C | 2000 | 100000 | 50 |
| Total of countries sampled | 8000 | 5600000 |  |

1. Owing to the sampling characteristics of the DHS, each observation in the DHS is assigned a country-level weight. The sum of these weights is the same as the total sample size for that particular country, multiplied by 1 million. We simply converted that weight back to a distribution with a mean of 1.0 by dividing by 1 million. We called this component weight $\mathrm{w}_{\mathrm{i}}$, being the individual-level DHS weight for the $\mathrm{i}^{\text {th }}$ observation in each country.
2. We then weighted the individual DHS observations to be representative of country population by dividing the total population of the $j^{\text {th }}$ country $\left(N_{j}\right)$ by $\sum^{i} w_{1}$-the country-level weight. (Note that $\sum^{i} w_{i}$ is simply the DHS sample size for that particular country.) The product of the individual-level and country-level weights, $\mathrm{w}_{\mathrm{ij}}=\left(\mathrm{N}_{\mathrm{i}} / \sum^{\mathrm{i}} \mathrm{w}_{\mathrm{i}}\right) \times \mathrm{w}_{\mathrm{i}}$, was then assigned to the $\mathrm{i}^{\text {th }}$ observation in the $\mathrm{j}^{\text {th }}$ DHS country (within subregions). Note that within each country, the sum of $\mathrm{w}_{\mathrm{ij}}$ is simply the total population of that country.

To illustrate the necessity for the second weighting step, Table 24.9 provides hypothetical data for a given subregion. If each observation were entered unweighted into any analysis, the results would be skewed towards the pattern of risk factor by poverty present for the individuals "most represented". In Table 24.9, that would be the individuals in country C, where each observation represents only 50 people. To rectify this, the weights in step 2 above (i.e. those in the final column of Table 24.9) were combined with the DHS weights.

The application of the weights for the analysis using the indirect method was not simply a matter of weighting each individual observation. Rather, the asset score was modelled as a cumulative proportion of the population, i.e. a ranking. Thus, we used the weights to make the ranking representative of the total subregional population's ranking, not just the ranking in the available data samples, as described below.

Table 24.10 shows a hypothetical data set for 10 DHS observations (record numbers i , for $\mathrm{i}=1-10$ ). Without considering weights, each of these 10 observations represents $10 \%$ (or a proportion of 0.1 ) of all

Table 24.10 Hypothetical example of IO DHS observations and weighted "midpoint" of cumulative proportion

| Record number (i) | Midpoint of cumulative proportion distribution of $i$ | Weight | Sum of weights | Cumulative proportion of weights | Midpoint of cumulative proportion of weights |
| :---: | :---: | :---: | :---: | :---: | :---: |
| I | 0.05 | 200 | 200 | 0.040 | 0.020 |
| 2 | 0.15 | 700 | 900 | 0.180 | 0.110 |
| 3 | 0.25 | 900 | 1800 | 0.360 | 0.270 |
| 4 | 0.35 | 150 | 1950 | 0.390 | 0.375 |
| 5 | 0.45 | 1900 | 3850 | 0.770 | 0.580 |
| 6 | 0.55 | 200 | 4050 | 0.810 | 0.790 |
| 7 | 0.65 | 100 | 4150 | 0.830 | 0.820 |
| 8 | 0.75 | 400 | 4550 | 0.910 | 0.870 |
| 9 | 0.85 | 300 | 4850 | 0.970 | 0.940 |
| 10 | 0.95 | 150 | 5000 | 1.000 | 0.985 |

observations. The midpoint of the cumulative proportion distribution is therefore $0.05,0.15, \ldots, 0.95$, as shown in the second column of Table 24.10. Assume, however, that each of these 10 observations represents varying numbers of the total population, as represented by the weights in third column. The cumulative sum, cumulative proportion and "midpoint" of the cumulative proportion of the weights are shown in the final three columns of Table 24.10. For example, the weight for record 2 was 700 , and the sum of weights for records 1 and 2 was $200+700=900$. The sum of all weights was 5000 . Therefore, the cumulative proportion of weights up to record 2 was $900 / 5000=0.180$. The midpoint of the cumulative proportion distribution was half way between the cumulative proportion of weights for records 1 and 2, i.e. $0.040+((0.180-$ $0.040) / 2$ ) $=0.110$.

Thus, weighting of the midpoints of the cumulative proportion "repositions" the rank value between 0 and 1 . This repositioning aims to place each observation at about the position it would have been if the entire population of the subregion had been sampled.

## Comparison of asset scores and income in Pakistan

The Pakistan Integrated Household Survey 1991, one of a series of LSMS conducted by the World Bank, included direct estimates of household income as well as variables required to generate an asset score. Thus, we were able to examine the distribution of asset scores by income at the individual level within one country. Note that the available income data
were not consumption data. Also, the asset score variables were not identical to those on the DHS data sets.

We calculated an asset score similar to the method described above. It was not possible, however, to include a variable for urban-rural status, as there were no comparable data readily available from the survey.

Figure 24.9 is a whisker plot of asset scores by rank of household income. Each box-whisker plot is for a given asset score. The boxes show the 25 th and 75 th percentiles of rank income for a given asset score, and the whiskers show the 5th and 95th percentile ranks of income for that asset score. It is evident that, while there is an association in the expected direction of rank asset score and rank household income, there is also considerable variation of household income ranks within a given asset score.

It is possible that the wide distribution of income data in Figure 24.9 is due to measurement error. Also, incomes tend to be volatile whereas assets are a more stable indicator of long-term income. Therefore, while income and asset scores are not as closely associated as one might wish, this does not render asset scores an unsuitable proxy for income poverty. First, in developed countries we find similar associations between a range of socioeconomic factors and health despite considerable imperfections

Figure 24.9 Box-whisker plot of the normalized rank of estimated household income (NRinc) by normalized rank of household asset score for Pakistan, using LSMS data

Table 24.1 I Comparison of assigning income poverty level in Pakistan using asset score and household income score according to LSMS data

|  |  | Allocation to level of poverty by <br> household asset score |  |  |
| :--- | :---: | :---: | :---: | :---: |
|  |  | <US\$ 1 | US\$ I-2 | $>$ US\$2 |
| Allocation to level of poverty | <US\$ I | $17 \%$ | $14 \%$ | $1 \%$ |
| by household income score | US\$ I-2 | $16 \%$ | $35 \%$ | $3 \%$ |
|  | $>$ US\$2 | $1 \%$ | $10 \%$ | $3 \%$ |

in the correlation of these socioeconomic factors at individual level (Blakely and Pearce 2002; Blakely et al. 2002). Second, we cannot tell, from Figure 24.9, which is the better proxy for income poverty. Third, we treat income poverty here as a categorical variable. It may thus be more reasonable to compare household income score and asset score rank in assigning people to $<$ US $\$ 1$, US $\$ 1-2$ and $>$ US $\$ 2$ per day using the World Bank estimates of $31 \%$, $54 \%$ and $15 \%$, respectively (Table 24.11). Fifty-five per cent of households are correctly assigned to an income category using asset score rankings.

## Asset scores by gross national product (GNP)

There was a moderately strong correlation between the rank of weighted average asset score for each country and the rank of GNP per capita by country (Spearman rank correlation coefficient 0.68), providing further (albeit highly aggregated) evidence that the asset score is a proxy measure of income (Figure 24.10).

## Indirect method using DHS asset scores

We identified three possible pathways for estimating the joint distribution of poverty and risk factors at the subregional level.

1. Pool DHS data by subregion, directly estimate association of asset scores with risk factors and then derive relative risks of each risk factor by poverty categories.
2. Determine the association of asset scores and risk factors for each country, derive relative risks of each risk factor by poverty categories at the country level, then either: (a) pool (e.g. Maentel-Haenzel) the country-level relative risk estimates; or (b) estimate the number of people in each cell of the two by three table (risk factor by three-level poverty variable) for each country using population data, sum the numbers of people in each cell for all countries in the subregion with data, and then calculate subregional-level relative risks. (Note: 2 b estimates the "crude" relative risks by poverty at the subregional

Figure 24.10 Scatter plot of rank of a country's per capita GNP against the rank of a country's average asset score

level, whereas 2 a estimates the relative risks unconfounded by country.)

A priori we chose method 1 as our task was to estimate subregionallevel associations. We were not confident that the data would support country-level calculations for each risk factor, and we were concerned about instability arising from country-level working. However, a strength of method 2 was that it did not assume that a given asset score equated to the same income poverty across countries within subregions.

The principle of the indirect method applied directly to subregionallevel data is first illustrated using a simplified example of aggregate (quintile) data before the more detailed non-parametric regression techniques are considered.

Table 24.12 shows some hypothetical data for the distribution of childhood malnutrition by quintile of asset score at the subregional level. The midpoints of each quintile on a cumulative proportional distribution are shown in the last column.

Figure 24.11 shows a scatter plot of the prevalence of childhood malnutrition by these midpoints. If the plot is nearly linear (as in this case), a regression line is fitted. This method is similar to that used to calculate the relative and slope indices of inequalities (Mackenbach and Kunst 1997).

Table 24.12 Hypothetical distribution of childhood malnutrition by asset score

| Quintile of asset score | Prevalence of childhood <br> malnutrition (\%) | Midpoint on cumulative <br> proportion distribution |
| :--- | :---: | :---: |
| (poorest) | 22 | 0.1 |
| 2 | 17 | 0.3 |
| 3 | 12 | 0.5 |
| 4 | 9 | 0.7 |
| 5 | 6 | 0.9 |

Figure 24.II Percentage childhood malnutrition plotted against cumulative proportion of population ranked by asset score

Assuming that this regression line is similar to the unobserved line for poverty by underweight, it can be used to estimate the prevalence of malnutrition by level of poverty. For example, if in a particular subregion the percentage of children living on $<$ US $\$ 1$ per day is $20 \%$, the percentage living on US\$1-2 per day is $30 \%$, leaving $50 \%$ non-poor. The midpoints on the cumulative proportional distribution for these poverty groups would accordingly be $0.10,0.35$ and 0.75 . Solving the regression equation (shown in Figure 24.11) for each of these midpoints, we estimate the prevalence of underweight to be $21.2 \%, 16.2 \%$ and $8.2 \%$, respectively. Treating the non-poor as the reference group, these per-
centages equate to relative risks of 2.59 for children living on $<$ US $\$ 1$ per day (i.e. 21.2/8.2) and 1.98 for children living on US\$ 1-2 per day (i.e. 16.2/8.2). Also, the relative risk of underweight for children living on US $\$ 2$ per day compared to all those living on $>$ US $\$ 2$ can be estimated as 1.61 .

Locally linear kernel regression. While illustrative, this example is an oversimplification for two reasons. First, we needed to allow for nonlinear associations. Second, we wanted to use the fact that more than five values of the asset score were captured in the unit-level DHS data. These objectives can be met using a non-parametric regression technique: locally linear kernel regression. This method essentially fits separate linear regression curves for each unit increase in the independent variable(s). In so doing, observations closest to the midpoint are given more weight, and observations further away are given less weight. The outcome is a fitted curve comprising many linear segments that, together, give a smoothed regression line.

Given the large size of the data set, we were able to use the unit-level DHS data for this regression method only for the unsafe sex risk factor. For these unit-level analyses we modelled the logit in Stata. However, for underweight, and for water and sanitation, the observations were too many for efficient computation. Therefore, we calculated the average prevalence of each risk factor within categories of asset score. These aggregate data were then analysed with Proc Loess in SAS software. The procedure for a single risk factor within one subregion was as follows.

1. The normalized rank of each asset score value was calculated based on the DHS and country-level weights as before (section 2.3).
2. The average prevalence of the risk factor was estimated for each asset score value.
3. The prevalence of the risk factor was regressed on the asset score using locally linear kernel regression.
4. This analysis was weighted according to the number of DHS observations represented by each data point ("weight" option of Proc LOESS in SAS—otherwise the default options were used).

This method was repeated for each subregion, and the whole process repeated for each of the risk factors.

Estimating the joint association of poverty and risk factors. To estimate the joint association of absolute poverty and each risk factor, we determined the average prevalence of the risk factor over the range of asset score rankings equivalent to the poverty estimate.

1. Dummy observations were appended to the data set, representing $0.1 \%$ increments of asset score rank between the poorest (rank 0.00) and the least poor (rank 1.00).
2. The results of the locally linear kernel regression were linearly interpolated to provide estimated risk factor prevalences for each of the $0.1 \%$ increments of asset score ranking.
3. Average risk factor prevalences were estimated for the appropriate range of the dummy observations, to the nearest $0.1 \%$.

For example, if $20.5 \%$ of people in a given subregion lived on $<$ US $\$ 1$ per day, we estimated the percentage underweight among those living on $<$ US\$1 as the average prevalence under the interpolated curve representing asset score ranks of $0.000-0.205$. Thus, for each subregion, we estimated the prevalence of the risk factor for:

- people living on $<\mathrm{US} \$ 1$ per day;
- people living on (equal to) US\$ 1 per day;
- people living on US\$ 1-2 per day;
- people living on (equal to) US\$2 per day; and
- people living on $>$ US $\$ 2$ per day.

Using these prevalence estimates, we then estimated the following relative risks of each risk factor for each subregion:

- <US\$ 1 per day compared to $>$ US $\$ 2$ per day;
- US\$ 1-2 per day compared to >US\$2 per day;
- (equal to) US\$2 per day compared to $>$ US\$ 2 per day;
- <US\$ 1 per day compared to $>$ US\$ 1 per day; and
- (equal to) US\$ 1 per day compared to $>$ US\$ 1 per day.

## Living standards measurement survey (LSMS) Data

The LSMS protocol and questionnaires were developed by the World Bank in 1980 and have been carried out in a number of countries. The main purpose of the LSMS is to provide a tool for monitoring living standards and household behaviour in developing countries, with a focus on measuring and understanding poverty. There are three levels of questionnaires within the LSMS: household (household-level income, expenditure and possibly behavioural questions), community (information common to all members of the local community, such as availability of schools, water and electricity) and price (local market prices for basic commodities).

Table 24.13 LSMS countries available for analysis: total population of country and year surveyed

| Country | Subregion | Total population (000s) | Year surveyed $^{\text {a }}$ |
| :--- | :--- | :---: | :---: |
| Ghana | AFR-D | 18785 | $1998 / 1999$ |
| Côte d'lvoire | AFR-E | 15545 | 1988 |
| South Africa | AFR-E | 42106 | 1994 |
| Panama | AMR-B | 2811 | 1997 |
| Ecuador | AMR-D | 12412 | 1995 |
| Pakistan | EMR-D | 134790 | 1991 |
| Azerbaijan | EUR-B | 7983 | 1995 |
| Bulgaria | EUR-B | 8208 | 1995 |
| Tajikistan | EUR-B | 6237 | 1999 |
| Kazakhstan | EUR-C | 14927 | 1996 |
| Russian Federation | EUR-C | 146200 | 1992 |

a Where the country was surveyed in more than one year only the latest year's data were taken.

The questionnaires are made up of modules (not all of which are used by every country) and are often modified to suit the needs and the situation of the country in question. However, all LSMS surveys are run according to similar protocols, with rigorous quality control measures. They are designed to be quickly and easily administered in the field and rapidly entered into data entry programs.

There are currently about 25 countries listed on the World Bank web site as having LSMS data, some of which have been surveyed more than once. There are different access policies for data from the different countries: some have open data policies, while others allow only restricted access to data. The data set collected varies from country to country, but may include information on income, expenditure, cooking fuel, tobacco use, alcohol consumption, height and weight and many other variables. We were restricted in our analyses to countries for which we could access LSMS data within the given time frame, and to those for which income or expenditure information as well as appropriate risk factor information was available (Table 24.13). Unless otherwise stated, it was assumed that every LSMS survey was representative of the country; hence no survey weights were used in the analyses.

Table 24.14 summarizes the risk factor information available by country. As information on hypertension and physical inactivity were available for only one country each (Bulgaria and the Russian Federation, respectively), these risk factors were not analysed.

For Bulgaria, Ghana, South Africa and Tajikistan there was no question in the surveys asking about individual tobacco or alcohol consumption. The prevalence of this risk factor thus had to be calculated

Table 24.14 LSMS countries and risk factor information available from their data sets

| Country | Subregion | Indoor air <br> pollution | Tobacco <br> use | Alcohol <br> use | Hypertension | Physical <br> inactivity |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| Ghana | AFR-D | Yes | Yes* | Yes* | No | No |
| Côte d'lvoire | AFR-E | Yes | No | No | No | No |
| South Africa | AFR-E | Yes | Yes* | Yes* | No | No |
| Panama | AMR-B | Yes | Yes | Yes | No | No |
| Ecuador | AMR-D | Yes | Yes | Yes | No | No |

| Bulgaria | EUR-B | Yes | Yes* | Yes* | Yes | No |
| Tajikistan | EUR-B | Yes | Yes* | Yes* | No | No |
| Kazakhstan | EUR-C | No | Yes | Yes | No | No |
| Russian Federation | EUR-C | Yes | Yes | Yes | No | Yes |

Yes Variable is available.
No Variable is not available.

* Variable is available only in form of household spending on item.
** Alcohol and tobacco information available only in combined variable.
using household expenditure information for alcohol and for tobacco. A household was classified as using tobacco if any money was recorded as having been spent on cigarettes or tobacco within the expenditure section of the questionnaire. Likewise, a household was classified as using alcohol if any money had been spent on alcohol. While this is a rather crude measure, it should at least give us an approximate idea of the proportion of households with smokers and/or alcohol consumers.

For Azerbaijan the measure was even cruder, as there was only one variable to cover both alcohol and tobacco expenditure. Hence it could not be determined whether any money spent was on tobacco or alcohol or both.

Finally, it must be emphasized that the results based on LSMS data must be treated somewhat cautiously owing to the limited number of countries (and subregions) represented and the proxy nature of some of the risk factor variables.

## Calculation of income

LSMS data sets included information on income. A pre-generated aggregate per capita income variable was used if one was provided with the data set; otherwise an income variable of this type was generated using the available data. All income variables were equivalized by dividing by the square root of the number of members of the household, if this had
not already been performed within the generated variable. For Ecuador, only aggregated per capita expenditure was used.

As these income variables were generated in different ways, and to allow for purchasing power parities between countries, each country's income data were treated separately and ranked on a continuous scale from 0 to 1 for further analysis. For example, the household with the median LSMS income in a given country was assigned a ranked income value of 0.5 .

## Indirect method using LSMS income data

Since we were concerned about purchasing power parities between subregions, we did not pool the data by subregion to estimate the association of poverty with risk factors. Rather, we estimated associations at country level and aggregated these to subregions. Unlike the DHS data, the LSMS analyses were unweighted. Also, the smaller data sets allowed regression analyses on unit-level data (rather than using aggregated data). The associations between income and the various risk factors were determined by categorizing each risk factor into a dichotomous variable and then using the indirect method at the country level to estimate relative risks by poverty (see section 2.3).

Having obtained country-level joint distributions of the total population for poverty by the risk factor, we then aggregated these to estimate the association at the subregional level. Table 24.15 shows, as an example, the distribution of indoor air pollution by countries within subregion EUR-B.

Thus, the estimated subregional prevalence of indoor air pollution in EUR-B for those living on $<$ US $\$ 1$ per day is $0.36 \times 64 \%+0.37 \times 20 \%$ $+0.28 \times 74 \%=0.51$. The final subregional estimates are based only on those countries for which we had data (as for the DHS analyses).

Table 24.15 Distribution of indoor air pollution by countries in EUR-B for which data were available

| Country | Population (000s) | Proportion of population | Prevalence of indoor air pollution by poverty category (\%) |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: |
|  |  |  | <US\$ I/day | US\$ I-2/day | >US\$ 2/day |
| Azerbaijan | 7983 | 0.36 | 64 | 62 | 43 |
| Bulgaria | 8208 | 0.37 | 20 | 22 | 17 |
| Tajikistan | 6237 | 0.28 | 74 | 76 | 74 |
| Total | 22428 | 1.00 |  |  |  |

## Data for China

We used data from the 1993 China Health and Nutrition Survey (CHNS). The information on this survey that follows is adapted from the web site of the Carolina Population Center at the University of North Carolina at Chapel Hill (http://www.cpc.unc.edu/china, accessed 23 June 2003).

The study population is drawn from the provinces of Guangxi, Guizhou, Heilongjiang, Henan, Hubei, Hunan, Jiangsu, Liaoning and Shandong. This sample is diverse, with variation in a wide range of socioeconomic factors (income, employment, education, modernization) and other related health, nutritional and demographic measures.

A multistage, random cluster process was used to draw the sample surveyed in each of the provinces. Counties in the nine provinces were stratified by income (low, middle, high) and a weighted sampling scheme was used to randomly select four counties in each province. In addition, the provincial capital and a lower-income city were selected. Villages and townships within the counties, and urban and suburban neighbourhoods within the cities, were selected randomly. The 190 primary sampling units consisted of 32 urban neighbourhoods, 30 suburban neighbourhoods, 32 towns and 96 villages. In 1989-1993 there were 190 primary sampling units and about 3800 households in the overall survey, covering some 16000 individuals.

All household members in 1993 provided individual data on dietary intake, body fat distribution, blood pressure, medical history and healthrelated behaviour (e.g. smoking, beverage consumption, medication, key chronic diseases). The following risk factor variables were available.

- Underweight ( $n=702$ children)

Weight-for-age $z$-scores, calculated using the EpiNut program, ranged from -5.08 to 9.98 (mean -0.313 ). Using a cut-off $z$-score of $\leq-2.0$, $12.4 \%$ of children were malnourished.

- Water and sanitation $(n=3422)$

Data on how households obtained water and type of toilet facilities were used to assign $63.9 \%$ of households as having "improved water and sanitation".

- Indoor air pollution $(n=3412)$

Data on fuel used for cooking was used to assign $81.4 \%$ of households as using "smoky" fuels (coal, wood, sticks, straw and charcoal).

- Tobacco ( $n=8617$ )

A total of $31.9 \%$ of subjects were assigned as smokers.

- Alcohol ( $n=8659$ )

A total of $34.5 \%$ of subjects were assigned as alcohol drinkers.

- Body weight ( $n=4465$ )

## Calculation of income

Questions on income and time allocation look for any possible activity that each person might have engaged in during the previous year, both inside and outside the formal market. Full income from market and nonmarket activities can be imputed. The variable we used for income was the aggregated deflated total per capita income variable. We considered this a better option than creating a new equivalized household income variable. Also, it was not exactly clear how many people there were in each household to allow for equivalization. Some exploratory analyses (not reported) suggested that the results for an equivalized household income variable were very similar to the deflated per capita income variable. Estimated deflated per capita household income was used to generate income rankings.

The association between income and the various risk factors was determined by categorizing each risk factor into a dichotomous variable. The indirect method, using locally weighted sum of squares regression in the same manner as described below for DHS asset scores and LSMS income data, was then used to estimate the relationship between the normalized rank of income and the dichotomous risk factor variable. The income-poverty cut-offs were then superimposed to estimate the prevalence of each risk factor within each income-poverty category. A total of $18.5 \%$ of the Chinese population were assumed to be living on <US\$ 1 per day, $35.2 \%$ on US $\$ 1-2$ per day and $46.3 \%$ on $>$ US $\$ 2$ per day.

Other methods adopted for specific risk factors

## Ambient air pollution

Asset scores were used to estimate income distribution in urban and rural populations. For this purpose, the urban-rural variable in the DHS data was reclassified as follows: 0 or $1=$ urban; 2 or $3=$ rural.

We assumed that the distribution of asset scores in the DHS data was representative of the distribution in the relevant subregion. The approximate income distribution of urban and rural populations was estimated based on subregional asset-score cut-offs as before. Because the estimates of urban and rural income were approximate, we used only two income categories: <US $\$ 1$ per day and $>$ US $\$ 1$ per day.

We assumed that rural populations (proportions c and d in Table 24.16) were uniformly exposed to a particulate level of $5 \mu \mathrm{~g} / \mathrm{m}^{3}$ in all subregions. We further assumed that, within subregions, the exposure of urban populations (proportions a and b in Table 24.16) was independent of income. Average urban air pollution exposures by subregion were obtained from chapter 17. The exposure estimates were weighted accord-

Table 24.16 Proportion of population within urban/rural category

|  | Income |  |
| :--- | :---: | :---: |
|  | <US\$I per day | $>$ US\$ I per day |
| Urban | a | b |
| Rural | c | d |

ing to the proportions in Table 24.16. For example, the average exposure in populations living on $<\mathrm{US} \$ 1$ per day $=$ ( a xexposure in urban areas) + (cxexposure in rural areas).

## Body weight

The only body weight (body mass index) data we had available were for women in the DHS data set with children aged $<5$ years. Thus our analyses were restricted to this group.

## Systematic literature reviews

We conducted eight literature reviews focusing on the developing world for tobacco, alcohol, illicit drugs, hypertension, cholesterol, body weight, physical inactivity and lead (see section 4). We also conducted some less rigorous literature reviews for malnutrition, water and sanitation and unsafe sex (see Appendix C).

An initial literature search was conducted using Medline. Papers were limited to those published in English between 1990 and 2001. Four search domains were specified, as shown in Table 24.17. Search domains 1-3 were common to all, while domain 4 was risk-factor-specific.

There was substantial heterogeneity among the retrieved papers with regard to:

- subregions included;
- socioeconomic factor(s) used;
- measurement of the risk factor (e.g. not many of the protein malnutrition papers used weight-for-age [underweight]; they used rather height-for-age [stunting] or weight-for-height [wasting]);
- time period (a particular problem if the prevalence of poverty or the patterning of risk factor [e.g. tobacco] by socioeconomic position was rapidly changing during the 1980s and 1990s);
- study population sampling (e.g. many studies were conducted among poor communities, not as random population samples);
- study population demographics (e.g. limited to certain age groups); and

Table 24.17 Search domains and Medline search strategy

| Search domain | Medline search strategy |
| :--- | :--- |
| I. Socioeconomic | Poverty.af or socioeconomic:.af or income:.af <br> position or poverty <br> MeSH headings <br> Socioeconomic factors (exploded to include subheadings: <br> career mobility, poverty, poverty areas, social class, social mobility) |

| (exploded) or Polynesia (exploded) |  |
| Where possible, we used the same Medline search strategy as |  |
| that used for other chapters of this publication |  |

a The suffix ".af" in the Medline search strategy refers to "all fields".

- reporting of results (e.g. only odds ratios reported with no prevalence data, only multivariate results reported, or only $P$ values reported with no effect estimate).

For the more rigorous literature reviews, additional searches were performed as follows.

The Cochrane Library was searched for relevant systematic reviews. While Cochrane reviews have been shown to be of higher quality and to be less biased on average than other systematic reviews, they nevertheless have limitations. Other systematic reviews were searched for in the Database of Abstracts of Reviews of Effectiveness and by the recommended methods for review identification (Glanville and Lefebvre 2000).

Medline searches were conducted for the period 1980 to February 2002. The key search terms for the topics included: smoking, tobacco, alcohol, illicit, cannabis, marijuana, opiate, amphetamine, cocaine, inhalant, hypertension, blood pressure, cholesterol, obesity, body weight, inactivity, exercise, lead and poisoning, and blood lead. The key search terms for socioeconomic status included: poverty, inequality and socioeconomic factors. Where more detailed searches were undertaken, additional search terms included: social class, education, occupation and income.

Other references were identified from the reference lists of key review articles and from a WHO key informant.

## 3. Quantitative results

### 3.1 Underweight

Underweight in children was defined as a weight-for-age $z$-score $<-2$, using the NCHS or Harvard reference populations (see chapter 2). For the developing world, excluding WPR-B, underweight information was ascertained using DHS data sets. For WPR-B, for which we had no applicable DHS data set, underweight prevalence information was obtained using the CHNS data set.

As shown in Table 24.18, there were reasonable numbers of children available for analysis in all subregions except EUR-C and WPR-B. Thus, results for those two subregions should be treated with caution.

Locally linear kernel regression smooth plots ("Loess plots") of underweight according to weighted asset score ranking at the subregional level are shown in Figure 24.12. Each sub-figure plots the proportion of malnourished children (y-axis ranging from 0 to 1 ) by asset score rank for the subregion (x-axis ranging from 0 [poorest] to 1 [least poor in subregion]). The centre point of each plotted circle depicts the prevalence of underweight children at that given asset score rank, and the size of each circle is proportional to the number of observations. The middle line is the fitted curve and the upper and lower lines are the $95 \%$ confidence bands. (More weight is given to those observations with larger numbers as indicated by a larger circle size.)

From Figure 24.12 it is clear that children living in households with low asset scores (and by inference also living in absolute income poverty) were substantially more likely to be underweight in all subregions. This is consistent with expectation and the findings of Wagstaff and

Table 24.18 Sample sizes for child underweight by subregion

Figure 24.12 Loess plots of the prevalence of underweight children ( $y$ axis) by normalized rank of asset score (scale $0-I$, x-axis)

Watanabe (2001). Other than the overall differences in prevalence of underweight by subregion, the only other notable difference between subregions was a prevalence of underweight that did not vary greatly among those with lowest ranked asset scores for EMR-D and SEAR-D, but then dropped off more rapidly among those with higher ranked asset scores (i.e. a "shoulder effect"). The EMR-D analyses were based on only two countries-Morocco and Pakistan. With nearly five times the population of Morocco, Pakistan dominates the empirical estimates for EMR-D. An inspection of the Pakistan-only Loess plot (not shown) demonstrates a shoulder effect similar to that for EMR-D in Figure 24.12, although not as marked. Morocco, with only $2 \%$ of its population living on <US\$ 1 per day, had much lower levels of underweight children than Pakistan, further exaggerating the apparent shoulder effect. Using only the Pakistan data, we would have estimated relative risks of 2.3 and 1.8 for those living on <US $\$ 1$ per day and on US $\$ 1-2$ per day, respectively, compared to >US\$2 per day. The overall relative risk estimates for EMR-D were both 1.7 (Table 24.19). The sensitivity analysis presented below also suggests that the results for EMR-D set out in Table 24.19 should be treated with considerable caution.

The SEAR-D analyses were based on three countries-Bangladesh, India and Nepal. India makes up about $87 \%$ of the population of these three countries combined, and therefore dominates the SEAR-D estimates. The Loess plot for India (not shown) also demonstrates a shoulder effect. Some $86 \%$ of the Indian population lives on $<$ US $\$ 2$ per day ( $44 \%$ on <US $\$ 1$ per day). It appears that the steeply declining levels of underweight at the right-hand end of the SEAR-D plot in Figure 24.12 are due to the non-poor (and often financially quite well-off) Indian population living on $>$ US $\$ 2$ per day.

Inspection of the remaining country-level Loess plots (not shown) did not disclose any other countries with a distinctly different pattern of underweight by asset score rank. Consequently, we conclude that the remaining subregional-level plots in Figure 24.12 provide an approximate summary of the country-level associations.

Based on the smoothed curves in Figure 24.12 and a subregional-level analysis of asset scores by underweight, we estimated the relative risks of underweight by level of absolute poverty, as shown in the final column of Table 24.19. For example, we estimated that children in AFR-D living on $<$ US $\$ 1$ per day were 2.3 times more likely to be underweight than children living on >US $\$ 2$ per day. Likewise, children living on US \$1-2 per day were estimated to be 1.4 times more likely to be underweight, and children living on exactly US $\$ 2$ per day were estimated to be 1.2 times more likely to be underweight. Using these first two relative risk estimates and the fixed marginal prevalences of absolute poverty and underweight (shown in italics to the right of the two by three tables), we calculated the values for each of the cells within the two by three tables. Finally, the middle column of Table 24.19 simply presents the prevalence

Table 24.19 Cell prevalence of weight-for-age by poverty, prevalence of underweight by poverty, and relative risk of underweight by poverty, by subregion, for children aged $0-5$ years for a US\$2 per day cut-off

| Subregion | Weight-for-age |  |  |  | Prevalence of underweight by poverty (\%) |  | Relative risk of underweight |  |

[^92]of underweight children within strata (or "rows") of poverty level. For example, the prevalence of underweight children among those living on $<$ US\$ 1 per day in AFR-D was 22.5/55.5 = 40.5 \% .

The results in Table 24.19 demonstrate a reasonably consistent association of underweight with absolute poverty across subregions. Aggregating the 11 subregions to give a total developing world summary, we estimated that children living on $<$ US $\$ 1$ per day were 3.1 times more likely to be malnourished than children living on $>$ US $\$ 2$ per day. Table 24.20 shows the calculations for a cut-off of US\$ 1 per day.

## SENSITIVITY ANALYSIS

An alternative way of estimating the association of poverty and DHS risk factors for subregions was to conduct analyses for each country (i.e. to apply the indirect method at the country level to estimate the joint distribution of income poverty and risk factors), then aggregate up to subregions. The advantage of this method is that it allows for instances in which a given asset score does not equate to a similar income poverty level in different countries. The main disadvantages are that for many risk factors country-level estimates of the association of asset score and risk factors are unstable, and that countries without a World Bank estimate of income poverty could not be included. In terms of the latter, we had to exclude six countries from AFR-D (Benin, Cameroon, Chad, the Comoros, Guinea and Togo), Malawi from AFR-E, Nicaragua from AMR-D and Kyrgyzstan from EUR-B from country-level analyses. (See section 2 for discussion on the relative advantages of the country-level and subregional-level alternatives.) The country-level estimates, together

| EUR-B | $2.0(1.9)$ | $1.7(1.6)$ |
| EUR-C | $2.3(2.4)$ | $2.1(1.9)$ |
| SEAR-D | $2.0(2.1)$ | $1.6(1.7)$ |

with the subregional-level estimates from Table 24.20 (in parentheses), are shown in Table 24.21.

The country and subregional-level estimates vary notably for AFR-D, but any conclusion as to which method is more valid is difficult owing to the absence of six countries from the country-level sensitivity analysis. The other notable disagreement was for EMR-D (Morocco and Pakistan only). Closer scrutiny revealed a low estimate of absolute poverty in Morocco compared to Pakistan ( $7.5 \%$ and $85 \%$ <US $\$ 2$ per day, respectively), yet the asset scores in Morocco and Pakistan largely overlapped, and the prevalence of underweight children was much less in Morocco than in Pakistan. Correspondingly, the subregional-level relative risk estimates of 1.7 and 1.7 should be treated with some caution. More generally, the subregional-level estimates for EMR-D for water and sanitation, and overweight should also be treated with caution. For other subregions there was insufficient reason to prefer the country-level to the subregional-level estimates presented in sections 3.1, 3.2, 3.3 and 3.9 using DHS data. However, the findings for EMR-D illustrate the importance of scale. Relationships between income, asset score and risk factors may vary, not only between countries but also within national populations.

### 3.2 Unsafe water and poor sanitation

Water and sanitation availability was defined as a two-level categorical variable:

- no water supply and/or no sanitation (categories ${ }^{3} \mathrm{Va}, \mathrm{Vb}$ and VI in Prüss et al. 2001); and
- improved water and improved sanitation (category IV in Prüss et al. 2001).

Table 24.22 shows the actual samples sizes for the water and sanitation analyses. CHNS data were used in WPR-B (see Appendix B).

Table 24.22 Sample sizes for water and sanitation by subregion

| Subregion | No water and/or no sanitation |  | Improved water and sanitation |  |
| :---: | :---: | :---: | :---: | :---: |
|  | n | Percentage | n | Percentage |
| AFR-D | 49323 | 55 | 39968 | 45 |
| AFR-E | 43815 | 53 | 38781 | 47 |
| AMR-B | 6554 | 14 | 40314 | 86 |
| AMR-D | 16422 | 32 | 35647 | 68 |
| EMR-B | 1154 | 28 | 3030 | 72 |
| EMR-D | 13217 | 33 | 26650 | 67 |
| EUR-B | 826 | 10 | 7336 | 90 |
| EUR-C | 74 | 2 | 4472 | 98 |
| SEAR-B | 9346 | 74 | 3339 | 26 |
| SEAR-D | 67293 | 64 | 38647 | 36 |
| WPR-B | 2185 | 64 | 1237 | 36 |

Smoothed scatter-plots of water and sanitation according to household asset score rankings showed increasing availability of water and sanitation with increasing asset score, despite considerable variation in the shape of the curves (Figure 24.13). Conversely, households living in absolute poverty were more likely to lack water and/or sanitation.

Table 24.23 presents the relative risks derived from the smoothed plots in Figure 24.13 and the two by three tables. Note that the data in Table 24.23 are expressed for unimproved water and sanitation, i.e. 1 category IV, where category IV is according to Prüss et al. (2001). The strength of the association was even stronger than that for childhood underweight, with relative risks for people living on $<$ US $\$ 1$ per day compared to people living on $>$ US $\$ 2$ per day ranging from 2.0 to 15.1. Given this wide range of relative risks, the aggregated global results should be treated with caution. Full tabular results for a US\$ 1 per day cut-off are presented in Table 24.24.

### 3.3 Unsafe sex

To derive estimates of unsafe sex, we estimated the prevalence of sex with a non-marital partner (variable UN1 on DHS data) and, of those having sex with a non-marital partner, the proportion using a condom (variable UN2 on DHS data).

| UNI Higher-risk sex in <br> the last year | All who had sex in the last year <br> (denominator) | Sex with non-marital partner <br> in the last year (numerator) |
| :--- | :--- | :--- |
| UN2 Condom use at | All who had higher-risk sex in the | People who used condom at <br> latest higher-risk sex <br> last year and were asked about <br> condom use at the latest time <br> (denominator) | | latest higher-risk sex |
| :--- |
| (numerator) |

a The results for EMR-D should be interpreted with caution.
b Summary of the subregions in the table, including the subregional-level estimates for EMR-D.

For males, the relatively low sample sizes meant that it was possible to perform locally linear kernel regression directly on the unit-level (binary) data using logistic regression (see Figure 24.14). Thus, in Figure 24.14 (unlike the other figures of smooth plots) there are no "bubbles", since there was no need to use aggregate data. For females, the same aggregated procedure was used as for the other risk factors in this chapter, using the prevalence of each risk factor at the discrete values of the asset score. From the smoothed curves, we estimated the distribution of UN1 and UN2 within categories of income and by subregion, as before. Table 24.25 gives sample sizes by subregion.

Sample sizes were inadequate for several subregions. In EUR-B and EUR-C, adequate data were available only for women and detailed results for these subregions are not presented. Sex with a non-marital partner and condom use among those having sex with a non-marital partner were each less common among poor males and females within subregions (see Figures 24.14-24.16).

The prevalence of higher-risk (non-marital) sex by poverty for a US\$2 per day cut-off is shown in Tables 24.26 (males) and 24.27 (females). The prevalence of condom use during higher-risk sex by poverty for a US $\$ 2$ per day cut-off is shown in Tables 24.28 (males) and 24.29 (females). The corresponding values for a US\$1 per day cut-off are given in Tables 24.30-24.33.

Table 24.24 Cell prevalence of unimproved water supply by poverty, prevalence of unimproved water supply by poverty, and relative risk of unimproved water supply by poverty, by subregion, for a US\$ I per day cut-off

[^100]
### 3.4 Indoor air pollution

LSMS data for 10 countries were used for the indoor air pollution analyses (see Table 24.14). Supplementary data were also used for three DHS countries-Colombia (AMR-B), Indonesia (SEAR-B) and India (SEARD). Two other demographic and health surveys (Ethiopia plus Zimbabwe combined and Panama) had some indoor air pollution data, but could not be used owing to inadequate sample sizes among the non-poor. The combined sample sizes and distribution are shown in Table 24.34.

We used estimates of indoor air pollution unadjusted for ventilation. The survey data questions we used to determine the joint association were compatible with these unadjusted estimates.

Locally linear kernel regression smooth plots of smoke-producing cooking fuel use according to normalized equivalized income ranking are shown in Figure 24.17. Each subfigure plots the proportion of households using smoke-producing cooking fuels ( $y$-axis ranging from 0 to 1 ) by normalized equivalized income rank for the country ( x -axis ranging from 0 [poorest] to 1 [richest in the country]).

Table 24.35 shows the estimated association of absolute poverty and indoor air pollution for a cut-off of US\$ 2 per day, using the area under the curves in Figure 24.17. There is considerable variation between subregions in the average level of exposure to indoor air pollution and in the relative differences within subregions by poverty. In both African subregions, and to a lesser extent in both South-East Asian subregions, there is both an extraordinarily high prevalence of exposure to indoor air

pollution and little relative difference between the poor and non-poor. Analyses for SEAR-B are presented only for a cut-off of US\$ 1 per day (Table 24.36), as the data were insufficient for analyses based on a US\$2 per day cut-off.

For the 11 subregions, it was estimated that indoor air pollution was 2.2 times more likely among those living on <US\$ 1 per day than among those living on $>$ US $\$ 2$ per day. We stress that this estimate obscures considerable heterogeneity between subregions.

### 3.5 OUTDOOR AIR POLLUTION

The estimated exposures to ambient particulate air pollution $\left(\mathrm{PM}_{10}\right)$ by income category and subregion are shown in Table 24.37. The method used assumed that people living in urban areas are all exposed to a constant level of outdoor air pollution, and likewise those living in rural areas. However, the uneven distribution of income poverty between urban and rural areas allowed us to make (crude) estimates of varying

exposure to air pollution by income poverty levels. (See section 2 for further details.)

Exposure to outdoor air pollution was estimated to be substantially higher in the higher-income category (those living on >US\$ 1 per day) in all subregions. This is due to a greater proportion of poor people living in rural areas, where there is less outdoor air pollution. These summary estimates inevitably obscure considerable heterogeneity within countries and even within cities, where particular patterns of air pollution emissions and meteorological conditions may combine to produce local variations in air pollution.

### 3.6 Tobacco use

Chapter 11 uses an indirect method based on lung cancer mortality to estimate the contribution of tobacco use to the global burden of disease, and the prevalence of tobacco use by subregion was not estimated. We took estimates of subregional prevalence of tobacco use
from the web site of the WHO Tobacco or Health Programme (http://www.cdc.gov/tobacco/who/whofirst.htm).

Analyses for tobacco were based on LSMS data for 10 countries in seven subregions-AFR-D (Ghana), AFR-E (South Africa), AMR-B (Panama), AMR-D (Ecuador), EMR-D (Pakistan), EUR-B (Azerbaijan, Bulgaria, Tajikistan) and EUR-C (Kazakhstan, the Russian Federation). Data on tobacco for Bulgaria, Ghana, South Africa and Tajikistan were available only in the form of household expenditure data, and for Azerbaijan as a composite variable of combined alcohol and tobacco expenditure. A household was classified as a smoking household if any money was spent on cigarettes or tobacco. While this is a rather crude measure, it should at least give an approximation of the proportion of households containing smokers, assuming that all purchases made by the household were for household use and that these items were not received through other means. For the remaining countries, questions were asked in the surveys on whether the individual was a smoker or not. For these countries, analyses were confined to individuals aged $>15$ years. Because of the incorporation of proxy expenditure data, the quantitative results in this section should be treated cautiously and interpreted in the light of the literature review in section 4.

The sample sizes for tobacco use by subregion are shown in Table 24.38.

Locally linear kernel regression smooth plots of tobacco use according to normalized equivalized income ranking are shown in Figure 24.18. Each subfigure plots the proportion of tobacco use ( y -axis ranging from 0 to 1 ) by normalized equivalized income rank for the country ( x -axis ranging from 0 [poorest] to 1 [richest in the country]).

Table 24.38 Sample sizes for tobacco use by subregion

| Subregion | Persons using tobacco |  | Persons not using tobacco |  |
| :---: | :---: | :---: | :---: | :---: |
|  | $n$ | Percentage | n | Percentage |
| AFR-D | 557 | 9 | 5441 | 91 |

- No data.

Figure 24.18 Loess plots of the prevalence of tobacco use ( $y$-axis) by normalized income rank (x-axis)

Figure 24.18 Loess plots of the prevalence of tobacco use (y-axis) by normalized income rank (x-axis) (continued)

Full tabular results for US $\$ 2$ and US $\$ 1$ cut-offs are given in Tables 24.39 and 24.40, respectively, using the area under the curves in Figure 24.18.

Perhaps the most important result shown in Table 24.39 is the considerable variation between subregions in overall average tobacco use, but the relatively weak association of tobacco use within subregions by individual-level poverty. Thus the average prevalence of tobacco use in each subregion is a more useful predictor of individual tobacco use than absolute level of poverty.

Variation in the prevalence of tobacco use by poverty level within subregions was of secondary importance, and variable in direction. In AFRE (South Africa data only) and AMR-D (Ecuador data only) there was a suggestion of lower prevalence of tobacco use among the poorest, and in EMR-B (Pakistan only) the converse. No reliable socioeconomic patterning of tobacco use was evident for other subregions. We emphasize that these are crude measures of tobacco use, possibly obscuring

Table 24.39 Cell prevalence of tobacco use by poverty, prevalence of tobacco use by poverty and relative risk of tobacco use by poverty, by subregion, for a US\$2 per day cut-off

[^104]important differences, for example between men and women or between age groups.

### 3.7 Alcohol use

Analyses for alcohol were based on LSMS data for nine countries in six subregions-AFR-D (Ghana), AFR-E (South Africa), AMR-B (Panama), AMR-D (Ecuador), EUR-B (Azerbaijan, Bulgaria, Tajikistan) and EURC (Kazakhstan, the Russian Federation). As for the data on tobacco (section 3.6), data for Bulgaria, Ghana, South Africa and Tajikistan were available only in the form of household expenditure data, and for Azerbaijan as a composite variable of combined expenditure on alcohol and tobacco. A household was classified as an alcohol-consuming household if any money was spent on alcohol. While this is a rather crude measure, it should at least give an approximation of the proportion of households containing consumers of alcohol, assuming that all purchases made by the household were for household use and that these items were not received through other means. For the remaining countries, questions were asked in the surveys on whether the individual consumed alcohol or not. For these countries, analyses were confined to individuals aged $>15$ years. As with the tobacco analyses, these quantitative results for alcohol should be treated cautiously and interpreted in the light of the literature review presented in section 4.

The sample sizes for alcohol use by subregion are shown in Table 24.41.

Locally linear kernel regression smooth plots of alcohol use according to normalized equivalized income ranking are shown in Figure 24.19.

Table 24.4 I Sample sizes for alcohol use by subregion

|  | Persons using alcohol |  |  | Persons not using alcohol |  |
| :--- | :---: | :---: | :---: | :---: | :---: |

- No data.

Figure 24.19 Loess plots of the prevalence of alcohol use ( $y$-axis) by normalized income rank (y-axis)

Figure 24.19 Loess plots of the prevalence of alcohol use ( $y$-axis) by normalized income rank (y-axis) (continued)

Each subfigure plots the proportion of alcohol use (y-axis ranging from 0 to 1) by normalized equivalized income rank for the country ( x -axis ranging from 0 [poorest] to 1 [richest in the country]).

Full tabular results for US $\$ 2$ and US $\$ 1$ cut-offs are given in Tables 24.42 and 24.43, respectively, based on the area under the curves in Figure 24.19. The results presented in Tables 24.42 and 24.43 demonstrate a more marked variation in overall average prevalence of alcohol use between subregions than within subregions by individual-level absolute poverty. In none of the subregions analysed was there a suggestion of increasing prevalence of alcohol use among the poorest. Also, in two subregions-AFR-E (South Africa data only) and AMR-B (Panama only)—poor people had approximately half the prevalence of alcohol use of non-poor people.

### 3.8 OvERWEIGHT (WOMEN ONLY)

For developing countries (excluding those in WPR-B) we used DHS data for maternal weight, and the body weight results reported here are

[^106]Table 24.44 Sample sizes for overweight mothers by subregion (DHS data)

| Subregion | $n$ |
| :--- | :---: |
| AFR-D | 38005 |
| AFR-E | 43880 |
| AMR-B | 15177 |
| AMR-D | 29398 |
| EMR-B | - |
| EMR-D | 3314 |
| EUR-B | 10722 |
| EUR-C | - |
| SEAR-B | - |
| SEAR-D | 8187 |
| WPR-B | 4469 |
| No data. |  |

therefore for mothers only. Overweight was defined as a body mass index (BMI) of between 25 and $29.9 \mathrm{~kg} / \mathrm{m}^{2}$. The overall proportion of overweight women within each subregion was estimated using data from chapter 8.

For WPR-B, for which we had no applicable DHS data set, prevalence information was obtained using the CHNS data set. To make the WPR-B values comparable with those obtained using the DHS data, analysis of body weight was restricted to adult women (aged $>15$ years) only. As shown in Table 24.44, there were sufficient sample sizes available for analysis in all subregions except EMR-B, EUR-C and SEAR-B. Because all analyses were limited to women with children aged $<5$ years and do not correct for pregnancy, the results must be treated with caution.

Full tabular results for US $\$ 2$ and US\$ 1 cut-offs are given in Tables 24.45 and 24.46, respectively. For both African subregions and SEARD (dominated by India) the prevalence of overweight among poor women was less than half that among non-poor women (Table 24.45). For WPR-B (dominated by China) there was no discernible socioeconomic gradient. For the remaining subregions (Central and South American countries, and the south-eastern European and central Asian countries) there was a tendency for overweight to be about $20 \%$ less common among poor women than among non-poor women.

### 3.9 Results summary - Relative risks and risk differences

## ReLative risks

Table 24.47 shows the relative risks for the prevalence of each risk factor for people living on $<$ US\$ 1, US\$ 1-2 and exactly US\$ 2 per day

Table 24.45 Cell prevalence of overweight by poverty, prevalence of overweight by poverty and relative risk of overweight by poverty, by subregion, for a US\$2 per day cut-off (women only)

compared to the baseline of $>$ US $\$ 2$ per day. The equivalent summary relative risks for the dichotomous poverty variable are shown in Table 24.48.

The only difference from the relative risk results presented previously is the inclusion of both a crude and a pooled "total" summary relative risk for the 11 subregions included in this chapter. The crude total relative risk is simply the estimated relative risk comparing people by poverty stratum, regardless of the subregion in which they live. This relative risk estimate is crude in the sense that it does not allow for confounding by subregion; nevertheless, it is easily understood.

The "pooled" relative risk is a Mantel-Haenszel pooled relative risk across subregions. The actual sample sizes for each subregion are used to create the weights. This total relative risk estimate seeks to summarize the within-subregion associations, and will vary from the crude total estimate if there is independent variation across subregions in both poverty levels and risk factor prevalence.

It should be noted that there is marked heterogeneity between subregions in the association of income poverty with most of the risk factors considered here. The association of income poverty with lack of water and sanitation is stronger in AMR-B, AFR-D, EMR-D and EUR-C, and that with indoor air pollution is stronger in AMR-B and AMR-D. Thus, the pooled relative risk estimates for the total developing world should be treated cautiously. Nevertheless, comparing the crude and pooled total relative risks in Table 24.47 reveals substantial differences for unimproved water and sanitation and indoor air pollution. In both these instances, the pooled relative risk is greater than the crude. Thus, there are (on average) stronger associations of poverty with these two risk factors within subregions than those suggested by a crude global analysis. Put another way, subregion confounds the association of individual income poverty with unsafe water and sanitation, since more poor subregions have higher prevalences of these two risk factors independent of personal income poverty.

## RISK DIFFERENCES

All the summary statistics thus far in this chapter are relative risks. However, as the prevalence of risk factors varies by subregion, a constant relative risk across subregions will correspond to differences in the absolute difference in prevalence of risk factor between poverty levels. Tables 24.49 and 24.50 present risk difference estimates by subregion for the three-level and two-level poverty estimates, respectively.

For ease of interpretation, the risk differences are presented as the difference between the poor and the referent group. For example, it was estimated that the prevalence of underweight among 0-4 year olds living on $<$ US $\$ 1$ per day in AFR-D was $22.6 \%$ greater than that among $0-4$ year olds living on $>$ US $\$ 2$ per day (Table 24.49). The actual risk factor prevalence in the referent group is also given. Thus, the prevalence of

| a Total refers to the 11 out of 14 subregions included in this report. The crude "total" estimate is derived by summing the estimated number factor within each poverty stratum, then recalculating the relative risks at this total level. It is crude in so far as it does not allow for confou risk association. |  |  |  |  |  |  |  |  |  |  |  |
| Total refers to the II out of 14 subregions included in this report. Unlike the crude estimate, the pooled estimate uses Mantel-Haenszel wei subregions. The actual DHS or LSMS sample sizes are used to calculate the Mantel-Haenszel weights. |  |  |  |  |  |  |  |  |  |  |  |

| (women) |  |  |  |  |  |  |  |  |  |  |

[^109]underweight among children living on $>$ US $\$ 2$ per day in AFR-D was $17.9 \%$. Accordingly the prevalence of underweight among children living on <US\$ 1 per day can be deduced from the data in Table 24.49, i.e. $22.6+17.9=40.5 \%$.

While the relative risks across subregions for underweight were somewhat similar, the risk differences by poverty varied markedly given the different overall prevalences of underweight between subregions. There were also notable differences in the risk differences across subregions for unimproved water and sanitation and for indoor air pollution.

Finally, the negative risk differences correspond to those risk factors where the prevalence among the poor was less than that among the non-poor.

## 4. Systematic literature Reviews

### 4.1 Tobacco use

## Literature on developing countries

## Smoking associated with low socioeconomic status (SES)

The International Clinical Epidemiology Network (INCLEN) study collected data on risk factors for cardiovascular disease in men from 12 centres in seven developing countries (INCLEN 1994). It found significant SES trends (using education, occupation or income) for increased smoking among men of low SES in two centres in China and one in rural Thailand. No significant associations were obtained from the centres in Brazil, Chile, Colombia, Indonesia and the Philippines.

China. Marked gradients in smoking prevalence for men and women (increasing prevalence with lower levels of educational attainment) have been described in an urban Chinese population (Yu et al. 2000). Over the period 1989-1996 the gradient became less steep in men (owing largely to an increase in smoking by better educated men), whereas in women it changed little over the same period. This study also showed that less educated men smoked more cigarettes per day, but that this gap also decreased over the period 1989-1996. Another urban study revealed that those with lower and middle levels of education (particularly men but also women) had the highest prevalence of smoking (Koong et al. 1991). In contrast, a cohort study of urban male workers reported no association of SES with smoking prevalence, but daily cigarette consumption was significantly greater among men with low educational attainment (Siegrist et al. 1990). Surveys in three provinces of rural China also showed an increased prevalence of smoking among adults with low educational attainment ( Hu and Tsai 2000). Also, among urban adolescents, prevalence of smoking was found to be associated with lower parental SES (Zhu et al. 1996).

South Asia. Low educational attainment was found to be associated with smoking in men and women in urban populations in India (Narayan et al. 1996; Singh et al. 1998). One of these studies also reported that the smoking of beedi or chutta was associated with a low level of education and with manual occupations (Narayan et al. 1996). Another study in India also reported this finding for beedi smoking, and that smoking this type of cigarette (compared to other cigarettes) was independently associated with a higher frequency of respiratory symptoms and poorer lung function on clinical testing (Chhabra et al. 2001). In rural populations in India, the same pattern of increased smoking prevalence with lower SES was described for educational attainment in both men and women (Gupta et al. 1994) and for social class in men (Singh et al. 1997a) (with the smoking prevalence for women in this latter study being very low). Similarly, a national survey in Pakistan found that, among both males and females, illiteracy was strongly associated with higher smoking rates (Alam 1998). Also, among Bangladeshi male adolescents, a much higher rate of smoking was reported among slum dwellers with no formal education than among students (Ahsan et al. 1998).

Other Asian countries. In the Republic of Korea, smoking prevalence was found to be associated with low educational attainment in men but not in women (women had a very low smoking prevalence) (Chung et al. 1992). This was also the case for men in Cambodia (Smith et al. 1998). Studies of rural populations in Malaysia found the prevalence of smokeless tobacco use to be significantly higher among less educated women (Gan 1995, 1998). In the latter study, however, education was not associated with prevalence of tobacco smoking.

Middle East. In Saudi Arabian adults in three regions of the country, smoking prevalence was higher among uneducated people and among certain occupations of low SES such as manual workers (Jarallah et al. 1999). Similarly, in Bahrain (Hamadeh and Musaiger 2000) and Kuwait (Memon et al. 2000) low educational attainment was associated with increased smoking prevalence in adults.

Other countries. In urban Brazil, increased smoking prevalence was associated with low educational attainment in men and low social class in women (Duncan et al. 1993). Similarly, it was associated with more poor and uneducated adults in Nigeria (Obot 1990), men and women with low educational attainment in Tonga (Woodward et al. 1994) and men with low educational attainment on a Caribbean island (the results for women were not statistically significant) (Grol et al. 1997b). In the latter study, however, men and women of high SES who did smoke consumed significantly more cigarettes per day.

## Smoking associated with high SES

A gradient of increased smoking prevalence with higher SES was described in an urban study in Brazil for women of high social class (with no significant gradient among men and in contrast to the other Brazilian study described above) (Martins et al. 1995). This pattern was also described for adolescent smoking in the United Arab Emirates (Bener and al-Ketbi 1999) (based on paternal educational attainment and family income) and Ghana (for high SES homes, though no precise data were provided) (Amonoo-Lartson and Pappoe 1992).

## Smoking not associated with SES

As mentioned above, the INCLEN study (INCLEN 1994) found no significant associations between smoking prevalence and SES from the centres in Brazil, Chile, Colombia, Indonesia and the Philippines. Similar findings were obtained from surveys of villagers in India (Singh et al. 1997b) and of a town and village population in India (using level of educational attainment) (Chaturvedi et al. 1998). In this latter study, however, there was a higher rate of smoking among the unemployed than among the employed. Surveys of women in five Indian cities also found no significant gradient for smoking prevalence (Singh et al. 1999).

## LITERATURE ON DEVELOPED COUNTRIES

## Smoking associated with low SES

A review by Stellman and Resnicow (1997) found that in most developed countries, the prevalence of cigarette smoking is currently higher in low-SES groups. However, they note that in some of these countries smoking had been more prevalent among the higher social classes during the first half of the twentieth century. Studies examined in this review that reported an occupational class gradient by smoking prevalence (increased smoking among low-SES groups) come from Australia (with gradients for men and women); the United Kingdom of Great Britain and Northern Ireland (based on multiple surveys); and the United States of America (three studies cited with gradients for both men and women). The same pattern was seen for SES gradients determined by educational attainment in studies from France; Italy and Spain (for men under 65 years only); the United Kingdom; and the United States (seven studies cited). In the French study it was reported that less educated men much preferred nonfilter cigarettes manufactured with black tobacco. Similarly, there are survey data from the United States showing that better educated men tended to smoke cigarettes with lower tar yields.

The same pattern was seen when considering SES as determined by income in Australia (for men and women), the United Kingdom (based on housing data to reflect SES) (Stellman and Resnicow 1997) and the United States (owing principally to smoking cessation among the more affluent).

Similarly, the INTERSALT study involving 52 centres in 18 developed and 12 developing countries (ICRG 1988) found that smoking prevalence was related to low educational attainment (Stamler et al. 1992). Also, a review of smoking among adolescents identified four studies in which low SES was associated with increased smoking prevalence in developed countries (Canada, Finland, New Zealand and Norway) (Tyas and Pederson 1998).

Other data not detailed in the above-mentioned reviews also conform to this pattern of increased smoking prevalence by low-SES groups for:

- adults in the United Kingdom, based on occupational class for men and women (Acheson 1998);
- young people leaving school in the United Kingdom, for educational disadvantage independent of parental SES and parental smoking status (Glendinning et al. 1994; Green et al. 1991);
- students in the United States, for school performance and smoking prevalence and attempts to quit smoking (Hu et al. 1998);
- pregnant women in the United States, by educational attainment (Pamuk et al. 1998);
- adult New Zealanders, based on national data from the census (Borman et al. 1999; Crampton et al. 2000; Davis et al. 1999; Hay and Foster 1984), national health surveys (Howden-Chapman and Tobias 2000; Ministry of Health 1999) and other community surveys (Jackson et al. 1990; Klemp et al. 1998; Statistics New Zealand/ Ministry of Health 1993; Whitlock et al. 1997); and
- pregnant women in New Zealand (occupational class) (Fergusson et al. 1998).

Furthermore, low-SES adults who do not smoke were found to suffer from increased exposure to second-hand smoke (Whitlock et al. 1998).

## Tobacco-related disease and low SES

Stellman and Resnicow (1997) reported that "a large body of evidence confirms the inverse association of lung cancer and social class in many developed countries". These authors noted that in some situations it was "satisfactorily demonstrated" that such gradients were attributable to social class gradients in tobacco use. In general, however, the SES patterning of lung cancer cannot be fully explained by SES patterns of tobacco use (given some likely additional role for various dietary and occupational risk factors and access to health care). This review provided data for the following countries, all of which demonstrated increased tobacco-related disease rates among low-SES groups:

- Denmark, where there was a very strong occupational class gradient (lung and bladder cancer) in men and women;
- England and Wales, for cancer incidence and mortality;
- Italy, with a very strong relationship between educational attainment and various tobacco-related cancers (but not lung cancer); and
- New Zealand, where smoking patterns explained much of the increased mortality risk for social classes III and IV.

Other data from New Zealand also suggest that SES gradients for tobacco-related disease reflect SES gradients for smoking rates (higher smoking rates with lower SES) (Kawachi et al. 1991; Pearce 1997). Indeed, the latest analysis on smoking and inequality in New Zealand suggests that "at least one-third of the deprivation gradient in life expectancy at birth or older ages, one-quarter of the corresponding ethnic disparity, and one-fifth of the corresponding gender gap, is accounted for by tobacco consumption" (Ministry of Health 2001).

## Smoking associated with high SES

The review by Stellman and Resnicow (1997) reported that in the United Kingdom in the late 1940s and early to mid-1950s, smoking was more common among the higher social classes (based on data from multiple surveys). This review also reported on Spanish data indicating that smoking prevalence was relatively higher among college-educated men aged $>65$ years. Also, there was a very strong association with higher levels of education and smoking among younger Spanish women (in marked contrast to the data for men) (1987 data). More recent data from Spain suggest that the gap in smoking cessation rates by educational level has become wider over time (i.e. cessation rates are higher for those with higher levels of education) (Fernandez et al. 2001). This pattern was also apparent for women with higher educational levels. Similarly, other data from Spain suggest that the quitting rate is higher among women aged 25-44 years with non-manual occupations compared to those with manual occupations (Regidor et al. 2001). A review of smoking among adolescents identified studies in five developed countries (Iceland, Japan, New Zealand, Sweden and the United Kingdom) in which higher personal income was associated with higher levels of smoking (Tyas and Pederson 1998).

## Smoking not associated with SES

One review identified two studies that reported non-significant effects of parental education on adolescent smoking in Canada and the United States (Tyas and Pederson 1998). However, these studies examined maternal education only. In the United Kingdom there was little occupational class gradient in the proportion of children who had ever smoked (although some gradient existed for higher average consumption of cigarettes with lower occupational class) (Acheson 1998). It has been suggested that smoking in adolescence is an indicator of occupational
class of destination rather than occupational class of origin (Glendinning et al. 1994).

## DISCUSSION

## The relationship

In general in developing countries, lower SES was associated with higher prevalence of smoking. The association was generally stronger for men. There was also a much lower smoking prevalence among women in most developing countries. Nevertheless, some studies in the developing world actually show the opposite pattern, with high-SES adults and adolescents having higher smoking rates, while other studies show no association. This overall pattern contrasts with that for other cardiovascular disease risk factors in developing countries (cholesterol level, obesity, blood pressure and to some extent physical inactivity). This might reflect the low cost of tobacco products in many developing countries and the influence of advertising and the mass media in promoting their use. Nevertheless, there is a need for more historical data on smoking in developing countries to better interpret this pattern.

In developed countries the gradient of increased smoking with lower SES is even more predominant. There are still some exceptions, however, such as for adolescent smoking in some settings and for Spanish women. Furthermore, the SES gradient for tobacco-related disease and overall mortality is likely to be partly explained by the SES gradient for tobacco use.

In both developing and developed countries there is some evidence that the type of tobacco product smoked by low-SES adults may also be more hazardous (e.g. beedis in India) than that consumed by high-SES adults. Similarly, the number of cigarettes consumed daily may be higher among low-SES adults.

## Possible mechanism

Several factors are likely to be involved in the relatively increased prevalence of smoking by lower-SES groups.

- Cultural effects relating to health values and risk perception may be relevant. Similarly, neighbourhood effects may be important, such as the influence of disadvantaged neighbourhoods on smoking in men (though not women) described in the United States by Ross (2000).
- Parental influences on adolescent smoking may possibly be more important in low-SES populations (e.g. in countering the benefits of education about the risks of smoking).
- Access to cheap tobacco in tobacco-producing rural areas of the developing world may be relevant.
- Lower educational attainment may lead to poorer knowledge of the hazards of smoking and of how to obtain support for quitting.
- The relative lack of restrictions on smoking at the workplace for many blue-collar workers could reduce incentives to quit (compared to those in higher occupational classes).
- Lower rates of smoking cessation in low-SES groups might be related to a greater burden of psychosocial stress and the effect of others smoking.

Advertising by the tobacco industry is probably an important determinant of smoking trends (Stellman and Resnicow 1997), particularly the aggressive marketing in developing countries (Connolly 1992; Mackay 1992).

### 4.2 Hazardous alcohol use

## LITERATURE ON DEVELOPING COUNTRIES

## Hazardous alcohol use associated with low SES

In China, one cohort study of urban male workers reported that high levels of daily alcohol consumption were significantly more prevalent among men with low educational attainment (Siegrist et al. 1990). Similarly, a Brazilian study of urban residents (using a logistic regression model) found that both heavy drinking and alcohol dependence were associated with low educational attainment and low income (Moreira et al. 1996). Another study in a Brazilian city found that low social class was significantly associated with excessive alcohol consumption in both men and women (Duncan et al. 1993).

A study in a Caribbean island reported that men and women of low SES (based on educational attainment) drank more alcohol per week (Grol et al. 1997b). However, high-SES women were more likely to be regular drinkers than low-SES women. Of the two African studies identified, one in Ethiopia found that problem drinking (based on the CAGE screening instrument) was associated with a lower level of educational attainment among residents of Addis Ababa (Kebede and Alem 1999). Similarly, in a Nigerian study, alcohol consumption was higher in those with low SES (Bunker et al. 1992). In Brazil, the results of one study suggested that higher rates of oesophageal cancer among lower-SES groups are likely to be attributable to the higher use of sugar-cane spirit, black tobacco and mate in these groups (Bouchardy et al. 1993). In contrast, data from Colombia indicate that the incidence of alcohol-related cancers tended to show positive social class gradients (Cuello et al. 1982).

## Hazardous alcohol use associated with high SES

In an Ethiopian study, problem drinking (based on the CAGE screening instrument) was associated with higher income and education among men or women in a rural district (Alem et al. 1999) (in contrast to another Ethiopian study described above). In Thailand, a study reported that hazardous alcohol use (based on AUDIT scores) was associated with higher income among those seeking emergency treatment (Lapham et al. 1998). By contrast, the study found that those with a university degree were significantly less likely to have positive AUDIT scores. A study in the Republic of Korea found a trend towards greater alcohol consumption with increasing years of education among women, but no such trend among men (Chung et al. 1992). Alcohol intake among high-SES males explained a small but statistically significant part of the relationship between hypertension and high SES in villagers in North India (Singh et al. 1997b). This suggests that at least some members of this population were drinking fairly large quantities of alcohol.

## No association with SES

A study in a metropolitan area in Brazil found no statistically significant differences in alcohol use associated with SES, although there was a trend towards higher rates of drinking among low-SES men (Martins et al. 1995).

## Literature on developed countries

## Hazardous alcohol use associated with low SES

A major review of alcohol drinking, social class and cancer suggested a very likely role for alcohol drinking in the observed negative social class gradients for alcohol-related cancers in men in France, Italy and New Zealand (Moller and Tonnesen 1997). Evidence that was less strong, but still suggestive of such a role, was also reported for men in Denmark, Switzerland and the United Kingdom. This review identified studies showing associations between hazardous alcohol use and low SES in Denmark (for average number of drinks per week in men and women); Finland (for rates of alcohol intoxication and rates of hospital admission for acute alcohol-related conditions for men and women); France (for prevalence of "heavy drinkers" in men); Sweden (alcoholism and high alcohol consumption in young people); Switzerland (for alcoholism); the United Kingdom (for the proportion of heavy drinkers in manual vs non-manual occupations among men); and the United States (for heavy consumption-five or more drinks on one occasion in men and women).

The major review by Colhoun et al. (1998) on hypertension and SES reported that higher alcohol consumption by low-SES men explains part, though not all, of the association between SES and blood pressure in men in developed countries. This collectively considered the findings of
studies in Australia, Israel, the Netherlands, Norway, the United Kingdom (two studies) and the United States (two studies). Similarly, the INTERSALT study, involving 52 centres in 18 developed and 12 developing countries, found that adjusting for alcohol (along with BMI, smoking, and sodium and potassium excretion) halved the association between low SES and higher blood pressure in men so that it was no longer statistically significant (Stamler et al. 1992).

A combined analysis of population samples from France, Italy, Spain and Switzerland (Pequignot et al. 1988) found that daily alcohol consumption was higher in male manual workers than in male professionals, whereas in women there was no significant variation by occupational group. More recent data from the United Kingdom indicated that 10\% of low-SES men (social classes IV and V) were dependent on alcohol compared to $5 \%$ of high-SES men (social classes I and II) (Acheson 1998). Similarly, in the United States, heavy alcohol use was reported to be higher among those with poorer education among men and women in virtually all ethnic groups (Pamuk et al. 1998).

Data from surveys in 48 American states showed that hazardous consumption of alcohol was significantly more frequent in households with below-median income and in those with a lower educational level (for five or more drinks on one occasion at least once a week during the previous year) (Midanik and Clark 1994). For weekly drinking, however, the pattern was the opposite, being higher in those with above-median income and a higher level of education.

In a national survey in New Zealand based on AUDIT scores, lower social class was associated with an increased risk of a hazardous pattern of alcohol use (Howden-Chapman and Tobias 2000). There was some suggestion that lower educational attainment was associated with a more hazardous pattern of alcohol use, but this was not statistically significant. Earlier New Zealand work indicated that the pattern of drinking "high quantities but less often" was more common in the lower social classes, along with an increased prevalence of high daily consumption (Casswell and Gordon 1984).

## Hazardous alcohol use associated with high SES

The review by Moller and Tonnesen (1997) reported a French study indicating that high-SES women were more likely to be regular consumers of alcohol, and that in Sweden high alcohol consumption was associated with high SES among older people. The review by Colhoun et al. (1998) on hypertension and SES reported that higher alcohol consumption among high-SES women had been identified in studies in Australia and England (two studies) and in the INTERSALT study, where some of 52 centres collected data on alcohol.

A study in Wales revealed a tendency towards a higher prevalence of consumption of 22 drinks or more per week in the higher social classes (Farrow et al. 1988). A study of three regions in the United Kingdom
reported that weekly alcohol consumption increased with household income in both men and women (Crawford 1988), but that manual workers drank more alcohol than non-manual workers. In the United States, a combined analysis of 10 surveys showed some positive gradient for the frequency of alcohol drinking with SES (Knupfer 1989). However, there was a weakly inverse gradient for "frequent drunkenness". Among employees in Minneapolis-St Paul, the frequency of alcohol drinking was associated with high SES in women but not in men (Jeffery et al. 1991). A national survey in New Zealand (Statistics New Zealand/Ministry of Health 1993) reported a higher alcohol intake with greater educational attainment, in contrast to the other results from New Zealand detailed above.

## No association with SES

The review by Colhoun et al. (1998) reported on two British studies that showed no SES gradient with alcohol consumption. Similarly, there was no association with social class among a sample of attendees at a London health centre (King 1986). In New Zealand, a child cohort study found that family SES did not have a marked impact on drinking behaviour, but that those from low-SES families in this cohort drank more at age 15 years (Connolly 1992).

The international review of alcohol drinking, social class and cancer by Moller and Tonnesen (1997) found no evidence for such an association for Japan, except that women in the highest social classes had slightly elevated mortality from liver cirrhosis. There was a similar finding for Finland and for Sweden, except that pharyngeal cancer in Swedish women was more prevalent in low-SES women. Nevertheless, these two countries do show some evidence for SES gradients in hazardous alcohol use (as detailed above).

## DISCUSSION

## The relationship

The general pattern in developed countries is for lower-SES men to have a more hazardous pattern of alcohol consumption in terms of high or excessive intake of alcohol. This pattern is also evident in the distribution of alcohol-related disease, particularly alcohol-related cancers. The pattern for women can resemble that for men, although there are also many studies indicating excessive alcohol use among high-SES women. Different studies in the same countries sometimes show contrasting patterns that may reflect temporal trends, regional variation and different methodological approaches.

The pattern is also mixed in developing countries, although in this review more studies were identified that indicated that lower SES was associated with a more hazardous pattern of alcohol consumption. This pattern is similar to that found for tobacco use, but it does contrast with
the SES gradient seen for other disease risk factors where high SES is associated with increased risk (e.g. for cholesterol level, obesity, blood pressure and to some extent physical inactivity).

## Possible mechanisms

Some of the factors likely to be involved in the excessive use of alcohol by lower-SES groups include:

- cultural influences, including the presence of greater numbers of alcohol users in certain areas and the social acceptability of heavy drinking;
- the existence of psychological stressors associated with poverty and inequality from which alcohol users may seek to escape;
- access to cheap alcohol, especially in rural areas of the developing world and where alcohol is not taxed; and
- the effect of lower educational attainment on poorer knowledge of the hazards of excessive alcohol use.

High levels of alcohol use among higher-SES groups (especially women) may reflect in particular cultural patterns and the role of additional income in settings where alcohol is relatively expensive. The alcohol industry may also target advertising at those with the highest incomes. It is also plausible that alcohol is used as a coping mechanism by high-SES women who have heavy demands on their time.

Some of the studies in this review also reported higher levels of abstinence among lower-SES groups. This behavioural pattern may have health benefits in those aged $<50$ years (e.g. in terms of injury prevention), but abstinence could be considered a potential risk factor when considering the evidence for cardioprotective effects of moderate alcohol consumption in older populations (Rimm et al. 1996).

### 4.3 ILlicit DRUG USE

## LITERATURE ON DEVELOPING COUNTRIES

## Substance use associated with poverty

In an Indian city, substance abuse by adolescents (covering tobacco, alcohol and cannabis) was more common among those from Hindu families with low educational status and low family income (Kushwaha et al. 1992). Similarly, in Nepal, a small qualitative study suggested that urban poverty was a factor in substance use (Jutkowitz et al. 1997). In Brazil, youths living on the streets were significantly (eight times) more likely to use drugs (generally inhalants and marijuana) than those living at home (Pinto et al. 1994). Other work has documented relatively heavy drug use by street children in Brazilian cities, such as half of $7-8$-yearold street children in São Paulo (Carlini 1990). A study of military con-
scripts in Kuwait found that amphetamine use was associated with lower educational attainment and unemployment (Bilal et al. 1992).

## Substance use associated with high SES

A survey of students in an Indian city found that regular cannabis users "were mainly from professional colleges, hailing from metropolitan cities and with relatively higher amount of pocket money at their disposal" (Reddy et al. 1993). Also, a study of marijuana-related hospital admissions in Malawi found that the marijuana-abusing group had significantly more schooling than the control group (Carr et al. 1994).

## No relationshiplinadequate information

In Zimbabwe, there were no particularly pronounced differences in the use of inhalants and cannabis by students of different SES subgroups, in contrast to that of tobacco and alcohol (Eide and Acuda 1996). A review of the use of non-prescription psychoactive substances in Nigeria reported that: "as a result of insufficient information, it could not be established who uses the substances more among different age, religious, social class, educational, and occupational categories" (Omoluabi 1995).

## LIterature on developed countries

## Substance use associated with low SES

A United States study reported that people living in areas with high rates of poverty had relatively high rates of illicit drug use (marijuana or cocaine/crack) in the past year compared to a national sample (Ensminger et al. 1997). Also, frequent cocaine use in the United States was reported to be more prevalent in low-income urban areas than elsewhere (Brownsberger 1997). Another United States study found that social disadvantage was moderately associated with drug-related behaviour (Boardman et al. 2001). This work suggested that this was related to increased social stressors and higher levels of psychological distress among residents of disadvantaged neighbourhoods. Supporting evidence for such an association also comes from United States data on the early wave of injecting drug users with AIDS, who were characteristically poor or from ethnic minorities (Schrager et al. 1991).

Poverty and lower levels of education were associated with marijuana use in pregnancy in a United States review (Day et al. 1993). This review also reported work that found that cocaine use in pregnancy was associated with low educational attainment. In another United States review (Hans 1999), the studies reviewed suggested similar rates of substance use during pregnancy by women of different racial and social class categories (for all substances including alcohol). However, it did report that black women and poorer women were more likely to use illicit substances, particularly cocaine. Another United States review of
substance use in pregnancy also noted its association with poverty (Howell et al. 1999). A more recent study found that neighbourhood poverty was associated with higher rates of the use by pregnant women of cocaine, opiates, amphetamines and all illicit drugs (Finch et al. 2001).

A Swedish study suggested that low SES at the time of birth, relative to the general population, might be associated with dependence on amphetamines as an adult (Nyberg et al. 1992). However, this relationship did not exist for opiate dependence. In New Zealand, there is evidence that the Maori population has a significantly greater rate of cannabis use (Fergusson and Horwood 2000) and a relatively high rate of treatment for cannabis use (Adamson et al. 2000; Pomare et al. 1995). Similarly, Australian school survey data show that a relatively disadvantaged ethnic group (Aboriginal and Torres Strait Islander students) were more likely to have tried cannabis and other illicit substances (as well as cigarettes) than other students (Forero et al. 1999).

In terms of educational attainment and substance use, student survey data in the United States indicate that lower parental educational level was significantly associated with higher rates of substance use (Robinson et al. 1987), although "substance use" covered alcohol and tobacco as well as illicit drugs. A New Zealand cohort study found that adolescents who had less well educated mothers had significantly higher "deviant peer affiliations", i.e. associations with delinquent or substanceusing peers (Fergusson and Horwood 1999). These substances included alcohol, tobacco and other drugs.

## Substance use associated with high SES

Some United States research suggested higher rates of substance use among affluent, suburban or white youths than among poor, non-white, urban youths (Luthar and D'Avanzo 1999). Other work suggested minimal SES patterning for substance use: one United States study reported that illicit drug use was only 1.3 times more likely in disadvantaged neighbourhoods compared to the least disadvantaged ones (Saxe et al. 2001). However, visible drug sales were 6.3 times more likely to be reported in these disadvantaged neighbourhoods.

## DISCUSSION

## The relationship

The available literature in general suggests a relationship between SES disadvantage and increased prevalence of use of illicit substances. This relationship appears to exist in both developing and developed countries. Nevertheless, some studies suggest that, for some substances in some settings, the opposite relationship exists. A further complication is that not all the studies on this relationship appropriately adjust for relevant confounding variables such as ethnic status and religious affiliation. In India,
for example, caste was described as being a factor in determining substance use (Sharma 1996).

## Possible mechanisms

Many factors are likely to be significant in the relationship between poverty, low SES and drug use. For example, Finch et al. (2001) describe how neighbourhood poverty may increase substance use in a number of ways: ". . . the presence of greater numbers of substance users, access to substances, greater overall deviance, the social acceptability of substance use ...". These authors also consider that contextual effects might be involved: " $\ldots$. the increased stressors of poor housing conditions, a lack of health care and substance use services, and a general lack of social services within the community" (Finch et al. 2001). Specific United States data highlight the importance of exposure, with youths living in the most disadvantaged neighbourhoods being six times more likely to have been offered cocaine (Crum et al. 1996).

In drug production areas, it is likely that poor farmers and their neighbours will have relatively easy access to these substances at low cost. Evidence from Malawi suggests that the low cost of marijuana is a factor influencing its usage (Carr et al. 1994). Also, poverty may sustain illicit drug production in settings where other cash crops are less profitable.

On the demand side, it is plausible that lower educational attainment is associated with poorer knowledge of the hazards of illicit drug use. Also, the hardship of poverty may be associated with a greater demand for the temporary psychological escape achievable through drug use. Self-perceptions of low status may also be relevant, given that low social status may affect dopamine receptors in the brain that increase the addictiveness of some drugs (Morgan et al. 2002).

### 4.4 Hypertension/high blood pressure

## Literature on developing countries

A narrative systematic review covering literature published between 1966 and 1996 identified 13 studies in developing countries (Colhoun et al. 1998). Of these, a direct relationship between higher SES and higher blood pressure (BP) or hypertension was reported in five studies in India (three studies), Kenya and Nigeria. Another Indian study reported a non-significant direct relationship. The opposite pattern (of low SES associated with higher BP or hypertension) was reported in four studies in Brazil, India and Senegal and among South African Zulus. A further Indian study reported no relationship, while two studies in the Caribbean found conflicting results for males and females. Another review of cardiovascular disease risk factor data from 12 centres in seven developing countries also examined SES (three centres in Thailand, two each in Brazil, Chile and China and one each in

Colombia, Indonesia and the Philippines) (INCLEN 1994). For BP the associations with SES tended to be negative (i.e. similar to those from the developed world).

## High BP associated with high SES

A number of studies conducted in Asia and Africa showed this pattern, e.g. villagers in India (Singh et al. 1997b), urban residents in India (Singh et al. 1998), urban workers in Nigeria (Ekpo et al. 1992) and urban civil servants in two Nigerian cities (Markovic et al. 1998; Omokhodion et al. 2000). However, while another Nigerian study found this pattern for men it found the reverse for women, i.e. higher BP in those with less educational attainment (Kadiri et al. 1999). There was a positive association between BP and income among a rural population in Papua New Guinea, but this held for women only and did not reach statistical significance. Another Chinese study found that men paid according to a new, highly demanding salary system exhibited significant increases in systolic BP between the first and second screenings (Siegrist et al. 1990).

## High BP associated with low SES

Data from an urban population in China indicated that high BP and hypertension in men and women were associated with low SES (Yu et al. 2000). Over a seven-year period the SES gradient declined for men (systolic and diastolic BP). Over this period there was also an increase in systolic BP among better-educated women, while the reverse occurred in women with less education. A study in Saudi Arabia also found an association between high BP or hypertension and low SES (Wahid Saeed et al. 1996).

## Literature on developed countries

The narrative systematic review by Colhoun et al. (1998) identified 57 relevant studies in developed countries. The reviewers concluded that lower SES was associated with higher mean BP in almost all studies in developed countries. However, the magnitude of the association varied and was generally quite small (with age-adjusted mean systolic BP differences of about $2-3 \mathrm{mmHg}$ between the highest and lowest SES groups). Even so, this difference is still important in terms of its consequences for public health at the population level. This inverse gradient was both stronger and more consistently found in women than in men. An earlier review (the INTERSALT study) examined data on BP and educational attainment from 47 centres around the world (in 18 developed and 12 developing countries) (Stamler et al. 1992). It found an inverse association for men in 28 centres and for women in 38 centres. Ageadjusted systolic BP in men was significantly higher $(1.3 \mathrm{mmHg}$ higher for 10 fewer years of education), while for women the association was even more significant at 4.5 mmHg higher. Yet when the adjustment
included five lifestyle factors (24-hour sodium and potassium excretion, BMI, alcohol intake and smoking) these estimates were reduced by about $50 \%$. Furthermore, after this adjustment the inverse association was no longer significant for men. The results obtained for diastolic BP were similar to those for systolic BP. Of ten studies on children in developed countries, only four reported significant differences in BP associated with SES (Colhoun et al. 1998). All four showed that systolic BP was higher in children of low SES, although in two the association disappeared after adjustment, e.g. for weight or fitness.

## DISCUSSION

## The relationship

In developing countries there is a mixed picture, although slightly more studies have suggested a direct association between high SES and high BP. This pattern is consistent with that generally seen for the SES distribution of other cardiovascular disease risk factors in developing countries (obesity, hypertension, cholesterol level and to some extent physical inactivity). Nevertheless, in a number of developing countries the pattern is similar to the fairly consistent pattern in the developed world, with high BP associated with low SES. The pattern seen in developed countries is consistent with the evidence that mortality from hypertensionrelated diseases such as ischaemic heart disease, hypertensive heart disease, stroke and end-stage renal disease also shows an association with low SES (Colhoun et al. 1998).

## Possible mechanisms

Colhoun et al. (1998) suggested that the SES gradient in BP seen in the developed world was unlikely to be explained by differential treatment rates. Indeed, these authors considered that a substantial part of it was accounted for by the SES gradient in BMI (see also section 4.7). Also, alcohol consumption across SES groups accounted for part of the association in men (although this issue was examined in only a few studies). Furthermore, these reviewers considered there to be little evidence that adverse psychosocial factors associated with low SES caused chronic elevations in BP. Nevertheless, they noted that stronger relationships might exist between BP and more specific stressful aspects of low SES such as unemployment or job insecurity.

The INTERSALT study reported that those with less education had on average higher sodium excretion, lower potassium excretion, greater body mass and higher alcohol intake (Stamler et al. 1992). All of these are factors that tend to be associated with increased BP.

For some developing countries, the review by Colhoun et al. (1998) suggested that the direct association between higher SES and higher BP may reflect a higher prevalence of obesity and higher salt and alcohol intakes among those of higher SES. Other dietary factors (e.g. more
animal products) and less physical activity in these groups might also play a role. Furthermore, a Brazilian review concluded that the higher people's "cultural consonance" the lower their BP (with cultural consonance referring to how individuals are able to approximate, in their own behaviour, shared cultural models of life) (Dressler and Santos 2000).

In those developing countries where low SES is associated with high BP , poor maternal and perinatal nutrition may be important factors. Indeed, there is growing evidence from animal studies (Edwards et al. 1999; Ozanne 2001) and human studies (Roseboom et al. 2001) for the Barker hypothesis on the fetal origins of adult disease.

Regardless of the mechanisms involved, it is important to note that there is evidence that the intensive medical management of hypertension can abolish SES differences in hypertension-associated mortality (Anonymous 1977).

### 4.5 Serum cholesterol and lipid levels

Literature on developing countries

## Adverse lipid profile associated with high SES

Data from 12 centres in seven countries (the INCLEN study) found such a relationship for total cholesterol (TC) in six centres. These included centres in Brazil (for occupational class and income); Chile; China (for occupational class); the Philippines (for education, occupational class and income); and Thailand (one centre for income and one for education) (INCLEN 1994).

China. A study of an urban population reported that high-SES people had a more unfavourable serum lipid profile (for TC, HDL-c, LDL-c and triglycerides [TG]) than those in lower-SES groups (Yu et al. 2002). This significant association was especially apparent in men, and education seemed to be the most important predictor of serum lipids compared to the other SES indicators of occupation and income. A cohort study of urban male workers found that blood lipid profiles were less favourable in the better-educated groups (Siegrist et al. 1990). LDL-c and LDL-c/HDL-c ratio were significantly higher and HDL-c was significantly lower. Similar results were obtained using occupational class.

India. A study of an urban population found a significant SES gradient for both men and women for hypercholesterolaemia, TC, LDL-c, HDLc and TG (Singh et al. 1998). Similarly, surveys of women in five Indian cities found positive gradients by social class for TC and HDL-c (Singh et al. 1998). A study of an elderly urban population also found an association between hypercholesterolaemia and income (Singh et al. 1995). In rural India, one study found a significant SES gradient for hypercholesterolaemia, for TC and for TG in women (Singh et al. 1997a), but the
trends for higher LDL-c and HDL-c in both men and women were not significant.

Other countries. In a white rural South African population, the prevalence of hypercholesterolaemia increased with income for men but there was no association with education or between HDL-c and SES (Rossouw et al. 1990). Low HDL-c was more prevalent in women (by income and educational attainment) but, in contrast to the men, there was less hypercholesterolaemia with increasing level of income.

A study in Mauritius found that professional and skilled men had significantly higher mean TG, higher LDL-c and lower mean HDL-c than unskilled workers (Pereira et al. 1998). Unskilled and partly skilled women had lower TG compared with "homemakers". Also, in contrast to the men, professional and skilled women had higher HDL-c than unskilled women (with no significant association for LDL-c).

A study in Turkey found an association between income and TC in urban men and women and rural men, but not rural women (Onat et al. 1992). Another Turkish study found higher TC and HDL-c levels in high-SES than in low-SES children (Mahley et al. 2001). The high-SES group also consumed more saturated fat of animal origin and less carbohydrate.

## Lipid profile and development

Cholesterol levels in the population appear to increase with the modernization and economic development of a country. For example, a study of adult men in 13 countries in 1980 reported that mean TC levels were low in those from Africa, intermediate in those from Hungary, Pakistan, the Philippines, Poland, Suriname and the Mediterranean countries, and high in those from Finland and the Netherlands (Knuiman et al. 1982). HDL-c tended to be lower in men from Africa, Asia and Suriname than in those from Europe (with the highest values for both TC and HDL-c being found in Finnish men). The HDL-c:TC ratio was on average slightly higher in those from Africa than it was in those from Europe and from Asia and Suriname.

Another multi-country study found low TC levels in Amazonian Indians and Africans (traditional Bantu population) compared to Italian and Polish populations (Pavan et al. 1999). Other studies found relatively low TC levels in other traditional societies with diets based on complex carbohydrates and vegetables (Mancilha-Carvalho and Crews 1990). Even in developing countries, such a Zimbabwe, there appears to be an increase in TC levels in urban relative to rural populations (Allain et al. 1997).

## Adverse lipid profile associated with low SES

Some of the results for specific aspects of the lipid profile detailed in studies described above fit this pattern (e.g. low-SES white rural South

African women and hypercholesterolaemia, and unskilled women in Mauritius and HDL-c). Furthermore, data from the INCLEN study revealed such a relationship in one centre (Shanghai in China for low occupational class and raised TC) (INCLEN 1994). In India it was reported that TC and LDL-c were high in urban slum dwellers (Misra et al. 2001), but this study did not involve a comparison group.

## No association (lipid profile and SES)

Data from the INCLEN study found no significant relationship for TC in five centres in Brazil, Chile, Colombia, Indonesia and Thailand. In a rural population in western India there was no association of SES with the prevalence of hypercholesterolaemia (for TC, LDL-c, HDL-c and TG) in men and women by educational status. Similarly, SES was not related to HDL-c levels in adults, in contrast to the results for Turkish children detailed above (INCLEN 1994).

## Literature on developed countries

A review of cardiovascular disease risk factors and SES by Pickering (1999) reported that the SES gradient for TC was generally minimal or non-existent. He reviewed studies in England (two studies), Norway (one study) and the United States (four studies). However, further work has subsequently been published, some of which is described below.

## Adverse lipid profile associated with high SES

In a multi-country study (mainly in developed countries) the lipid profile was worse with increasing years of schooling for men in China, Poland and the Russian Federation (for raised TC, LDL-c and TG and lower HDL-c) (Perova et al. 2001). However, the findings were less consistent for women and for Israeli and American blacks of both sexes. Also, the opposite pattern was seen among white men from the United States.

A study in Scotland found that TC levels were higher in the nonmanual social class groups, for both men and women (Davey Smith et al. 1998). A study of working Japanese men showed that those in higher employment grades had lower levels of HDL-c (Martikainen et al. 2001).

A study of an economically depressed agricultural area in the United States revealed that those with low educational attainment and income below the poverty level had lower mean TC levels than the rest of the population in the area (Gold and Franks 1990), despite the fact that the low-SES groups in this population had a greater intake of dietary cholesterol.

## Adverse lipid profile associated with low SES

Perova et al. (2001) showed that white men in the United States with low educational attainment had an adverse lipid profile. Similarly, a national survey in the United States found that for whites, HDL-c levels
were highest for those in the highest category of earnings (although blacks generally had lower levels of HDL-c with increased earnings) (Linn et al. 1989). In a multivariate model, predictors of higher HDL-c included a higher frequency of alcohol intake and reported high physical activity, with smoking and high BMI being strongly negatively related to HDL-c levels. The authors of this national study suggested that the findings "support previous findings in selected populations in the United States".

In Finland, cholesterol levels were found to be higher in blue-collar than white-collar workers, for both men and women (Vartiainen et al. 1998). This study found that the decline in cholesterol levels between 1972 and 1987 was similar for men in both groups, but greater among white-collar women than blue-collar women. Similarly, in Norway, poverty during childhood was positively associated with age-adjusted levels of TC in adults (Arnesen and Forsdahl 1985). In Sweden, women of high SES were found to have a better lipid profile than low-SES women (lower levels of TC, LDL-c and TG and raised HDL-c), but there was no relation between occupational status and lipid levels for men.

In the Whitehall II longitudinal study of men and women in the United Kingdom, it was found that high occupational status was associated with lower cardiovascular disease risk factors, including HDL-c levels (Brunner et al. 1999). This study also reported that social position in childhood was associated with HDL-c level in women. Another study of working men in England found that higher occupational class was associated with a favourable lipid profile (for HDL-c and TC) (Martikainen et al. 2001).

In Greece, TC levels were found to be inversely associated with educational level in both sexes, and especially in women (Benetou et al. 2000). The authors report that this SES pattern contrasted with the previous pattern that existed two decades before in Greece. HDL-c levels were inversely associated with educational level in men, but the association was not clear for women.

## No association (lipid profile and SES)

In a German study, no poverty-related differences were found for prevalence of hypercholesterolaemia, despite a much higher prevalence of obesity in persons with an income below the poverty line (Helmert et al. 1997). In a national survey in New Zealand there was no overall SES gradient in TC levels (Howden-Chapman and Tobias 2000). In European men and Maori women, however, relatively higher TC levels were seen with high SES while, in contrast, higher TC levels were seen in lowSES European women (based on educational attainment).

TC levels for children in a disadvantaged inner-city population in the United States were not significantly different from those of other children from several large studies of North American populations (Wadowski et al. 1994).

## DISCUSSION

## The relationship

In the developing world, the predominant pattern is for the population as a whole to develop an adverse lipid profile along with industrialization and urbanization. Furthermore, within developing countries, highSES groups appear to have the most hazardous lipid profiles. This pattern is consistent with that generally seen for the SES distribution of other cardiovascular disease risk factors in developing countries (obesity, hypertension and to some extent physical inactivity).

The picture is more mixed in the developed world, but the predominant pattern is for low-SES groups to have the most adverse lipid profiles (particularly in the most developed countries in this group). Such a pattern is also consistent with that generally seen for the SES distribution of other cardiovascular disease risk factors in developed countries (smoking, obesity, hypertension and physical inactivity). It is also consistent with the relatively higher rates of cardiovascular disease among low-SES groups in many developed countries.

## Possible mechanisms

In the developing world, it is likely that dietary change is a key factor in the development of adverse lipid profiles associated with industrialization and urbanization. Higher total calories and increased intakes of animal products are probably important. Nevertheless, other factors may be relevant: a Brazilian study found significant interactions between elevated cholesterol levels and smoking, obesity and physical inactivity (Martins et al. 1995).

In developed countries, the generally poorer diet of low-SES groups is also likely to be a factor in generating adverse lipid profiles. For example, increased dietary intake of cholesterol was described among various United States populations, including poor elderly people (Prothro and Rosenbloom 1999), poor children (Casey et al. 2001) and children whose parents smoked (a crude marker for low SES) (Johnson et al. 1996). Similarly, the higher BMI of low-SES groups is likely to play a role: a 13country survey by Knuiman et al. (1982) found a direct relationship of BMI with TC and an inverse relationship with HDL-c and HDL-c:TC ratio.

Physical inactivity may also be relevant (given that it contributes to obesity) and there is some evidence that it is associated with a poorer lipid profile, although studies have reported conflicting results (Sowers et al. 1995). Regular consumption of modest quantities of alcohol may also play a role in improving the lipid profile of high-SES groups. For example, a recent French study found that wine drinkers had higher HDL-c levels than non-wine drinkers (Ruidavets et al. 2002). However, the authors reported that such differences became non-significant after adjustment for SES parameters.

Furthermore, there may be psychosocial pathways for determining lipid profiles in different populations. For example, a case-control study in England suggested that "lifestyle incongruity" is associated with higher cholesterol levels (Dressler et al. 1992). This variable is a type of status incongruence, involving the degree to which lifestyle (material consumption and status-enhancing behaviour) exceeds occupational status.

Low birth weight may play a role in influencing lipid metabolism in the adult. This is one component of the still controversial "Barker hypothesis" discussed in section 4.4.

In some developed countries there may also be SES patterning of cholesterol screening, awareness of the risks of elevated cholesterol levels, willingness to change one's diet to reduce cholesterol levels and access to cholesterol-lowering drugs.

### 4.6 Overweight/obesity

## Literature on developing countries

## Obesity associated with high SES

A review of 144 published studies on the relationship between SES and obesity was published by Sobal and Stunkard (1989). It revealed a strong direct relationship between SES and obesity in women in 10 studies in developing and non-Western societies (with another study showing no relationship and one showing the opposite relationship). For men, 12 studies found a relationship and two found no relationship. In children and adolescents, this pattern was seen in 14 studies in girls (with two other studies showing no relationship) and in 13 studies in boys (with two others showing no relationship). A subsequent review by Colhoun et al. (1998) reported that BMI and SES were measured in seven out of 13 studies on BP and SES in developing countries. In four of these studies-in rural India (two studies), rural Kenya and urban NigeriaBMI increased with higher SES. In Senegal, BMI did not vary with SES and in two studies the relationship of SES to BMI was not reported. These reviewers concluded that, overall, the SES differences in BMI "probably account for a substantial part, though not all, of the SES-BP association".

The INCLEN study collected cardiovascular disease risk factor data on men from 12 centres in seven developing countries (INCLEN 1994). It found significant trends for increasing BMI with higher SES in five out of the 12 centres. These were in urban China (by occupation and income), urban Indonesia (by education), urban Philippines (by education, occupation and income), rural Thailand (by education and income) and urban Thailand (by occupation and income). A recent analysis of obesity in women based on nationally representative surveys ( 39 surveys from 38 developing countries) (Martorell et al. 2000) reported that in developing countries, such as those in sub-Saharan Africa, obesity levels were higher among better educated women and urban women. Yet in
more developed countries, such as those in Latin America and central and eastern Europe, obesity levels were more equally distributed in the general population. At a national level, levels of obesity in countries increased sharply up to a GNP of US\$ 1500 per capita (1992 values) and then changed little thereafter.

Another multi-country study of developing and developed countries used data for children aged 6-18 years from nationwide surveys in China, the Russian Federation and the United States (NHANES III, 1988-1994) (Wang 2001). It found that higher-SES subjects were more likely to be obese in China and the Russian Federation, while in the United States low-SES groups were at higher risk. A review of preschool children by Martorell et al. (2000) examined 71 national nutrition surveys since 1986 from 50 developing countries. It found that in 22 countries (mainly those from Latin America, the Caribbean, the Middle East and North Africa) overweight was significantly more common in children of mothers with higher education. Overweight was also significantly more common in urban areas in 24 countries (and only more common in rural areas in two countries). At national level, the prevalence of overweight among preschool children tended to increase with increasing GNP ( $r=0.28, P=0.05$ ).

In China, a nationwide longitudinal survey conducted in 1989 and 1991 (Popkin et al. 1995a) found evidence that increased household income was significantly associated with increased BMI. Urban residence and higher income were associated with lower energy intake, higher fat intake and lower levels of physical activity compared to rural residence and other income categories. Diet was considered to be a particularly important determinant of body weight in this population (Paeratakul et al. 1998).

## Obesity associated with low SES

The INCLEN study (INCLEN 1994) found significant trends for increasing BMI with lower SES in two out of 12 centres. These were in urban Colombia (by education and occupation) and rural Thailand (by occupation). The review by Sobal and Stunkard (1989) found no studies reporting an association between obesity and low SES. Similarly, the review of overweight among preschool children from 50 developing countries found none in which overweight was significantly more common in the children of poorly educated women (Martorell et al. 2000).

A review of obesity in developing countries (Popkin et al. 1995b) cited evidence for increased obesity among low-SES groups from urban Brazil. Another recent review by Pena and Bacallao (2000) reported such a finding for urban Chile, for women in Uruguay and for urban Peru. A book on obesity in Latin America described the higher prevalence of obesity in middle-income compared to high-income women (Monteiro 2000).

A significant gradient was described for BMI and obesity prevalence by education level for urban women in China (i.e. greatest among those with the least education) (Yu et al. 2000). Over the period 1989-1996 this gradient declined for women, along with a decrease in BMI across all educational strata. The results for men suggest no significant gradient in BMI and obesity and no significant time trends.

## No association (obesity and SES)

The review by Colhoun et al. (1998) reported one country (Senegal) where there was no association found between BMI and SES. Also, the INCLEN study (INCLEN 1994) found no significant associations for BMI and SES in five out of 12 of the centres. These were in Brazil (two sites), Chile (two sites) and China. The review of overweight among preschool children from developing countries by Martorell et al. (2000) found no association with maternal education in 28 out of 50 countries. The review by Sobal and Stunkard (1989) found no association in one out of 11 studies of women. The equivalent figures for men, boys and girls, respectively, were $2 / 14,2 / 15$ and $2 / 16$. One multi-country study examined the prevalence of the coexisting underweight and overweight individuals in households using survey data from Brazil, China and the Russian Federation (Doak et al. 2000). It found no clear pattern in the prevalence of underweight/overweight in households by income, but this coexistence pattern was highest in the urban environment in all three countries.

## Literature on developed countries

## Obesity associated with low SES

The review by Colhoun et al. (1998) reported that adjustment for BMI in 26 studies (along with other variables) usually attenuated observed SES gradients in BP (increasing BP with lower SES). Furthermore, in five studies in Germany, the Netherlands, Sweden and the United States (two studies), in which adjustment was made for age and BMI only, this SES gradient was abolished completely. Some of the studies described showed stronger gradients for women compared to men for increased BMI and low SES (Shewry et al. 1992) and in some settings the association applied only to women. Similarly, the INTERSALT study found that increased BMI was significantly associated with lower SES, particularly for women (Stamler et al. 1992).

Surveys associated with WHO's MONICA (MONItoring of CArdiovascular diseases) Project collected data on BMI and years of schooling for 26 populations in the period 1979-1996 ( 25 developed countries plus China) (Molarius et al. 2000). An analysis of the combined data found that, for women, almost all populations ( 22 out of 26 ) showed a statistically significant association between lower educational level and increased BMI (the difference between the highest and the lowest edu-
cational tertiles ranged from -3.3 to $0.4 \mathrm{~kg} / \mathrm{m}^{2}$ ). For men, there was the same association in six out of 26 of the populations (with the equivalent range being from -1.5 to $2.2 \mathrm{~kg} / \mathrm{m}^{2}$ ). In about two thirds of the populations, the differences in BMI between the educational levels increased over the 10 -year period.

The earlier review of 144 published studies on SES and obesity by Sobal and Stunkard (1989) also revealed a strong inverse relationship among women in developed societies. There were 28 United States studies showing this relationship for women and 18 from other developed countries (with only seven studies showing no relationship). For men there were 12 United States studies and 22 studies from other developed countries that found this relationship (while 20 found the opposite relationship and 11 found no relationship). In children and adolescents this pattern was seen in 13 studies for girls (with eight showing the opposite relationship and 11 showing no relationship) and similarly in 11 studies in boys (with nine showing the opposite relationship and 14 showing no relationship).

More recently, a systematic review by Parsons et al. (1999) found that in developed countries there was a strong consistent relationship observed between low SES in early life and overweight in adulthood. These reviewers found that women who changed social class (social mobility) adopted the prevalence of obesity of the class they joined, while this association was not present in men. More recent survey data from various developed countries is consistent with the relationship described above of increased BMI being associated with low SES, for example New Zealand (e.g. for education) (Dryson et al. 1992; Howden-Chapman and Tobias 2000; Statistics New Zealand/Ministry of Health 1993); the United Kingdom (for occupational class among men and women) (Acheson 1998); and the United States (for education among men and women) (Pamuk et al. 1998).

## Obesity associated with high SES

The review by Sobal and Stunkard (1989) found this relationship for men in three United States studies and in eight studies from other developed countries. It was found in only one study of women (among migrants in Belgium). In the 26 MONICA Project populations this association was reported in two populations for men (in Poland and the Russian Federation) and none in women (Molarius et al. 2000). Among children, this relationship was reported for eight studies in girls and nine in boys.

## No association (obesity and SES)

The review by Sobal and Stunkard (1989) found no association between SES and obesity in men in 11 studies, in women in seven studies, in boys in 14 studies and in girls in 11 studies. Of the 26 MONICA Project surveys, 18 found no significant association between BMI and SES in
men and four found no such association for women (Molarius et al. 2000). Similarly, the lack of an association was described for many studies for men and children in the earlier review by Sobal and Stunkard (1989).

The systematic review by Parsons et al. (1999) found no clear relationship between SES in early life and overweight as a child, even though a relationship was reported for low SES in early life and overweight as an adult. These reviewers reported that very few of the relevant studies investigating SES considered confounding by parental obesity. Such findings are consistent with an examination of United States survey data on 12 states between 1980 and 1989, which found in general that children from low-income families did not have a greater prevalence of overweight than children from higher-income families (Yip et al. 1993). (In two states, however, low-income school-aged children and adolescents did show significant increases in body weight in relation to height.)

## DISCUSSION

## The relationship

A very large body of evidence from studies in developed countries indicates that the predominant gradient is that of lower SES being associated with increased body weight. This relationship appears very strong and consistent for women, but only six of the 26 MONICA Project surveys found such a relationship for men. Also, a systematic review found no clear relationship between SES in early life and childhood obesity, although a relationship was reported for low SES in early life and adult obesity.

The predominant pattern in developing countries is for higher-SES men and women to have higher body weight. Nevertheless, some studies have found no relationship and in some regions (e.g. Latin America) the opposite pattern appears to be emerging. Among preschool children there is also evidence that being overweight was significantly more common in those with mothers with higher education (in 22 out of 50 countries).

## Possible mechanisms

In developing countries the association between BMI and higher SES is probably related to a "nutrition transition" (Popkin 2001) to diets higher in fat. A trend towards poorer diets (e.g. increased dietary fat) with increasing income was described for China and the Philippines in a review by Popkin et al. (1995b). Societal attitudes to obesity and thinness, as described by Sobal and Stunkard (1989) may also be relevant in determining dietary restraint and participation in physical activity. For example, mild obesity appears to be equated with physical attractiveness in some countries. Fetal and infant nutrition may also be relevant in determining subsequent obesity, although a recent review of this evidence
in a developing country context suggests the relationship is not as clear for obesity as it is for hypertension (Dryson and Martorell 2000). Reduced physical activity was considered to be a relevant factor for obesity in high-SES groups (see also section 4.7), but reduced physical activity might also be an important factor for obesity in low-SES groups (Torun 2000).

In developed countries it is likely that nutrition also plays a key role in the association between low SES and increased BMI. A review by Potter (1997) reported evidence of poorer nutrition with low SES in a number of developed countries: Australia (three studies), Canada, Denmark, Finland and the United States (four studies). In all these studies the dietary pattern was suggestive of that associated with the greatest risk of excessive calorie intake (i.e. low in vegetables, fruit or wholegrain cereals and/or high in fat, meat, butter or whole milk). In particular, the relationship between dietary fat intake and obesity was fairly well established (Bray and Popkin 1998). Similarly a meta-analysis of 11 studies from seven European countries found lower vegetable and fruit intake in low-SES groups (using education and occupation) for both men and women (Irala-Estevez et al. 2000). Data from other studies provide further evidence for this pattern, for example for New Zealand (Howden-Chapman and Tobias 2000) and the United Kingdom (Acheson 1998). The SES gradient for breastfeeding, e.g. in the United Kingdom (Acheson 1998), might also be relevant in determining subsequent BMI in childhood.

In some developed countries, physical inactivity might well play a role in the SES-BMI gradient (see section 4.7). Other explanations include "a complex mix of poverty of information and skills, a distorted view of "status foods" and an approach to dietary priorities typical of the 1940 s, which was then much more focused on protein and calories" (Potter 1997). Furthermore, cultural attitudes to thinness and dietary restraint may be important (Sobal and Stunkard 1989).

When considering potential explanations for the relationship between SES of origin and adult obesity, Power and Parsons (2000) suggested that SES of origin may actually be confounded by parental body size. Alternative explanations include "(1) nutrition in infancy and childhood, either over- or undernutrition, followed subsequently by over nutrition; (2) psychological factors, possibly involving emotional deprivation in childhood; (3) cultural or social norms regarding dietary restraint and attitudes to fatness that may be acquired during childhood".

### 4.7 Physical inactivity

Literature on Developing countries

## Physical inactivity associated with low SES

In an urban Chinese population, low level of education was found to be associated with leisure-time physical inactivity in both men and women
(Yu et al. 2000). However, this gradient declined over the seven-year study period, particularly for men. Other Chinese survey data indicate that urban residents are far more sedentary than rural residents (Paeratakul et al. 1998). A study of a metropolitan area in Brazil found that high-SES women were less likely to be physically inactive (Martins et al. 1995). This was also the pattern for the skilled working class relative to the unskilled working class. A study in a Caribbean island reported that low-SES men and women (based on educational attainment) were reported to exercise less often (Grol et al. 1997b).

## Physical inactivity associated with high SES

In India, physical inactivity was reported to be more prevalent among those of higher SES in women in five cities (Singh et al. 1999), in men and women in villages (for SES based on occupation) (Singh et al. 1997b) and in men and women in a city (Singh et al. 1998). For SES based on educational attainment, the same pattern was seen in another study of men and women in Indian villages (Gupta et al. 1994). This pattern was also reported for men in a Brazilian city for overall physical activity, although there was no association for leisure-time activity (Duncan et al. 1993). In contrast, the higher-SES women in this Brazilian city had higher levels of physical activity. A study in Puerto Rico reported that urban men with more education had lower levels of physical activity (Sorlie and Garcia-Palmieri 1990). Also, in Mauritius, unskilled workers were reported to be significantly more physically active than members of other occupational groups (attributable largely to occupational rather than to leisure-time physical activity) (Pereira et al. 1998).

## Literature on developed countries

## Physical inactivity associated with low SES

In the United States, national survey data indicated increased leisure-time physical inactivity with lower SES (including people who were less educated, who lived below the poverty line and who lived in low-income households) (Crespo et al. 1999). Previous national survey data also showed this pattern (USDHHS 2001). However, these indicators still do not seem to explain the higher prevalence of leisure-time physical inactivity among specific populations (African Americans and Mexican Americans) (Crespo et al. 2000).

Consistent with these results are studies of specific United States population groups, for example for income and education in a disadvantaged urban community (Diez-Roux 1998); educational level and women among members of a health maintenance organization in California (Sternfeld et al. 1999); and educational level and income among Minneapolis-St Paul residents). The latter study reported time trends for leisure-time physical activity, indicating greater gains among men with
low SES and among less affluent women. There is also United States evidence that living in an poor area is independently associated with physical inactivity and in a decline in physical activity levels over time (Yen and Kaplan 1998).

Similarly, the Whitehall II longitudinal study in the United Kingdom found that low-status occupation was associated with leisure-time physical inactivity for both men and women (Brunner et al. 1999). Adjustment for earlier SES position (using father's social class and own education level simultaneously) did not weaken the effects of SES position as an adult. Other United Kingdom work showed non-participation in sport to be associated with low SES, and no significant changes in this gradient occurred between 1984 and 1993 (Bartley et al. 2000).

Survey data from Germany have also suggested that lack of regular exercise (for both sexes) was one of the most striking poverty-related differences in terms of cardiovascular disease risk factors (Helmert et al. 1997). Other German work has reported that high-SES men and women were, respectively, four and three times more likely to have an active leisure time than those with low SES (Mensink et al. 1997). Similarly, survey data on elderly people of low SES in Switzerland suggest that they get less physical exercise (Abelin and Schlettwein-Gsell 1986). In the Netherlands, a cohort study reported that lower levels of educational attainment were associated with physical inactivity (Schrijvers et al. 1999), as did a cross-sectional study (Droomers et al. 1998).

A Swedish cohort study (Lindstrom et al. 2001) reported increased levels of physical inactivity among skilled and unskilled male manual workers and unskilled female manual workers compared to high-level non-manual employees. However, it was found that adjusting for social participation almost completely erased the SES differences (social participation included involvement in political parties and organizations and was a strong predictor of increased physical activity). In Australia, it was reported that multicentre cross-sectional community survey data indicate a "clear socioeconomic gradient between leisure-time physical activity and education attainment" (Bennett 1995). Nevertheless, time-trend data indicate that walking for recreation or exercise has become more popular among older men of low education. Another Australian study found that a higher proportion of students participating in organized sport and health and fitness activities came from the higher-SES group (based on parental occupation) (Blanksby et al. 1996).

## Physical inactivity associated with high SES

Survey data from a Spanish city between 1983 and 1994 found that physical inactivity in men was always more prevalent in social classes I and II (for total daily activity including activity at work) (Borrell et al. 2000). This difference increased over time as more people of advantaged classes became physically inactive. Among men in the United Kingdom, those
in the manual classes had a higher level of physical activity than those in the non-manual classes, owing partly to work-related physical activity (Acheson 1998). However, the general pattern for the United Kingdom is for physical inactivity to be associated with low SES (as discussed above).

## No relationship

In New Zealand, the most recent national survey found no significant relationship between physical inactivity and social class or educational attainment (Howden-Chapman and Tobias 2000). This was in contrast to earlier New Zealand national survey data, which showed a gradient for lower levels of physical inactivity with higher educational attainment (for more than four hours of exercise in the previous seven days) (Statistics New Zealand/Ministry of Health 1993).

## DISCUSSION

## The relationship

In general, physical inactivity is associated with low SES in developed countries, with a fairly marked gradient. Nevertheless, there are some exceptions, such as the reverse pattern among men in Spain. The relationship is more mixed for developing countries, with opposing gradients seen for China and India (with the latter showing the pattern of the developed world).

For the developed countries, this relationship appears to have impacts on disease outcomes. A United States review suggested that SES gradients in cardiovascular disease may be partly attributable to SES gradients in physical activity (Pickering 1999). A Dutch cohort study also reported that physical inactivity partly explained the relationship between poor educational attainment and mortality rates (Schrijvers et al. 1999). In general terms, the pattern of low SES being associated with physical inactivity is consistent with the evidence from developed countries that low SES in men is associated with increased risk of developing cardiovascular disease (Gonzalez et al. 1998).

## Possible mechanisms

Physical inactivity and low SES. In the United Kingdom, barriers to exercise among low-income people include illness or disability, lack of money and lack of transport (Chinn et al. 1999). Fear of crime may also have an effect on walking and the use of parks in some neighbourhoods, along with access to such parks, recreational facilities and gymnasiums. Swedish data suggest that high-SES groups have increased social participation, and it may be that leisure-time physical activity is partly mediated by a higher extent of encouragement/peer pressure to participate in physical activity (Lindstrom et al. 2001). United States data also indicate that social support and confidence in one's ability to continue to
exercise when faced with other pressures and demands is important in determining levels of physical activity in women (Sternfeld et al. 1999).

Physical inactivity and high SES. In at least some parts of the developing world, the move to sedentary occupations among those with high SES appears to be an important factor in the SES patterning of physical inactivity (Singh et al. 1998). A decline in walking to work among members of this group may also be important (Duncan et al. 1993). Also, in some low-income neighbourhoods there may be "contagion effects" where a culture of being out on the streets and walking around prevails (Ross 2000), possibly combined with higher-density housing. In the United Kingdom, barriers to participation in physical activity among high-income people include lack of leisure-time and lack of motivation (Chinn et al. 1999).

### 4.8 Blood-lead levels

## Literature on developing countries

A review of lead poisoning in children in China found 17 relevant publications. Those children residing in industrial areas and areas with heavy traffic had average blood-lead levels of 21.8-67.9 $\mu \mathrm{g} / \mathrm{dl}$ (Shen et al. 1996). The percentages of blood-lead levels above $10 \mu \mathrm{~g} / \mathrm{dl}$, which defines lead poisoning in children, ranged from 64.9 to 99.5 . A more recent study in a Chinese city (Wuxi City) in children aged 1-5 years also found that blood-lead levels were significantly higher for those living in industrial areas (Gao et al. 2001).

In a survey in India of children aged from 6 months to 6 years, risk factors for elevated blood-lead levels were living in houses painted with lead-based paint, recent exposure to lead-based paint and the use of the eye cosmetic "ma". However, they also found that high caste was a risk factor. No association was found with traffic, parental occupational exposure or nutritional status.

In a study in a Mexican city, low family income was one of the most important factors related to raised blood-lead levels in children, along with family use of lead-glazed pottery and the use of animal fat in cooking (Azcona-Cruz et al. 2000). Another study examined blood-lead levels in pregnant women in Mexico City attending public hospital prenatal clinics (representing primarily women of low SES) and private hospitals (primarily women of high SES) (Farias et al. 1996). Overall, blood-lead levels were significantly higher in the public hospital group. Consumption of milk products significantly reduced lead levels in the higher-SES group, and taking calcium supplements lowered blood-lead levels in those women whose diets were deficient in calcium. The authors concluded that avoiding the use of lead-glazed ceramics, consuming diets rich in calcium and, if needed, taking calcium supplements would be
expected to result in a substantial lowering of blood-lead levels, especially in pregnant women of low SES.

A study of 4-12-year-old schoolchildren in Bangladesh found that elevated blood-lead levels were significantly associated with low parental education (odds ratio of $2.7,95 \%$ CI $2.0-3.8$ ) and living close to major roads (odds ratio of $2.3,95 \%$ CI 1.2-4.3) along with soil-eating and increasing age (Kaiser et al. 2001). The authors considered that living near major roads may be related to low SES in this population.

A study in South Africa (KwaZulu-Natal) examined children aged 3-5 and 8-10 years (Nriagu et al. 1997). Household factors that were significantly associated with blood-lead levels included distance from tarred roads, overcrowding, hygienic habits in the household and the burning of solid waste for heating or cooking, all of which are related to poverty and low SES. The lack of significant associations with risk behaviour in this study was attributed by the authors to "the over-riding influence of high levels of contaminated dusts both indoor and outdoor". Another study in South Africa found that low parental education and income were associated with raised blood-lead levels, along with dusty homes, homes in a poor state of repair and overcrowding (von Schirnding et al. 1991).

## LITERATURE ON DEVELOPED COUNTRIES

A recent review (Tong et al. 2000b) reported that in developed countries chronic exposure to low levels of lead is still a public health issue, "especially among some minorities and socioeconomically disadvantaged groups". Similarly, a review in the United States reported that poor and minority children have higher rates of elevated blood-lead levels (Powell and Stewart 2001).

National survey data on United States children aged 1-5 years found that independent risk factors for elevated blood-lead levels included: "being of minority race/ethnicity, living in an older home, residing in the northeast or midwest regions of the United States, being on Medicaid, having a head of household with $<12$ years of education, and having a history of anemia" (Kaufmann et al. 2000). Some of these factors are associated with SES disadvantage (living in older housing and low level of education). An earlier national survey also reported associations between blood-lead levels in children and low income and low parental educational attainment (Pirkle et al. 1994).

Another study in the United States found that lead concentrations in the tibia were significantly higher in men who did not graduate from high school than in men with $\geq 4$ years of college education (Elreedy et al. 1999). Living in an area with a poor level of education was associated with a significantly higher tibia lead level among those not graduating from high school, but not among college graduates. The authors concluded that the influence of individual SES on cumulative lead
exposure is modified by geographical area. This study also identified a significant relationship between low individual annual income and increased bone lead levels.

In Australia, a cohort study found that residential area and father's place of employment were the two variables most strongly predictive of a child's blood-lead concentration at the end of primary school (Baghurst et al. 1999). A poorer-quality home environment was also found to be an independent contributor to blood-lead concentrations. Other work on this cohort, however, did not find statistically significant interactions between lifetime average blood-lead concentration and parents' occupational status (used as a surrogate of SES) (Tong et al. 2000a).

In New Zealand, a study of a cohort at age 21 years found significant associations between higher blood-lead levels and high-risk occupational activities, living close to a main road, smoking and recreational exposure (Fawcett et al. 1996). Some of these risk factors have associations with SES (occupation and smoking). However, a study of this same cohort at age 11 years found no significant correlation between bloodlead levels and SES (Silva et al. 1986).

## DISCUSSION

## The relationship

The overall pattern in both developed and developing countries is that poverty and low SES are associated with elevated blood-lead levels in children and adults. Nevertheless, there is still a minority of studies in which such a relationship is not apparent (for example, high caste Indian children, who may have greater exposure to cosmetics and crayons containing lead).

## Possible mechanisms

The literature suggests a number of possible mechanisms for a relationship between poverty and elevated blood-lead levels.

- Air pollution from vehicle exhausts. People living near major roads are likely to have increased exposure to airborne lead in countries where lead is still added to petrol. In the United States, air pollution exposures and associated health risks appear to affect disproportionately populations that are poor and non-Caucasian (see section 3.5 for further details).
- Older and dilapidated housing. Older houses have an increased probability of having been painted with lead-based paint, and these tend to be concentrated in older urban centres where many disadvantaged groups live. In these settings, and where houses are not properly maintained, children are more likely to ingest flakes of lead-based paint.
- Housing in the developing world. It has been suggested that the type of construction of some low-income housing and its location close to roads may make it difficult to keep these houses free from lead in dust and soil (Kaiser et al. 2001).
- Emissions from industry. Poor people are more likely to be exposed to such emissions, since they more often live in or close to heavily industrialized areas. One United States review noted that: "minority and poor families disproportionately live in communities with landfills, hazardous waste facilities, incinerators, industrial plants, and old housing with poor indoor air quality and lead-based paint" (Powell and Stewart 2001).
- Occupational hazards. Certain occupations are associated with increased risks of high blood-lead levels (e.g. lead smelting and battery manufacture). Many of these blue-collar factory workers are in relatively disadvantaged groups. Also, these workers sometimes bring lead dust into the home environment and thereby expose family members. In developing countries poor people can be exposed to lead in cottage industries.
- Smoking. Smoking is a risk factor for high blood-lead levels and is generally more common in low-income groups.
- Home remedies. Some home remedies used in developing countries are known to contain high levels of lead (Azcona-Cruz et al. 2000). Poor people might be more likely to use such remedies than those who can afford to seek treatment from a health professional.
- Poor nutrition. The dangers of lead exposure are increased by several dietary conditions (Mahaffey 1990) that are more frequently present in economically disadvantaged children.
- Knowledge of risks and preventive measures. Poorly educated parents may be less likely to know of the risks of lead exposure and to make use of preventive measures (such as frequent hand-washing with soap and water; thoroughly cleaning fruit and vegetables; regularly dusting and sweeping the house; and preventing children sucking fingers, toys or pencils or eating soil).
- Overcrowding. In a South African study (von Schirnding et al. 1991) it was suggested that "the over-crowded nature of the homes could have a direct bearing on the quality of the care-giving environment, providing opportunity for children's activities to go unsupervised. This could lead young children to be more exposed to accessible sources of lead associated with poor housing conditions".

Poverty and low SES might also actually accentuate the effect of lead poisoning. An Australian cohort study found that, after adjustment for
a wide range of covariates, children from socially disadvantaged backgrounds were more sensitive to the effects of lead on their IQ relative to those of a higher SES (Tong et al. 2000a). This finding is generally consistent with the results of some (but not all) other studies of children. It is also consistent with the results of a recent animal study (Schneider et al. 2001).

## 5. Discussion

We estimated associations between risk factors and absolute poverty across the developing subregions of the world, and calculated attributable risks based on these, but without adjustment for confounding. Many of the causes of ill-health that we studied tend to weigh most heavily on the poorest groups in each of the 11 subregions. However, the socioeconomic gradient is not uniform across all the risk factors, and in some instances the associations vary between subregions. For some risk factors, variation between subregions in overall risk factor prevalence appears to be more important than variation by individual-level poverty within subregions. Our findings are based on a combination of quantitative analyses of existing survey data, and literature reviews for selected risk factors with some limitations.

### 5.1 Limitations

## CONCEPTUAL LIMITATIONS

We examined the individual-level association of poverty with risk factors, whereas previous work had examined the global differences in health status and poverty using country-level analyses (e.g. Gwatkin et al. 1999). Our presentation of individual-level analyses is arguably preferable to country- or subregional-level analyses of poverty and health. However, it is important not to let our analyses distract from two issues: societies tend to adopt health behaviours collectively; and the greatest income inequalities in the world are between countries rather than within countries. Regarding the former point, it is interesting to note that the between-region variation in the overall prevalence of risk factors such as tobacco use, indoor air pollution and unsafe water and sanitation was more strongly associated with individual risk than income poverty.

There are several other limitations to our analyses of the association of poverty with risk factors, including the inability to make causal inferences, lack of consideration of the role of time-lags, exclusion of residual income heterogeneity within level of absolute poverty, and exclusion of the heterogeneity of the association of poverty with risk factors within and between countries in each subregion. Consequently, the results must be interpreted as a mapping of risk factors by income poverty. They should not be interpreted as a determination of the causal association
of poverty and risk factors or as a determination of the causal impact fractions of poverty for various risk factors.

## Quantitative analyses

The major limitation was data availability. First, both poverty and risk factor data were available for only some countries within each subregion, requiring extrapolations from those countries with data. Second, some subregions had no data at all for some risk factors (e.g. unsafe sex, alcohol), limiting the number of subregions for which we could conduct analyses. Third, all results were based on survey data with their own random and systematic errors.

It was necessary to make methodological assumptions in order to map risk factors by absolute poverty. The most important of these assumptions was that we could use the association of risk factors with a composite measure of socioeconomic position (e.g. asset scores in DHS data) to estimate the (unobserved) association with income poverty.

The definition and measurement of risk factors also need to be considered when interpreting the findings. In some instances, the variables used are indirect measures. Tobacco use, for example, was estimated in some subregions from household expenditure on tobacco (which would probably skew the distribution of use by socioeconomic group towards the better off). Other variables may not fully capture all aspects of risk. For example, alcohol use was also based on expenditure data.

### 5.2 Key findings

Having accepted the limitations described above, many striking results appeared that are highly unlikely to be spurious. For several important risk factors the effect of poverty appears to be very strong. Lack of improved water and sanitation, for instance, was 10-15 times more common in households living on <US\$ 1 per day than in those living on more than $>$ US $\$ 2$ per day. Indeed, lack of adequate water and sanitation is widely accepted as being so closely aligned to poverty that it is used as a variable in asset scores to measure poverty. (Note that we did not use water or sanitation in the estimation of asset scores.) Worldwide, we estimated that $36-51 \%$ of instances of inadequate water and/or sanitation could be prevented if the prevalence of inadequate water and/or sanitation among people living on $<$ US $\$ 2$ per day was the same as that of people living on $>$ US $\$ 2$ per day (assuming a causal relationship).

We found a consistently strong association of absolute poverty with underweight children in all subregions except WPR-B, which is dominated by the China analyses (see Table 24.19). Previous research also found the same strong association, including for China (Chen 1996; Li et al. 1999; Popkin et al. 1993). Thus, our estimate of there being little association of poverty with underweight children in China is probably due to the small sample size in that survey. Putting China aside, the con-
sistency of the relative association of absolute poverty with underweight children across other subregions was notable. Put another way, regardless of where children live in the world the relative increase in underweight children with increasing socioeconomic deprivation is remarkably consistent. Across all developing countries, we estimated that 23-37\% of cases of underweight could be prevented if the prevalence of underweight among children living on $<$ US $\$ 2$ per day was changed to that of children living on $>$ US $\$ 2$ per day. Assuming a causal relationship, poverty appears to have a strong and important association with child malnutrition.

The third risk factor in our quantitative analyses that demonstrated a strong association with poverty was indoor air pollution-although with some interesting heterogeneity between subregions (see Table 24.35). Regardless of the level of poverty in AFR-E, exposure to indoor air pollution appeared to be very high. In other subregions (often based on analyses for just one country per subregion), the associations appeared somewhat variable with regard to overall level of exposure to indoor air pollution and the relative risk association. Nevertheless, there was no exception to the general rule that those living in absolute poverty are exposed more frequently to indoor air pollution. Using the population impact fraction estimates (US\$2 per day cut-off), we estimate that a third to a half of the exposure to indoor air pollution in developing countries could be averted if the poor had the exposure prevalence of the nonpoor (assuming a causal relationship).

Beyond these three risk factors (underweight, water and sanitation and indoor air pollution), the associations we found in our quantitative analyses tended to be weaker and more variable between subregions. Data were limited in our quantitative analyses on unsafe sex, and the most reliable overall conclusion was of no consistent pattern of unsafe sex by poverty within subregions. However, behind the summary variable of "unsafe sex", it was interesting that "sex with a non-marital partner" and "condom use among those having sex with a non-marital partner" were less common among poor males and females. Also, there was some indication of variation in the association by sex. In AFR-E for instance, unsafe sex was associated with poverty among men but there was no apparent association for women (see Tables 24.26 and 24.27).

We carried out quantitative analyses for outdoor air, although these were not conducted in the same manner as for other risk factors. The results for outdoor air pollution show lower exposures to fine particles in those living on <US $\$ 1$ per day in all subregions studied (see Table 24.37). Our method assigned people in urban or rural areas the same outdoor air pollution exposure regardless of income. Because rural areas have lower air pollution, and poor people tend to live in rural areas, this means that the poorest (on average) are exposed to lower levels of outdoor air pollution. However, this result is likely to obscure some
reverse socioeconomic patterns within urban centres, where it is the poorest people who live in the more polluted areas. This within-urban socioeconomic difference is likely to partially offset the urban-rural effect that gives rise to our results, but by how much is unclear. Without doubt, however, our method overstated the degree to which the poorest people are protected from outdoor air pollution relative to those who are less poor.

The quantitative analyses for overweight were based on DHS data (probably superior to LSMS data) supplemented by CHNS data, but only analyses for maternal overweight were possible. Nevertheless, a clear pattern emerged. Among the poorest subregions of the world (Africa and South East Asia) poor women were only half as likely to be overweight as the non-poor, whereas among subregions without quite the same depth of poverty (south-eastern Europe, central Asia, Central and South America) poor women were only about $20 \%$ less likely to be overweight. The relationship in WPR-B (dominated by China) was flat. We are uncertain about the accuracy of the data for China, but Yu et al. (2000) observed a higher prevalence of obesity among the least educated women in urban China. Our literature review tended to support the pattern of obesity becoming a greater problem among lower socioeconomic groups in South American countries. Popkin et al. (1995b) commented that the socioeconomic gradient in developing countries is shifting towards a developed world pattern of increased obesity among groups of low SES. Indeed, this is already occurring in some urbanized parts of Latin America. It is interesting to speculate whether the patterns we found were simply due to individuals in more poor subregions living in deeper poverty or whether this pattern is due to the socioeconomic gradient starting to "tip the other way" in countries with increasing affluence.

The final two risk factors for which we were able to conduct quantitative analyses-tobacco and alcohol consumption-showed weak and variable associations between subregions. The data used in the analyses were not of high quality, being often based on expenditure data and income. Summarizing the analyses as a (rather crude) estimate, there was little "net" association: the "total" population impact fractions for subregions with data combined were less than $10 \%$. Nevertheless, there were some indications of between-subregion variability. For example, it is reasonable to conclude that if poor people in Africa (AFR-D and AFRE ) adopted the lifestyle of the non-poor, the prevalence of alcohol consumption might increase by approximately $20-40 \%$.

In terms of tobacco and alcohol consumption, we may expect a variable association between subregions. It has often been the experience of the developed world that higher socioeconomic groups initially adopt adverse behavioural patterns (such as smoking) then discard them on learning of the health consequences. For various reasons, possibly asso-
ciated with economics or marketing, lower socioeconomic groups take up such behavioural patterns later. It is not unreasonable to expect the current pattern among developing countries to reflect historical patterns in the developed world. Moreover, it seems likely that such transitions might be at different stages in different subregions. Our quantitative analyses are not inconsistent with this conjecture, but neither can they offer strong support for it. For example, one might expect to see a stronger association of poverty with tobacco in subregions with relatively high prevalence of tobacco use, assuming that prevalence is related to the stage of the tobacco "epidemic". This was not apparent in our data.

Regarding the international literature on tobacco, the general pattern in developing countries is for a higher prevalence of smoking in those of lower SES, with a generally stronger association for men. Nevertheless, some studies in the poorer countries actually show the opposite pattern, with adults and adolescents of high SES having higher smoking rates, while some studies show no association. Our quantitative analyses mostly demonstrated a null association of poverty with prevalence of tobacco use except in EMR-D (i.e. Pakistan), where there seemed to be higher prevalence of tobacco use among more poor people (see Table 24.39). It should be noted that our quantitative analyses may have underestimated tobacco use among poor people, owing to our having to rely on expenditure data. Conversely, it is possible that the published literature has tended to arise from less poor areas of the developing world.

Our literature review demonstrated a tendency towards more hazardous alcohol consumption among lower socioeconomic groups in the developing world. However, the pattern varied between countries and studies. Our quantitative analyses were based on the prevalence of alcohol use, as indicated by expenditure on alcohol. This approach might have underestimated an adverse socioeconomic gradient for hazardous alcohol consumption.

The local effects of poverty are important, but it must be noted that variations in prevalence between subregions are frequently greater than the variations in risk factors by income within subregions. Tobacco use and exposure to indoor air pollution are two examples. The effect of poverty on smoking rates might be considered as a (not insignificant) ripple on a much larger wave, with "peak" subregions having smoking prevalence figures four times greater than those of the subregions in the "trough". Global tobacco control must deal with both the forces that generate disadvantage for lower income groups within populations and those forces (mostly on the supply side) operating at the level of countries and subregions.

We have included detailed literature reviews for risk factors for which we were unable to conduct quantitative analyses. For cholesterol and
lipids, hypertension and physical inactivity, the general patterns in the developing world were of either a mixed pattern or of more adverse profiles among higher socioeconomic groups. However, just as with obesity and overweight, it seems likely that in the future the average profile for these risk factors will worsen in the developing world, and become more concentrated among lower socioeconomic groups.

## Acknowledgements

We thank Cara Marshall for assisting with the retrieval of journal articles; Emmanuela Gakidou for advice on factor analysis; and Majid Ezzati, Alan Lopez and Anthony Rodgers for ongoing guidance and advice. We are also indebted to the other risk factor teams, who forwarded data and reports to assist in the analysis.

Funding for this work was provided by WHO.

## Notes

1 See preface for an explanation of this term.
2 For the 11 subregions with DHS data.
3 Referred to as scenarios in chapter 16.

## Appendix B: Loess plots for China data

Locally linear kernel regression smooth plots of the various risk factors according to normalized equivalized income ranking are shown in Figure B.1. Each sub-figure plots the proportion of individuals or households with the risk factor in question (y-axis ranging from 0 to 1 ) by normalized equivalized income rank for China (x-axis ranging from 0 [poorest] to 1 [richest in China]).

Figure B.I Loess plots of the prevalence of various risk factors ( $y$-axis) by normalized income rank (x-axis)

Appendix C: Literature review summaries

## UNDERWEIGHT

A total of 17 journal articles on malnutrition were summarized. These studies used several measures of nutritional status, including underweight, wasting and stunting. Many studies did not report results for underweight, but the pattern of the results was comparable across the three different measures and between studies. There were negative associations between malnutrition and income, maternal education, urban residence, availability of water or sanitation, and household goods such as a radio or television.

Wagstaff and Watanabe (2001) reviewed data on malnutrition in relation to equivalized household consumption for 20 developing countries. They found that malnutrition tended to decline monotonically with rising living standards. Inequalities in underweight tended to be larger than for wasting and stunting. Between-country differences in underweight were not statistically significant.

## Multivariate summary of results

## Comments

Model applied
Similar results as for bivariate analysis
Results not given in paper
No indication of how representative this study is for the Philippines as a whole. Weight-for-age given only at descriptive level, as investigators did not think it differentiated stunted from wasted children.
Investigators showed a clear socioeconomic difference between urban and rural households (in terms of housing characteristics such as water source, cooking fuel, ownership of television and radio, floor and wall materials, as well as parental education) but similar household size and density

## Water and sanitation

Good quality water and adequate sanitation are commonly regarded as basic socioeconomic prerequisites for health, and thus their lack is associated with low SES. It is difficult to find individual-level data on water supply, as most research on water quality examines the issue at aggregate rather than individual level.

As water quality and sanitation facilities are regarded as indicators of SES, and the relationship between poverty and poor water quality and sanitation is widely accepted, it was difficult to find appropriate articles as the relationship between these two factors is rarely examined. More often, water quality and/or sanitation are used as part of socioeconomic indices. As a result, only nine journal articles were revealed by the literature review search, of which three were retrieved. On examination, two of these articles were deemed unsuitable for our purposes and were discarded.

The remaining article reported on a study carried out in rural Bangladesh. However, some of the subjects of the study were recipients of support from nongovernmental organizations (NGOs) and thus were not necessarily typical in terms of education and access to water and sanitation. In general, however, there was a strong positive relationship between SES and safe sanitation and a weaker positive relationship between SES and safe waste disposal. A number of measures for SES were used, including educational level, housing level, occupation and land ownership. A similar pattern was seen across all these measures.

## Unsafe sex

Two journal articles on unsafe sex were retrieved of the 30 revealed by the literature search. One was unsuitable for our purposes and thus discarded. The remaining article was the result of a study on knowledge of sexually transmitted infections (particularly syphilis and gonorrhoea) among married women in rural Bangladesh. The results showed that increasing knowledge of these sexually transmitted infections correlated with increasing level of education among these women. This knowledge was also more common among women whose husbands were professionals or service-holders.

## Chapter 25

# Estimating attributable burden OF DISEASE FROM EXPOSURE AND HAZARD DATA 

Stephen Vander Hoorn, Majid Ezzati, Anthony Rodgers, Alan D. Lopez and Christopher J.L. Murray

## 1. Estimating population attributable FRACTIONS

As described in earlier chapters, the contribution of a risk factor to disease burden (expressed as the fraction of disease or death attributable to the risk factor in a population) is given by the generalized "potential impact fraction" (PIF) in Equation 1a (Drescher and Becher 1997; Eide and Heuch 2001; Walter 1980).

$$
\begin{equation*}
\text { PIF }=\frac{\int_{x=0}^{m} R R(x) P(x) d x-\int_{x=0}^{m} R R(x) P^{\prime}(x) d x}{\int_{x=0}^{m} R R(x) P(x) d x} \tag{1a}
\end{equation*}
$$

$R R(\mathrm{x})$ : relative risk at exposure level x
$P(x)$ : population distribution of exposure
$P^{\prime}(x)$ : counterfactual distribution of exposure, and
$m$ : maximum exposure level
The first and second terms in the numerator of Equation 1a represent the total exposure-weighted risk of disease or mortality in the population under current and counterfactual exposure distributions. The corresponding relationship when exposure is described as a discrete variable with $n$ levels is given by:

$$
\begin{equation*}
P I F=\frac{\sum_{i=1}^{n} P_{i} R R_{i}-\sum_{i=1}^{n} P_{i}^{\prime} R R_{i}}{\sum_{i=1}^{n} P_{i} R R_{i}} \tag{1b}
\end{equation*}
$$

The PIF equation can be used to estimate the population attributable fraction (PAF), defined as the proportional reduction in disease or death that would occur if exposure to the risk factor were reduced to the counterfactual exposure distribution. The remainder of this chapter outlines how data on exposure, hazard and disease burden were combined to derive estimates of attributable disease burden, with estimation of the population attributable fraction as the intermediate step. The application of Equations 1 a and 1 b in the context of the comparative risk assessment (CRA) project is discussed and several issues regarding its implementation are detailed.

## 2. Estimating attributable mortality and BURDEN OF DISEASE

For each risk factor-disease outcome pair, PAFs for each of the 224 age, sex, subregion ${ }^{1}$ groups were calculated using the relationships in Equation 1, separately for mortality $\left(P A F_{M}\right)$ and incidence $\left(P A F_{I}\right)$ when the relative risks for mortality and incidence were different. For each of these 224 groups, the estimates of mortality $\left(A M_{i j}\right)$ and burden of disease $\left(A B_{i j}\right)$ from disease $j$ attributable to risk factor $i$ were calculated as below. Burden of disease, reported annually in the annexes of the World Health Report, was expressed in disability-adjusted life years (DALYs), with methods and assumptions described elsewhere (Murray and Lopez 1996). Specifically:

$$
\begin{aligned}
A M_{i j} & =P A F_{M-i j} \times M_{j} \\
A Y L L_{i j} & =P A F_{M-i j} \times Y L L_{j} \\
A Y L D_{i j} & =P A F_{I-i j} \times Y L D_{j} \\
A B_{i j} & =A Y L L_{i j}+A Y L D_{i j}
\end{aligned}
$$

Where "A" indicates "attributable" and
YLL: years of life lost to premature mortality
YLD: years of life lived with disability due to disease incidence
For those risk factors with insufficient data to estimate a relative risk model (e.g. occupational or alcohol-caused injuries or the effects of lead exposure on blood pressure), disease burden or mortality was estimated using existing registers or corresponding hazard relationships. Estimates were then aggregated across age groups to obtain subregional estimates,
and across subregions to obtain global estimates. The details of this aggregation are described later in this chapter.

## 3. Counterfactual exposure distribution

The estimates of burden of disease and injuries due to risk factors in the CRA project are based on a counterfactual of theoretical-minimum-risk exposure distribution, defined in chapter 1 and described in individual risk factor chapters. By using the theoretical-minimum-risk exposure distribution, which by definition has a relative risk of 1.0, as the counterfactual exposure distribution or level, Equations 1a and 1b are reduced to:

$$
\begin{equation*}
A F=\frac{\int_{x=0}^{m} R R(x) P(x) d x-1}{\int_{x=0}^{m} R R(x) P(x) d x} \tag{2a}
\end{equation*}
$$

and

$$
\begin{equation*}
A F=\frac{\sum_{i=1}^{n} P_{i}\left(R R_{i}-1\right)}{\sum_{i=1}^{n} P_{i}\left(R R_{i}-1\right)+1} \tag{2b}
\end{equation*}
$$

### 3.1 Theoretical-MINIMUM-RISK EXPOSURE DISTRIBUTION FOR CONTINUOUS EXPOSURE VARIABLES

The theoretical-minimum-risk exposure distribution for continuous risk factors is itself often a distribution of exposure levels, vs a constant baseline. Figure 25.1, for example, illustrates a scenario for systolic blood pressure (SBP) with typical exposure levels in an older population (mean: $150 \mathrm{mmHg} ; \mathrm{SD}: 9 \mathrm{mmHg}$ ) compared with the theoretical-minimum-risk exposure distribution (mean: 115 mmHg ; SD: 6 mmHg ). The non-zero standard deviation of the theoretical-minimum-risk distribution reflects the reality that there always is some inter-person variability within any given population, even after hypothetical reductions such as that shown in Figure 25.1.

The optimal exposure distribution for a population would overlap precisely with the theoretical-minimum-risk exposure distribution. By definition of theoretical-minimum risk, such a population would be collectively without any increased risk and therefore with zero attributable burden due to the risk factor of interest. Any population containing individuals outside this distribution will then have a population attributable fraction greater than zero and exposure distributions converging on the

Figure 25.1 Theoretical-minimum-risk exposure distribution for continuous risk factors using systolic blood pressure (SBP) as an example

Note: Each point represents a hypothetical individual or small group of individuals in the population. The solid straight lines represent the increasing relative risk, on a log scale, for ischaemic heart disease with increasing SBP.
theoretical minimum will have attributable burden tending towards zero. The risk for any individual (or groups of individuals in a narrow range of exposure) in the population would be determined by the difference between her/his current exposure (SBP level) and the SBP level that s/he would have when the population distribution overlaps with the theoret-ical-minimum-risk exposure distribution.

Estimating the total hazard at the population level can be achieved using a micro-simulation approach in which individuals are drawn randomly from current and theoretical-minimum-risk exposure distributions. For most risk factors, however, individual exposures "track" over relatively long periods of time (Lauer and Clarke 1988; Voors et al. 1979; Wilsgaard et al. 2001). In other words, those with higher/lower exposure levels of a particular risk factor are expected to have higher/lower exposure levels within the theoretical-minimum-risk exposure distribution (see the hypothetical individuals in Figure 25.1). Random (uncorrelated) draws of individuals from current and theoretical-minimum-risk exposure distributions would be inconsistent with the empirical evidence on tracking. Consistent with this evidence, we assumed that the ordering of individuals in the exposure distribution remains unchanged (i.e.
the rank-order correlation of individual exposures equals 1 ) in the transition to the theoretical-minimum-risk distribution in estimating the PAF.

With correlated rank-ordering of individuals in current and theoretical-minimum-risk exposure distributions, if hazards were a linear function of exposure, then for those risks with symmetric distributions, shifting the population to the theoretical minimum distribution would be computationally equivalent to shifting everyone to the mean exposure of the theoretical-minimum-risk exposure distribution (i.e. the standard deviation of the theoretical-minimum-risk exposure distribution would not change the total hazard). This is because, with a linear hazard function, the changes in hazards for individuals above and below the mean, as a result of changing the standard deviation of the theoretical-minimum-risk exposure distribution, would fully compensate each other.

Risk is, however, an exponential function of exposure in most epidemiological models. With an exponential hazard function, when the baseline is the mean of theoretical-minimum-risk exposure distribution, the integrated risk is larger for those above the mean than those below the mean (Figure 25.2), compared to the case of treating theoretical-minimum-risk exposure as a distribution with non-zero standard deviation. The net difference would depend on both the steepness of the risk curve (i.e. increased risk per unit increase in exposure) and the standard deviations of the current and theoretical-minimum-risk exposure distributions.

For computational reasons, we estimated PAFs for continuous risk factors relative to the mean of the theoretical-minimum-risk exposure distribution. In these calculations, the relative risk for any individual in the population with an exposure below the mean of the theoretical-minimum-risk exposure distribution was set to 1.0 (e.g. in Figures 25.1 and 25.2, the lower tail of current blood pressure distribution is inside the theoretical minimum distribution with some individuals already at a level below 115 mmHg . These individuals were assigned a relative risk of 1.0). Sensitivity analysis showed that in the scenarios analysed in the CRA project, global PAFs estimated by integrating risk relative to the mean of the theoretical-minimum-risk exposure distribution were up to $2 \%$ larger than those estimated by integrating risk relative to the full distribution. As described above, this is because of the non-linear shape of most hazard functions.

## 4. Aggregation of attributable burden across age, sex and subregion

Within each of the 14 subregions, all-age-sex population attributable fractions $\left(P A F_{\text {subregion }}\right)$ were calculated by aggregating attributable burden estimates across the 16 age-sex-specific estimates within the subregion

Figure 25.2 Effect of a non-linear hazard function and choice of baseline on total population risk

Note: With an exponential hazard function, when theoretical-minimum-risk exposure is a distribution with a non-zero standard deviation, those falling above the mean of the current distribution (e.g. 155 mmHg for SBP) contribute more to total population hazard than those below it, relative to the case when the baseline is a constant level ( 115 mmHg for SBP). In the figure, the solid lines represent the hazard when the theoretical-minimum-risk exposure is a distribution, and the dotted line when a constant baseline is considered. The difference between the two relative risks on the right $\left(R R_{2}\right)$ is larger than those on the left $\left(R R_{1}\right)$. As a result of this imbalanced contribution to hazard, using the mean of theoretical-minimum-risk exposure distribution as baseline in estimating total population hazard would result in slightly larger PAFs than using the complete theoretical minimum distribution.
and then dividing by the total subregional disease burden using the relationship in Equation 3 (the estimates could similarly be aggregated across ages separately for males and females).

$$
\begin{equation*}
P A F_{\text {subregion }}=\frac{\sum_{\text {age,sex }} A B_{\text {subregion,age,sex }}}{\sum_{\text {age,sex }} B_{\text {subregion,age,sex }}} \tag{3}
\end{equation*}
$$

Similarly, for each age-sex group, world attributable fractions ( $P A F_{\text {age,sex }}$ ) were calculated by aggregating attributable burden estimates across all the 14 subregion-specific estimates and then dividing by the disease burden for that age-sex group using the relationship in Equation 4.

$$
\begin{equation*}
P A F_{\text {age,sex }}=\frac{\sum_{\text {subregion }=1}^{14} A B_{\text {subregion,age,sex }}}{\sum_{\text {subregion }=1}^{14} B_{\text {subregion,age,sex }}} \tag{4}
\end{equation*}
$$

This is shown in Tables 25.1-25.3 for the case of SBP and ischaemic heart disease (IHD). The non-italic numbers in Table 25.1 are the sub-region-age-sex specific PAFs estimated using Equation 2. Next, these fractions were applied to the Global Burden of Disease (GBD) 2000 estimates of disease burden for IHD, shown in Table 25.2, producing the estimates of IHD disease burden attributable to SBP in Table 25.3 (similar estimates could be made for mortality or YLL). Dividing the total attributable burden in any subregion (e.g. 1.548 million DALYs for AMR-A in the highlighted cell) by the total IHD burden for the subregion in the GBD database ( 3.506 million DALYs for AMR-A in the highlighted cell) gives the all-age-sex subregional PAFs ( $44 \%$ for AMR-A in the highlighted cell, obtained by dividing 1.548 by 3.506 ).

The all-age-sex PAF estimates for the remaining 13 subregions are also shown in Table 25.1 in italics. Similarly, world PAFs were calculated within each age and sex group, as well as overall, using Equation 4, and are shown in the bottom row of Table 25.1. For example, the world PAF for $60-69$ years old males was obtained by dividing the total attributable burden in that age-sex group ( 4.71 million DALYs) by the total world IHD burden in the GBD database ( 9.015 million DALYs), giving a PAF of $52 \%$.

Computationally, aggregate PAFs (whether aggregated across age-sex groups or subregions) are equivalent to weighted averages of the subre-gion-age-sex specific estimates, with weights being the same as the total number of events (i.e. deaths, YLL, or DALYs) for each subregion-agesex group. In the above example, total subregion-age-sex specific DALYs are the weighting factor. As a result, subregion and world PAFs are weighted more towards the ages and/or subregions that have higher DALYs (rather than those with larger populations). For each risk factor, these separate aggregate PAFs were estimated for deaths, YLL, and DALYs with the corresponding GBD estimates used as the denominator (or weighting factor). As a result, even when the age-sex-subregionspecific PAFs are the same for the three measures, the aggregate ones may differ.

For example, although the subregion-age-sex-specific PAFs are the same for deaths and DALYs in the case of elevated SBP and IHD, dividing the IHD deaths attributable to this risk factor in AMR-A (203000) by the total IHD deaths in this region (618000), gives a regional PAF for mortality of $33 \%$ in AMR-A. In fact, the smaller subregional PAF for mortality compared to that of DALYs highlights the higher weighting towards the older age PAFs (which are smaller) in the case of
Table 25.I PAFs for IHD attributable to increased SBP (\%), by age, sex and subregion

Table 25.3 Burden of IHD attributable to increased SBP (000s of DALYs), by age, sex and subregion

mortality, because greater numbers of IHD deaths occur in these age groups. On the other hand, because deaths at younger ages contribute to larger loss of life (YLL), when DALYs are considered, the contribution of PAFs at younger ages to the all-age-sex PAF becomes greater.

## 5. Exceptions to the general ESTIMATION PROCEDURE

The following list briefly describes the major departures from the standard analysis framework which were required so that all risk factors could be adequately assessed within the project. Further details are provided in the individual risk factor chapters.

- Theoretical minima varied by age, sex and subregion for iron deficiency, since this was the haemoglobin distribution that would be observed if iron deficiency were eliminated from each population.
- Theoretical minima varied by age, sex and subregion for lack of contraception as a risk factor to reflect different fertility preferences across populations.
- Fruit and vegetable intakes in any population were truncated at zero. In other words, all individuals falling below zero in the distribution were allocated a value of zero. Sensitivity analyses were also performed to assess the effects of possible skewness in the distribution of fruit and vegetable intake.
- The burden of cardiovascular diseases attributable to lead exposure was estimated by assessing different scenarios of elevated blood pressure due to lead and then estimating the total mediated effect through blood pressure.

## 6. Other methodological issues

It has been shown that the attributable fraction estimates using the PIF relationship in Equation 1 lead to biased estimates when the relative risk has been adjusted for confounding (Greenland 1984; Greenland and Robins 1988). This bias is in fact a result of the correlation among multiple risks (the risk factor of interest and other risk factors that act as confounders), as well as the diseases affected by them (Ezzati et al. 2003). Accounting for this correlation in the estimation of attributable burden, however, would require the availability of exposure and disease data stratified by the confounding variable(s). In general, such stratified data are not available and therefore reliance on the formula with direct use of the adjusted relative risk estimates was necessary. In the case of positive correlation among risk factors, this would generally result in an underestimation of population attributable fraction.

## Note

1 See preface for an explanation of this term.

## Chapter 26

# Mortality and burden of disease ATTRIBUTABLE TO INDIVIDUAL 

 RISK FACTORSMajid Ezzati, Anthony Rodgers, Alan D. Lopez, Stephen Vander Hoorn and Christopher J.L. Murray

Population attributable fractions (PAFs) for mortality and burden of disease attributable to individual risk factors were calculated, as described in chapter 25 , using risk factor exposure and hazard estimates provided in risk factor chapters. Mortality and burden of disease attributable to individual risk factors were then calculated by multiplying the PAFs by the estimates of total mortality and burden of disease from the Global Burden of Disease (GBD) databases in each of the 224 subregion-age-sex groups, as described in chapter 25 . These results are presented in the Annex Tables for each risk factor and summarized here across risks.

## 1. Aggregate disease burden attributable to INDIVIDUAL RISK FACTORS

All-cause mortality and burden of disease estimates for females and males attributable to CRA risk factors in the 14 subregions ${ }^{1}$ are presented in Table 26.1. Figure 26.1 shows the contribution of the 20 leading global risk factors to mortality and burden of disease in the world and three broad combinations of subregions-demographically and economically developed (AMR-A, EUR and WPR-A), low-mortality developing (AMR-B, EMR-B, SEAR-B and WPR-B) and high-mortality developing (AFR, AMR-D, EMR-D and SEAR-D). Figure 26.2 presents the burden of disease due to the leading 10 risk factors for each subregional grouping, also showing the cause composition, divided into broad groups of diseases and injuries. The different ordering of risk factors in their contributions to mortality and disease burden reflects the age profile of mortality (e.g. under-five mortality for underweight has larger

[^111]Figure 26.1 (a) Mortality and (b) burden of disease due to leading global risk factors

응

Note: High-mortality developing: AFR, AMR-D, EMR-D and SEAR-D subregions; low-mortality developing: AMR-B, EMR-B, SEAR-B and WPR-B; developed: AMR-A, EUR and WPR-A. The figure shows the estimated mortality and disease burden for each risk factor considered individually. These risks act in part through other risks and act jointly with other risks. Consequently, the burden due to groups of risk factors will usually be less than the sum of individual risks (see chapter 27).
ぜ

contribution to disease burden) and the non-fatal effects (e.g. neuropsychological outcomes of alcohol).

Despite disaggregation into underweight and micronutrient deficiency (which are not additive; see chapter 27) and methodological changes, undernutrition has remained the single leading global cause of health loss with comparable contributions in 1990 ( 220 million DALYs, 16\%, for malnutrition) (Murray and Lopez 1997) and 2000 ( 140 million DALYs, $9.5 \%$, for underweight; $2.4 \%, 1.8 \%, 1.9 \%$ for iron, vitamin A and zinc deficiency respectively; $0.1 \%$ for iodine deficiency disorders). This is because while prevalence of underweight has decreased in most regions of the world in the past decade, it has increased in sub-Saharan Africa (de Onis et al. 2000) where its effects are disproportionately large due to simultaneous exposure to other childhood disease risk factors. A substantial part of the decrease in the burden of disease due to poor water, sanitation and hygiene (from $6.8 \%$ in 1990 to $3.7 \%$ in 2000) is due to a decline in global diarrhoeal disease mortality (from 2.9 million deaths in 1990 to 2.1 million in 2000), and partly a result of improved case management interventions, particularly oral rehydration therapy.

Leading causes of burden of disease in all high-mortality developing subregions were childhood and maternal undernutrition-including underweight ( $14.9 \%$ ) and micronutrient deficiencies ( $3.1 \%$ for iron deficiency, $3.0 \%$ for vitamin A deficiency and $3.2 \%$ for zinc deficiency)unsafe sex $(10.2 \%)$, poor water, sanitation and hygiene (5.5\%) and indoor smoke from solid fuels ( $3.6 \%$ ). The relative contribution of unsafe sex was disproportionately larger (26\%) in AFR-E, where HIV/AIDS prevalence is the highest, making it the leading cause of burden of disease in this subregion. The outcomes of these risk factors were mostly communicable, maternal, perinatal and nutritional conditions (Figure 26.2) which dominate the disease burden in high-mortality developing subregions. Despite the very large contribution of these diseases and their underlying risk factors, tobacco, blood pressure and cholesterol already resulted in significant loss of healthy life years in these subregions. For example, in SEAR-D (dominated by India in terms of population) the burden of disease attributable to tobacco, blood pressure and cholesterol was already of comparable magnitude to micronutrient deficiencies and is only marginally smaller than indoor smoke from solid fuels and poor water, sanitation and hygiene. In addition to their relative magnitude, the absolute size of the loss of healthy life years attributed to risk factors in high-mortality developing subregions was substantial. Childhood and maternal underweight and unsafe sex in these subregions alone (with $38 \%$ of global population) contributed as much ( $>200$ million DALYs) to loss of healthy life as all diseases and injuries in developed countries (with $22 \%$ of global population).

Across developed subregions, tobacco ( $12.2 \%$ ), high blood pressure ( $10.9 \%$ ), alcohol ( $9.2 \%$ ), high cholesterol ( $7.6 \%$ ) and high BMI ( $7.4 \%$ ) were consistently the leading causes of loss of healthy life, contributing
mainly to noncommunicable diseases and injuries. Tobacco was the leading cause of disease burden in all developed subregions, except EURC (dominated by Russia) where high blood pressure and alcohol resulted in slightly larger loss of healthy life. The increase in the disease burden due to blood pressure compared to 1990 (Murray and Lopez 1997) (from $3.9 \%$ in the established market economies and $5.9 \%$ in the formerly socialist economies) mainly reflects new evidence on hazard size after correction for regression dilution bias (MacMahon et al. 1990). The contributions of these risk factors are consistently larger than those of leading diseases of the developed subregions (i.e. ischaemic heart disease [ $9.4 \%$ ], unipolar depressive disorders [7.2\%], cerebrovascular disease [ $6.0 \%$ ], etc.), which emphasizes the potential health gains from reducing risk factors.

The low-mortality developing subregions present possibly the most striking mixture of leading risk factors. The leading risk factors in these subregions ( $40 \%$ of global population) include those from both developed and high-mortality developing subregions with comparable magnitudes (e.g. underweight [3.1\%] and high BMI [2.7\%] had comparable contributions to the burden of disease. See also Monteiro et al. 2002). In addition, the decline in the share of burden of disease due to the risk factors in low-mortality developing subregions was less marked than that in high-mortality developing and developed subregions (e.g. the ratio of 1st to 10 th leading risk factors was smaller). This lower clustering of risk factor burden further emphasizes the role of a more extended and mixed group of risk factors in low-mortality developing subregions. Alcohol was the leading cause of burden of disease in low-mortality developing subregions as a whole ( $6.2 \%$ ) and in AMR-B and WPR-B, but made a relatively low contribution to the burden of disease in EMRB. In general, AMR-B and EMR-B had risk factor profiles similar to the developed subregions (tobacco, blood pressure, cholesterol, BMI and alcohol), while SEAR-B and WPR-B had a more mixed risk factor profile (with the leading five risks being underweight, blood pressure, tobacco, unsafe sex and alcohol in SEAR-B; alcohol, blood pressure, tobacco, underweight and indoor smoke from solid fuels in WPR-B).

An important finding of this analysis is the key role of nutrition in health worldwide. Approximately $13 \%$ of the global disease burden can be attributed to the joint effects of childhood and maternal underweight or micronutrient deficiencies. In addition, almost as much as $7 \%(16 \%$ for those aged 30 years and above) can be attributed to risk factors that have substantial dietary determinants-high blood pressure, high cholesterol, high BMI and low fruit and vegetable intake. These patterns are not uniform within subregions, however, and in some countries the transition has been healthier than in others (Lee et al. 2000; Popkin et al. 2001). Further, the major nutritional risk factors show interregional heterogeneity (e.g. the relative contributions of blood pressure, cholesterol and BMI were different in AMR-A, SEAR-D and WPR-B). This het-
erogeneity further illustrates the importance of concurrent and comparable quantification of distal and proximal risk factors to provide a more complete picture of the role of various distal and proximal risk factors in reducing disease.

This analysis also provides the first quantitative evidence of the public health consequences of a number of risk factors including indoor smoke from solid fuels ( $2.6 \%$ of global disease burden), high BMI ( $2.3 \%$ ) and zinc deficiency $(1.9 \%)$. On the other hand, the burden of disease due to some risks (e.g. physical inactivity) was lower than expected if the methodology and results from the limited number of industrialized countries had been extrapolated (Powell and Blair 1994). This is partially because of difficulties in measuring exposure to this risk factor. A categorical exposure variable with a conservative baseline of "sufficient" (vs vigorous) activity was used. In part, it also reflects the inclusion of occupational and transportation domains of activity (that are common among rural populations of developing countries) in this analysis, above and beyond leisure-time activity which is more relevant to developed countries and urban populations (Jacobs et al. 1993; Levine et al. 2001).

## 2. Distributions of risk factor-attributable disease burden

An important feature of risk assessment, with implications for broad prevention policies and specific interventions and programmes, is the distribution of disease burden among population subgroups. These subgroups may be defined by factors such as age, sex, socioeconomic status or the current level of exposure to a risk factor, if exposures are defined in multiple categories or continuously. For example, reducing the large disease burden due to road traffic accidents among young adult males, largely associated with binge alcohol consumption, would require designing interventions that focus on this population subgroup and their specific drinking behaviours. On the other hand, the majority of effects from risk factors such as blood pressure have been found to occur among those at moderately elevated levels, suggesting the need for interventions beyond those intended for clinical hypertension (Cook et al. 1995; Murray et al. 2003; Rodgers et al. 2000). While the distribution of health effects by age and by exposure level has been studied in specific cohorts and for specific risk factors (Peto et al. 1992; Rodgers and MacMahon 1999; Rose 1992), there are no such estimates at the global level and for multiple risks.

The distributions of mortality and disease burden attributable to the risk factors included in this book by age and sex is shown in Table 26.2. The estimated disease burden from childhood and maternal undernutrition, unsafe water, sanitation and hygiene, and global climate change (much of whose estimated effects are mediated through nutritional and water variables) was almost exclusively among children aged <5 years.
The distribution of risk factor-attributable mortality and burden of disease by age and sex

| Other selected risk factors |  |  |  |  |  |  |  |  |  |  |  |  |
| Contaminated injections in health care settings | 10 | 2 | 53 | 35 | 63 | 37 | 16 | 3 | 67 | 13 | 61 | 39 |
| Child sexual abuse | 0 | 0 | 81 | 22 | 48 | 52 | 0 | 0 | 96 | 4 | 36 | 64 |

For these risks, more than $85 \%$ of the total attributable burden occurred in this age group, with the exception of iron deficiency where $30 \%$ of burden was borne by women of childbearing age. The disease burden from other diet-related risks, tobacco and occupational risks (except injuries and back pain) was almost equally distributed among adults above and below the age of 60 years. For example, $43 \%$ and $61 \%$ of disease burden due to high blood pressure and tobacco respectively, occurred from adverse events in the 15-59-year age group.

More than $90 \%$ of disease burden attributable to lack of contraception, illicit drugs, occupational ergonomic stressors and risk factors for injury and child sexual abuse occurred in adults below the age of 60 years. About three-quarters (77-80\%) of disease burden for alcohol, unsafe sex and contaminated injections in health care settings occurred between the ages of 15 and 59 years. Most of the risks whose burden is concentrated in younger adults are those with outcomes that include HIV/AIDS, maternal conditions, neuropsychiatric diseases and injuries. Moreover, with the exception of alcohol, which has a global presence, the majority of disease burden from these risks is concentrated in developing countries (Figures 26.1 and 26.2). This illustrates the large, and at times neglected disease burden from risks that affect young adults in developing countries, with important consequences for economic development.

Only a small fraction of disease burden from the risk factors considered occurred among 5-14-year olds. This was because some of the leading causes of ill-health of this age group (e.g. motor vehicle accidents and other injuries, depression) have complex causes that could not easily be included in the current risk-based framework. For other leading diseases at these ages (e.g. diarrhoea and lower respiratory infections), most epidemiological studies have focused on children aged $<5$ years and do not provide hazard estimates for older children.

The disease burden attributable to underweight and micronutrient deficiencies in children was equally distributed among males and females, but the total all-age disease burden from iron and vitamin A deficiencies was slightly greater in females due to effects on maternal conditions. Other diet-related risks, physical inactivity, environmental risks and unsafe sex contributed almost equally to disease burden in males and females. Approximately $80 \%$ of disease burden from addictive substances and $60-90 \%$ from various occupational risks occurred among men. The former reflects the social, behavioural and economic forces that have so far made addictive substances more widely used by men, especially in developing countries. The latter was partially due to the inclusion of formal employment only and partially because men tend to make up most of the workforce engaged in heavy industrial jobs and formal agriculture. Women suffered an estimated two-thirds of disease burden from childhood sexual abuse and the entire burden caused by non-use and use of ineffective methods of contraception, as defined in chapter 15.

The distributions of disease burden attributable to risk factors by exposure levels are shown in Table 26.3 for those risks quantified using categorical variables, and in Figure 26.3 for those with continuous variables. For most of these risks a substantial proportion of attributable burden occurred among those with modest elevation of risk. For example, only $35 \%$ of the disease burden from underweight, the leading global risk, occurred in severely underweight children ( $<-3$ SD from referent group median); the rest was among those in the 1-3 SD below the median range. The large majority of the burden of disease from unsafe water, sanitation and hygiene was approximately equally distributed among three of the five exposure scenarios. This reflects the fact that the exposure categories were defined as the presence of water and sanitation technology-based interventions, and during decades of water and sanitation projects, many countries have "clustered" in a limited number of technology groups. However, there is likely to be large heterogeneity of exposure within each scenario (Curtis et al. 2000).

Figure 26.3(a) shows the distribution of the estimated cardiovascular (CVD) burden of disease (in DALYs) attributable to four major continuous risk factors, by exposure levels. Half the attributable burden occurs to the left of the solid vertical line and half occurs to the right. The dashed vertical lines indicate commonly used thresholds-140 or 160 mmHg for hypertension, $6.5 \mathrm{mmol} / \mathrm{l}$ for hypercholesterolaemia, and $30 \mathrm{~kg} / \mathrm{m}^{2}$ for obesity (the cut-off for hypertension is shown at 150 mmHg , between the two commonly used values of 140 and 160 mmHg ). Figure 26.3 (b) shows the cumulative percentage of attributable burden by exposure levels. In reality, a modest rightward skew (not modelled here) of distributions would lead to slightly more events occurring in those who were hypertensive, hypercholesterolaemic or obese.

Figure 26.3 shows that a substantial proportion of the disease burden attributable to high blood pressure, cholesterol and body mass index (BMI) and inadequate fruit and vegetable intake occurred in the "midrange" exposures. For example, the 2nd and 3rd quartiles (i.e. half of attributable burden) occurred between SBP of approximately 130 and 150 mmHg , cholesterol of 5.0 and $6.1 \mathrm{mmol} / 1 \mathrm{and}$ BMI of $25-32 \mathrm{~kg} / \mathrm{m}^{2}$ and fruit and vegetable intake of $150-300 \mathrm{~g} / \mathrm{day}$. This was similar to or greater than the amount of burden occurring among individuals with risk factor levels above the commonly used (but arbitrary) thresholds of hypertension, hypercholesterolaemia and obesity, as shown in Figure 26.3.

The distribution by levels of demographic and economic development suggest that the burden of disease due to risks such as undernutrition and unsafe water, sanitation and hygiene occurred virtually entirely in the high-mortality developing subregions of the world, whereas other risks, such as tobacco, alcohol and dietary risks had global effects (Figure 26.1). Categorization based on economic and demographic development was also a key modifier of the age distribution patterns. Most notably,
Table 26.3 Distribution by exposure level of attributable burden due to selected categorical risk factors

| Risk factor | Referent category | Exposure categories |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Childhood and maternal underweight | Same fraction of children <-I SD weight-for-age as the international reference group | $<-1$ to $<-2$ SD below the international reference group median | $<-2$ to $<-3$ SD below the international reference group median | <-3 SD below the international reference group median |  |  |
| Proportion of total attributable disease burden | 0 | 0.20 | 0.46 | 0.35 |  |  |
| Physical inactivity | All having at least 2.5 hours per week of moderate-intensity activity or equivalent ( $400 \mathrm{~kJ} /$ week) | Some but less than 2.5 hours per week of moderate-intensity activity | Little or no physical activity |  |  |  |
| Proportion of total attributable disease burden | 0 | 0.49 | 0.51 |  |  |  |
| Unsafe water, sanitation and hygiene | Absence of transmission of diarrhoeal disease through water, sanitation and hygiene | Regulated water supply and full sanitation coverage, with partial treatment for sewage | Improved water supply, basic sanitation, improved access to drinking water, improved personal hygiene and water disinfected at point of use | Improved water supply and basic sanitation | Basic sanitation but no improved water supply | No improved water supply and no basic sanitation |
| Proportion of total attributable disease burden | 0 | 0 | 0.39 | 0.03 | 0.28 | 0.30 |
| Child sexual abuse | No sexual abuse | Non-contact abuse | Contact abuse | Intercourse |  |  |
| Proportion of total attributable disease burden | 0 | 0.08 | 0.44 | 0.48 |  |  |

Figure 26.3 Distribution by exposure level of cardiovascular disease (CVD) burden attributable to selected continuous risk factors

Note: For blood pressure and cholesterol, the plots represent the estimated usual levels (MacMahon et al. 1990), which tend to be closer to population means than levels based on one-off measurements commonly used in population surveys. For example, the distribution of usual blood pressure is approximately half as wide as the distribution of one-off blood pressure measures and so less people would be classified as hypertensive if classifications were based on usual rather than one-off blood pressure. Thus, with a population mean systolic blood pressure (SBP) of 134 mmHg , the SD of one-off measures might be 17 mmHg (with about $18 \%$ of the population having one-off SBP over 150 mmHg ) and the SD of usual SBP 9 mmHg (hence about $5 \%$ of the population would have usual SBP over 150 mmHg ).
disease burden due to many major risks for chronic diseases occurred in younger ages in developing regions compared to developed regions. For example, in high-mortality developing subregions, $69 \%$ of disease burden attributable to tobacco occurred in people aged 15-59 years, whereas this share was $63 \%$ for low-mortality developing subregions and $55 \%$ for developed subregions. The different age structures across major world regions, together with exposure differences, resulted in different distributions of attributable burden by region. For example, Figure 26.4 shows that disease burden attributable to elevated blood pressure, cholesterol and BMI occurred at lower levels in developing regions compared to developed regions, mainly because of lower age-specific exposure levels in those populations (see chapters 6-8).

Figure 26.4 Distribution by exposure level of attributable cardiovascular disease (CVD) burden due to selected risk factors, by age and subregional grouping (see Figure 26.3 for details)

Figure 26.4 also shows that skewness of the distribution of disease burden was not substantially different across different age groups for BMI. This is because the comparatively larger relative risk per unitBMI at younger ages (which leads to more right-hand skew) is counterbalanced by the comparatively lower BMI at younger ages (which leads to left-hand skew). This is in contrast to blood pressure, for which disease burden in younger age groups occurred at lower exposures because the age patterns of exposure and relative risk do not entirely compensate.

## 3. Sources of uncertainty

Broad sources of uncertainty in risk assessment were discussed in chapter 1 of this book. Uncertainty about disease causation (Evans 1978; Hill 1965) in practice was secondary to uncertainty about hazard size, because when causality was uncertain, estimates of hazard needed for risk assessment were also unknown or uncertain. For example, while there is uncertainty about whether climate change would increase incidence of certain diseases, or whether the relationships between occupational factors or physical inactivity and lower back pain are causal, in each case quantitative risk assessment would also require estimates of hazard magnitude. The collectivity of scientific knowledge from disciplines such as behavioural science, vector biology, physiology, biomechanics and epidemiology would confirm the possibility of a causal relationship in the above cases, but would shift the debate to hazard size. As a result, for some risk factors, only the contribution to a subset of disease outcomes could be quantified because epidemiological studies did not provide enough information for hazard quantification for all risk factor-disease pairs, even when the causal relationships were believed or suspected.

Estimates of hazard size in individual studies were as far as possible adjusted for confounding. Extrapolation of hazard from a limited number of studies to other populations on the other hand has received less attention. While the robustness of relative risk measures has been confirmed for more proximal factors in studies across populations (Eastern Stroke and Coronary Heart Disease Collaborative Research Group 1998; Horton 2000; Law et al. 1994), hazard extrapolation is an important source of uncertainty for more distal risks (e.g. child sexual abuse) or those whose effects are heterogeneous (e.g. alcohol and injuries vs alcohol and cancer).

Direct exposure data for many risk factors were limited due to difficulties both in their measurement and under-investment in risk factor surveillance, especially in developing countries. To allow maximum use of available data, such risk factors were represented using indirect or aggregate indicators (e.g. smoking impact ratio (SIR) for accumulated hazards of smoking, weight-for-age for childhood undernutrition and use of solid fuels for indoor air pollution). For some risks, multiple data sources allowed limiting the possible range of exposure estimates. For example, in the absence of alcohol surveys, total alcohol production, trade and unrecorded consumption provided upper bounds on the fraction of population that would be in the highest consumption category. Finally, some of the risk factors in this analysis were represented using continuous exposure variables (e.g. high blood pressure). Others have used categorical variables (e.g. indoor smoke from solid fuels, underweight and physical inactivity) even though the health effects occur along a continuum. This choice reflected the availability of exposure data and
hazard estimates for categories. In such cases, the contribution to disease within the categories may be under-estimated.

The findings of this work should, therefore, be considered within the context of limited available data and subject to uncertainty. This uncertainty varies across risk factors and geographical regions. Further discussion of sources and quantification of uncertainty has been provided in individual risk factor chapters.

## 4. Discussion

Despite inherent uncertainties, the quantification of the burden of disease attributable to selected risk factors illustrates that the loss of health in the world is dominated by those risk factors that affect the poorest regions and populations, such as undernutrition, poor water, sanitation and hygiene and indoor smoke from solid fuels. Coupled with these are hazards such as alcohol, tobacco, high blood pressure and high cholesterol that in the year 2000-even compared to a decade earlier (Murray and Lopez 1997)—are widespread or are estimated to have large health impacts. Nowhere is this picture more apparent than in the lowmortality developing regions, which account for $48 \%$ of global population, and are affected by both groups of risk factors.

Comparing the burden attributable to risk factors across the three groupings of countries in this work (Figures 26.1 and 26.2) provides a cross-sectional picture of a "risk factor transition" in which the relative contribution of adult or noncommunicable disease risk factors increases as childhood and communicable disease risk factors decrease with economic development. Analysis of previous development-based transitions, such as changes in inequality or environment with economic development, has demonstrated the role of policy in inducing or delaying, and shaping the dynamics of the transition (Bowman 1997). Examples in public health include rapid control of vector-borne diseases (Chitsulo et al. 2000), high maternal mortality where contraception and abortions are not accessible for non-economic reasons, and potential HIV epidemics in some developed countries (MacLehose et al. 2002). At the same time, at least some risk factor transitions are confirmed by the increasing role of hazards such as tobacco and obesity over time (Ebbeling et al. 2002; Pelletier 1998; WHO 1997). The increase in the global burden of disease due to tobacco from $2.6 \%$ in 1990 to $4.1 \%$ in 2000, while partially due to new evidence on hazard size after correction for confounding (Thun et al. 2000), mostly reflects the increased accumulated hazards, and is most noticeable in developing countries. The cross-sectional comparison demonstrates that risk factors such as alcohol and high blood pressure and cholesterol, if not increasing in absolute terms (Popkin 2002; Reddy and Yusuf 1998), are important contributors to loss of health in all regions.

The large remaining burden from childhood disease and mortality risks such as undernutrition, poor water and sanitation, and indoor smoke from solid fuels shows the continued need for developing and delivering effective interventions. At the same time, four of the five leading causes of lost healthy life affect adults (Figure 26.1). Risk factors for both adult communicable and noncommunicable diseases already make substantial contributions even in regions with low income and high infant mortality. It is imperative therefore that health programmes and policy continually reassess the appropriate balance between interventions addressing childhood disease risk factors and those that affect adult health. Dynamic and systematic policy responses can mitigate the spread of such risk factors and their more distal causes to a large extent throughout the development process, such as a healthier nutritional or environmental transitions (Arrow et al. 1995; Lee et al. 2000). Also, as illustrated by the persistence of diseases such as malaria or the large increase in the disease burden due to HIV/AIDS and its risk factors since 1990 (e.g. unsafe sex from $3.5 \%$ to $6.3 \%$ ), as well as the potential for generalized HIV/AIDS epidemics in some eastern European countries (MacLehose et al. 2002) or China (Kaufman and Jing 2002), important communicable disease risk factors also need dynamic monitoring and policy responses.

There are a number of reasons why risk factors that were not among the leading global causes of disease burden should not be neglected. Most obviously, this analysis could be expanded with other risk factors that are both prevalent and hazardous. Second, although smaller than other risks, many such risk factors make non-negligible contributions to burden of disease in specific populations. For example in WPR-B (dominated by China in terms of population), where there is considerable industrial activity based on coal, ambient air pollution and lead exposure have health effects comparable to poor water, sanitation and hygiene and some micronutrient deficiencies. Similarly, lack of contraception was among the 10 leading risk factors for female burden of disease in a number of subregions.

Some risk factors with comparatively low global disease burden are highly concentrated among sectors of society (e.g. occupational exposures among mine workers) and have implications for health inequalities. This concentration may also imply that risks can be targeted more easily. For other risk factors, such as child sexual abuse, ethical considerations may outweigh direct contributions to disease burden in policy debate. Finally, while the burden of disease due to a risk factor may be comparatively small, effective or cost-effective interventions may be available. Examples include reducing the number of unnecessary medical injections coupled with the use of sterile syringes and reduction in exposure to lead or ambient air pollution in industrialized countries in the second half of the 20th century which often also led to benefits such as energy saving.

Beyond their total magnitude, this study has also provided a picture of the distribution of risk factor-attributable disease burden by age, sex and exposure. Analysis in multiple age and exposure categories, or along a continuum of exposures, suggests that globally a considerable proportion of the disease burden attributable to many major risk factors occurred among those with only moderately raised levels, not the extremes (e.g. hypertension, obesity or severe malnutrition).

For acute exposures and outcomes, the underlying relationship is more complex. For example, while in many societies the majority of alcoholattributable injury (e.g. traffic accidents) arises among people who on average drink moderately (Kreitman 1986), these people would be at the more extreme end of the distribution in a different dimension: volume of drinking before the injury. This finding suggests that the shapes of both exposure distributions and risk relationships are important determinants of the distribution of disease burden. If exposure to risk factors is clustered or the risk relationship does not follow a linear pattern, high exposure groups may indeed play a disproportionately important role (Lemmens 2001; Skog 1999). Further implications of these findings for research, and for policies and programmes aimed at improving population health, are discussed in chapter 29.

## Chapter 27

# Potential health gains from REDUCING MULTIPLE RISK FACTORS 

Majid Ezzati, Stephen Vander Hoorn, Anthony Rodgers, Alan D. Lopez, Colin D. Mathers and Christopher J.L. Murray

## 1. Introduction

Estimates of the burden of disease attributable to selected individual risk factors were presented in chapter 26. Diseases and injuries are, however, almost always caused by multiple risk factors (Rothman 1976; Walter 1980), motivating analysis of the health benefits of simultaneous reductions in multiple risks. Estimating the joint effects of multiple distal and proximal risks is particularly important because many factors act through other, intermediate, factors (Murray and Lopez 1999; Yerushalmy and Palmer 1959), or in combination with other factors, as we described in chapter 1 of this book. For example, education, occupation and income may affect smoking, physical activity and diet, which are risk factors for cardiovascular diseases, both directly and through further layers of intermediate factors such as body mass index (BMI), blood pressure and cholesterol. Multi-causality also means that a range of interventions can be used for disease prevention, with the specific choice determined by factors such as cost, technology availability, infrastructure and preferences.

A number of works have estimated the joint effects of two or more risk factors in specific cohorts (Hirayama 1990; Neaton and Wentworth 1992; Rothman and Keller 1972; Stampfer et al. 2000; Willet 2002), or for specific groups of diseases and risks (Doll and Peto 1981; Smith et al. 1999). Innovative models and methods have also been developed to quantify the complexity of multiple risk factor effects, especially as they interact over time (Manton et al. 1993; Robins 1999). Estimating joint risk factor effects beyond specific diseases or cohorts, however, remains relatively unexplored in epidemiology and population health. Using comprehensive reviews of data on selected major risk factors in various levels of causality, this chapter is an attempt to do so.

[^112]We further used the joint effects of multiple risk factors to estimate the potential gain in healthy life expectancy (HALE) from reducing these risks. Analysis of multiple risk factors, with heterogeneous contributions to disease burden in different populations, would also allow estimating how much of the cross-population health differentials (e.g. differences in HALE) are due to the selected risk factors. By estimating gains in HALE based on causes of disease, this work also contributes in a systematic way to the continued debate on the potential limits to life expectancy (Oeppen and Vaupel 2002; Riley 2001).

## 2. Methods

### 2.1 Estimating joint population attributable fractions

Methods and data sources for estimating the burden of disease attributable to individual risk factors were described in chapter 25 . The contribution of a risk factor to disease or mortality relative to some alternative exposure scenario (i.e. population attributable fraction, PAF, defined as the proportional reduction in population disease or mortality that would occur if exposure to the risk factor were reduced to an alternative exposure scenario [Eide and Heuch 2001; Miettinen 1974]) is given by the generalized "potential impact fraction" in Equation 1.

$$
\begin{equation*}
P I F=\frac{\int_{x=0}^{m} R R(x) P(x) d x-\int_{x=0}^{m} R R(x) P^{\prime}(x) d x}{\int_{x=0}^{m} R R(x) P(x) d x} \tag{1}
\end{equation*}
$$

where
$R R(x)$ : relative risk at exposure level $x$
$P(x)$ : population distribution of exposure
$P^{\prime}(x)$ : alternative or counterfactual distribution of exposure, and $m$ : maximum exposure level
In equation $1, R R, P$, and $P^{\prime}$ may represent joint relative risks and exposure distributions for multiple risk factors (i.e. $x$ may be a vector of risk factors), with $R R$ for each risk factor estimated at the appropriate level of the remaining ones (Eide and Heuch 2001). Alternatively, for $n$ biologically independent and uncorrelated risk factors, the joint PAF is given by equation 2 (Miettinen 1974; Walter 1976). If risk factors are independent and uncorrelated, the proportion of the remaining disease which is attributed to the $i$ th additional risk factor equals $P A F_{i}$ (and hence $1-P A F_{i}$ not attributable to this factor). Therefore, the second term in the right hand side of equation 2 (i.e. the product of all
[1 - $P A F_{i}$ ] terms) is the fraction of disease not attributable to any of the $n$ risk factors. One minus this term is the fraction attributable to the combined effects of the $n$ risk factors:

$$
\begin{equation*}
P A F=1-\prod_{i=1}^{n}\left(1-P A F_{i}\right) \tag{2}
\end{equation*}
$$

where $P A F_{i}$ is the PAF of individual risk factors
Estimating the joint effects of multiple risk factors is in practice complex for several reasons. First, some of the effects of the more distal factors (e.g. physical inactivity) are mediated through intermediate factors (e.g. high BMI itself through blood pressure) (Figure 27.1). Estimating the joint effects of distal and intermediate factors requires knowledge of independent hazards of the distal ones (vs individual risk factor effects, which are based on total hazard) (Figure 27.1). Second, the hazard due to a risk factor may depend on the presence of other risk factors (effect modification) (Koopman 1981; Rothman and Greenland 1998). Third, there may be correlation between exposure to various risk factors, because they are affected by the same distal factors and policies.

Figure 27.I Mediated and direct effects

For example, undernutrition, poor water and sanitation and the use of solid fuels are more common among poor rural households in developing countries, or smokers generally have higher and more harmful patterns of alcohol consumption and worse diet than non-smokers.

While the current literature refers to scenarios 1 and 2 as biological interaction and to scenario 3 as statistical interaction (Miettinen 1974; Rothman and Greenland 1998; Rothman et al. 1980), this distinction is somewhat arbitrary and the three scenarios may occur simultaneously. For example, zinc deficiency affects mortality from diarrhoea directly as well as through lowering growth (weight-for-age) (scenario 1) (Brown et al. 2002; Zinc Investigators' Collaborative Group 1999), and may also be correlated with underweight, other micronutrient deficiencies, and poor water and sanitation (scenario 3). Similarly alcohol and smoking may not only be correlated (scenario 3), but also affect each other's hazard for some diseases (scenario 2) (Rothman and Keller 1972). Although the epidemiological literature has placed much emphasis on removing or minimizing the effects of confounding covariates, mediated and stratified hazards have received disproportionately little empirical attention. Therefore, we used reviews of extant literature and re-analysed existing cohort data to strengthen the empirical basis for considering interactions in sensitivity analyses.

In one set of estimates (referred to as the unadjusted scenario), we assumed no mediated effects or interactions among risk factors. We then included the mediated effects and interactions described above in a second scenario (referred to as the adjusted scenario).

## JOINT EFFECTS OF CARDIOVASCULAR DISEASE RISK FACTORS

Epidemiological studies on the effects of high BMI, physical inactivity, and low fruit and vegetable intake on cardiovascular disease risk have illustrated some attenuation of the effects after adjustment for intermediate factors (e.g. blood pressure or cholesterol) (Berlin and Colditz 1990; Blair et al. 2001; Eaton 1992; Gaziano et al. 1995; Jarrett et al. 1982; Jousilahti et al. 1999; Khaw and Barrett-Connor 1987; Liu et al. 2001, 2000; Manson et al. 1990, 2002; Rosengren et al. 1999; Tate et al. 1998). This attenuation confirms that some of the hazard of the more distal factors is mediated through the intermediate ones (Figure 27.1). The attenuation has varied among studies but has consistently been less that one half of the excess risk of the distal factors. We used an upper bound of $50 \%$ as the proportion of the excess risk from these risk factors mediated through intermediate factors that are themselves among the selected risks.

To include effect modification, deviations from the multiplicative model of $10 \%$ for ischaemic heart disease (IHD) and $30 \%$ for ischaemic stroke were used based on existing studies (both sub-multiplicative) (Eastern Stroke and Coronary Heart Disease Collaborative Research Group 1998; Neaton and Wentworth 1992).

## Joint effects of smoking and other risk factors

Liu et al. (1998) found that in China, the relative risks for mortality from lung and other cancers, respiratory diseases and cardiovascular diseases were approximately constant in different cities whose non-smoker mortality rates from these diseases varied by a factor of 4-10 (see Figures 4 and 6 in Liu et al. 1998). This finding has also been confirmed in studies which stratified hazards for serum cholesterol (Jee et al. 1999).

## JOINT EFFECTS OF CHILDHOOD UNDERNUTRITION FOR INFECTIOUS DISEASES

Zinc affects child growth (Brown et al. 2002) and some of its effects on infectious diseases may be mediated through growth (e.g. underweight). As no published source for these mediated effects existed, data from some of the available zinc trials (Zinc Investigators’ Collaborative Group 1999) were re-analysed and an upper bound of $50 \%$ on the proportion of zinc deficiency risk mediated through underweight was used. Vitamin A deficiency, which affects some of the same diseases as underweight and zinc deficiency, has been found not to change the hazard size for the other two risk factors based on stratified results from clinical trials and recent reviews of micronutrient deficiency literature (Christian and West Jr. 1998; Ramakrishnan and Martorell 1998; Ramakrishnan et al. 1995; West et al. 1991).

## Joint effects of undernutrition and environmental risk factors in CHILDHOOD DISEASES

Anthropometric (growth) indicators of childhood nutrition (e.g. weight-for-age) are aggregate measures of multiple factors which include nutrition (e.g. protein-energy intake) and previous infection (Pelletier et al. 1993; Scrimshaw et al. 1968; UNICEF 1990). Therefore, some of the risks for indoor smoke from solid fuels and poor water, sanitation and hygiene (which result in acute lower respiratory infections [ALRI] and diarrhoea, respectively) may be mediated through underweight. In a review of existing literature, Briend (1990) concluded that attempts to disentangle direct and mediated contributions, especially over long time periods needed to affect population-level anthropometry, have not established diarrhoea as a significant cause of underweight. Other works, however, have found evidence that infection (especially diarrhoea) could result in reduced growth and increased the prevalence of underweight (Black 1991; Guerrant et al. 1992; Lutter et al. 1989, 1992; Martorell et al. 1975a, 1975b; Stephensen 1999). To account for potential mediated effects, we chose an upper bound of $50 \%$ for the proportion of the excess risks for indoor smoke from solid fuels and for poor water, sanitation and hygiene mediated through underweight in subregions ${ }^{1}$ where underweight was a cause of disease burden.

RISK FACTOR CORRELATION
To estimate the joint effects of risk factors with a continuous exposure variable (e.g. blood pressure and cholesterol), each integral in the PIF re-
lationship may be replaced with $\int_{x_{1}=0}^{m_{1}} \int_{x_{2}=0}^{m_{2}} R R_{1}\left(x_{1}\right) R R_{2}\left(x_{2}\right) P\left(x_{1}, x_{2}\right) d x_{1} d x_{2}$,
where subscripts 1 and 2 denote the two risk factors and $P$ is the joint distribution of the two exposures. If the joint $R R$ were a linear function of exposure levels ( $x_{1}$ and $x_{2}$ ), then correlation between the two risk factors would not affect total hazard. Because individual $R R s$ are nonlinear functions of exposure (e.g. in a logistic or Cox proportional hazard model) and joint RRs are the product of such terms, positive correlation between risk factors would, in general, imply a larger PAF than zero correlation, which in turn would be larger than negative correlation (submultiplicative effect modification could result in smaller PAF even with positive correlation for some $R R$ values). Similarly, for categorical risk factors, positive correlation would in general result in larger PAF (see also Greenland 1984).

For the range of exposures and relative risks observed here, this secondary effect of risk factor correlation would be considerably smaller than the joint attributable fraction, which may be confirmed by microsimulation of exposure distributions and relative risks. This is because the PAF relationship is an increasing concave function of individual or joint $R R$ (i.e. rate of increase declines with increasing $R R$ or prevalence) (Figure 27.2). Because the risk factors considered in this analysis individually accounted for large fractions of the diseases affected by them in populations where these diseases are important components of disease burden, the joint effects approached $100 \%$ asymptotically, limiting the overestimation potential (e.g. individually, underweight accounted for $60-70 \%$ of under-five diarrhoea in AFR-D, AFR-E and SEAR-D; poor water, sanitation and hygiene for approximately $90 \%$; vitamin A deficiency for $20 \%-30 \%$; and zinc deficiency for $10-17 \%$; similarly, in various developed subregions, individually, high blood pressure accounted for 44-64\% of IHD; high cholesterol for 51-68\%; high BMI for $17-36 \%$; low fruit and vegetable intake for $19-35 \%$; and physical inactivity for 15-16\%).

### 2.2 Gains in healthy life expectancy (HALE)

The incidence of many conditions (e.g. neuropsychiatric conditions or long-term effects of injuries) may cause ill health but not death. It is therefore important to capture both fatal and non-fatal health outcomes in describing population health. Healthy life expectancy or healthadjusted life expectancy (HALE) reduces total life expectancy into equivalent years of "full health" by taking into account the distribution and severity of health states in the population (Mathers 2002). Inputs to the calculation of HALE include the period life table (or age-sex-specific

Figure 27.2 PAF relationship as a function of prevalence and relative risk

Note: PAF relationship is an increasing concave function of both prevalence (seen in the shape of each curve) and RR (seen in the declining distance between each adjacent pair of curves). As a result, for joint risk factor PAF, errors due to deviations from a simple uncorrelated multiplicative model (due to risk factor correlation or effect modification) are secondary to the joint PAF. For example, for two risk factors with $R R=2$ and $R R=3$, a multiplicative model would result in a joint $R R$ of 6 . The PAF would be approximately correct even if the true joint RR were 5 or 7 , as the PAF curves are close for these RR values. This phenomenon becomes increasingly dominant with increasing number of risk factors (i.e. the curves for $R R=I I, I 2$, and 13 are even closer than those for $R R=$ 5,6 and 7). Further, the flattening of PAF curves at high exposures limits the error due to risk factor correlation.
mortality rates) and prevalences of health states (resulting from diseases, their sequelae, and their combinations) for each country. Methods for estimating HALE have been described in detail elsewhere (Mathers et al. 2001). Unlike estimates of the burden of disease which compare current mortality and disability to a normative survivorship function (Murray and Lopez 1996), estimates of the gain in HALE account for competing risks.

The estimates in this chapter show the improvements in HALE for the year 2000, that would have been observed if exposure to the selected risk factors had been reduced to the theoretical-minimum-risk counterfactual distribution, as described in each of the risk factor chapters. In each of the 14 subregions, joint disease-specific PAFs were estimated for all diseases affected by the 20 leading global risk factors (chapter 26; see also individual risk factor chapters), for all age and sex groups.

Mortality and incidence in the counterfactual scenario are ( $1-P A F_{M}$ ) and $\left(1-P A F_{I}\right)$ times their original values where $P A F_{M}$ and $P A F_{I}$ are the PAF of mortality and incidence attributable to the joint effects of the risk
factors. The age-sex-specific mortality and age-sex-cause-specific prevalence of diseases and their sequelae were adjusted to these levels to estimate the HALE gain as a result of multiple risk factor removal. Reduction in prevalence was obtained from reduction in incidence under equilibrium conditions (Kruijshaar et al. 2002). Cause-specific estimates were necessary for non-fatal conditions because of different disability weights (Murray and Lopez 1996) but not for fatal conditions.

## 3. Results

Table 27.1 shows the individual and joint contributions of the 20 selected risk factors for the 10 leading diseases in the world and in three broad combinations of subregions-high-mortality developing ( $38 \%$ of global population), lower-mortality developing ( $40 \%$ of global population) and demographically and economically developed ( $22 \%$ of global population). ${ }^{2}$ For most diseases, the joint effects of these risk factors were substantially less than the crude sum of the individual effects (e.g. globally four separate risk factors were each responsible for $10 \%, 18 \%, 45 \%$ and $88 \%$ of diarrhoeal disease, but with a joint PAF of $92-94 \%$ ), confirming that a large number of cases are caused by the joint actions of more than one of these risk factors acting as sufficient causes (Rothman 1976), or through other factors.

Globally, large fractions of diarrhoea (92-94\%), ALRI (55-62\%), lung cancer ( $72 \%$ ), upper aerodigestive cancer ( $60 \%$ ), chronic obstructive pulmonary disease (COPD) ( $60 \%$ ), IHD ( $83-89 \%$ ) and stroke ( $70-76 \%$ ) were attributable to the joint effects of the risk factors considered here (see Willet 2002 and Stampfer et al. 2000 for consistent vascular disease examples from specific cohorts). The joint PAFs for cancers other than lung and upper aerodigestive ( $23 \%$ ), perinatal conditions ( $23 \%$ ), maternal conditions ( $42 \%$ ), and intentional ( $29 \%$ ) and unintentional ( $20 \%$ ) injuries, which have more diverse risk factors, were smaller but non-negligible. Although the fraction of total malaria burden attributable to childhood undernutrition was relatively large ( $56-59 \%$ ), this was because of the contribution of mortality at younger ages to disease burden. No adult malaria was attributed to the above risk factors because the epidemiological literature has focused on quantifying increased risk of malaria as a result of childhood undernutrition only. Finally, with the exception of alcohol and drug dependence, which were fully attributable to their specific risk factors, very small fractions or none of neuropsychiatric conditions, tuberculosis, congenital anomalies, and a number of other diseases were attributed to the risk factors considered in this book.

Figure 27.3 shows the individual and joint contributions (including overlap) of selected major risk factors to each of the following disease categories in the three subregional groups described above: I. communicable, maternal, perinatal and nutritional conditions;

## Notes for Figure 27.3

Key: High-mortality developing subregions: AFR, AMR-D, EMR-D and SEAR-D. Low-mortality developing subregions: AMR-B, EMR-B, SEAR-B and WPR-B. Developed subregions: AMR-A, EUR and WPR-A. Group I: communicable, maternal, perinatal and nutritional conditions; Group II: noncommunicable diseases; Group III: injuries; WSH, water, sanitation and hygiene; BP, blood pressure.
Note: The size of each circle shows the absolute size of the burden (in millions of DALYs). Numbers for individual risk factors show the total burden including those overlapping with the remaining factors shown in lined pattern. Note that each risk factor may also have contributions to other disease groups (e.g. indoor smoke also causes COPD, which is in Group II and alcohol also causes injuries, which are in Group III). In reality, there is a small overlap between underweight and unsafe sex since underweight children with HIV/AIDS are likely to survive for a shorter period (not estimated in this work).
II. noncommunicable diseases; III. injuries. Communicable, maternal, perinatal and nutritional conditions, and their underlying risk factors, in high-mortality developing subregions contributed disproportionately to global loss of healthy life (i.e. large Group I disease burden and large fraction (54-56\%) attributable to the selected risk factors). Noncommunicable diseases and their risk factors (54-57\% attributable to the selected risk factors) dominated the burden of disease in developed subregions, although, by comparison, this was considerably smaller than total disease burden in high-mortality developing subregions. Both disease groups and their risk factors, with intermediate levels, affected low-mortality developing subregions.

Table 27.1 and Figure 27.3 also show that the selected risk factors for each disease group exhibited heterogeneous contributions to disease burden across clusters of countries and subregions. For Group I diseases, unsafe sex had the lowest proportional contribution in low-mortality developing countries but made a very large contribution in highmortality developing countries. For Group II diseases, the relative contributions of high cholesterol and tobacco varied across the three subregional groupings, with their relative contributions reversing from one to another. Similarly, for Group III, the relative contributions of alcohol and occupational factors showed considerable heterogeneity across subregional groups.

Gains in HALE from removing these 20 selected risk factors are shown in Figure 27.4. Globally, in the year 2000, an estimated $47 \%$ of mortality and $39 \%$ of disease burden were attributable to the joint effects of 20 selected risk factors. Global HALE would increase from 56.2 to 65.5 years in the absence of these risks (adjusted scenario). The corresponding results for the unadjusted scenario were nearly identical with HALE increasing to 66.0 years.

Figure 27.4 shows that the removal of major risk factors would not only have resulted in improvements in each subregion, but also, in general, reduced the health differentials across subregions (i.e. larger gains in subregions with lower HALE) with the largest gain in health in

Figure 27.4 The joint effects of leading 20 global risk factors on HALE in year 2000, by subregion (adjusted scenario)

Note: The numbers show the fraction of the total burden of disease in each subregion attributable to the selected risk factors.

AFR-E (16.1 years) and the smallest in WPR-A (4.4 years). Important exceptions to the monotonic decreasing relationship between HALE gain and initial HALE were EUR-C and EUR-B (mainly consisting of the countries of eastern and central Europe and the former Soviet Union). In these subregions, the leading global risk factors jointly account for a disproportionately larger share of disease burden (49\% in EUR-C and $37 \%$ in EUR-B) and led to substantial loss of healthy life years (10.7 in EUR-C and 8.3 in EUR-B), emphasizing the concentration of disease burden among a few important risk factors (alcohol, tobacco, high blood pressure and high cholesterol) in these two subregions.

## 4. Discussion

The estimates of the joint contributions of 20 selected leading global risk factors showed that these risks together were responsible for a considerable loss of healthy life in different regions of the world. In particular, for some of the leading global diseases (e.g. ALRI, diarrhoea, lung cancer, IHD and stroke), substantial proportions were attributable to these selected risk factors. Removing these 20 risk factors would not only have resulted in a 9.3 -year ( $17 \%$ ) gain in global HALE, but also would have
accounted for some of the interregional HALE differences. In fact, the analysis showed that even populations with currently high HALE (e.g. developed regions of the western Pacific and Europe) could further benefit from risk reduction. These results provide a guide to the potential gains in (healthy) life expectancy (estimated statistically from past trends [Oeppen and Vaupel 2002; Riley 2001]) through disease prevention by reducing known risks. Similar analyses for the leading 10 selected global risks suggest a gain of 8.1 years in HALE (vs 9.3 years for the leading 20). This concentration of disease burden further emphasizes the contribution of leading risks such as undernutrition, unsafe sex, high blood pressure, tobacco and alcohol to global loss of healthy life.

At the same time, the estimated joint contributions of these risk factors left an important part of the global disease burden unexplained and did not fully explain interregional HALE differentials. This was because only a small fraction of some important diseases was attributable to the selected risk factors considered here. These include diseases whose determinants: i) are diffuse among environmental and behavioural factors (e.g. some cancers, perinatal conditions, and neuropsychiatric diseases) (see Doll and Peto 1981 for examples from cancers); ii) have more complex, multi-factor etiology and often heterogeneous determinants in different populations and therefore difficult to quantify without data at very small scale (e.g. tuberculosis and injuries); iii) involve long delays; or iv) have limited quantitative research at the population level (e.g. neuropsychiatric diseases), often as a result of the above three factors as well as difficulties in measuring exposure or outcome (Evans 1978). Mitigation of many such diseases (e.g. malaria, tuberculosis or injuries) may be better guided by analyses of the effects of interventions tailored to individual settings than by risk factor analysis.

The results of this analysis changed little with plausible assumptions about mediated risks or effect modification among risk factors. An important reason for this is the concave shape of the PAF relationship (Figure 27.2). Because risk factors considered in the analysis individually accounted for large fractions of the diseases affected by them (e.g. diarrhoea and IHD), the joint affects approached $100 \%$ asymptotically limiting the sensitivity of results to assumptions about interaction. We emphasize that this does not include the considerably larger uncertainty in each of the individual PAF estimates discussed in detail in chapters 1 and 26 of this book. At the same time, since for many of the important causes of global disease burden (e.g. childhood infectious and vascular diseases), multiple important risk factors were included, the joint effects would likely remain large regardless of uncertainties in the individual PAF.

An additional important source of uncertainty, affecting both individual and joint risk factor estimates, is the concentration of both risks and diseases in specific subgroups (vs correlations of risks alone, discussed above). For many risk factors and diseases, exposure and outcome
are simultaneously higher in some groups (e.g. higher malnutrition, unsafe water, sanitation and hygiene, and indoor smoke in poor rural households in developing countries; unhealthy diet, and higher smoking and BMI in some groups in developed countries). In these circumstances, PAFs based on population averages would in general underestimate the effects compared to group-specific analysis, even if the relative risks are constant across groups (Greenland 1984) (also confirmed by microsimulation). Higher concentration of disease and mortality (e.g. childhood mortality and vascular diseases) in the same groups due to factors such as limited access to health services would magnify this effect, becoming an important contributor to underestimation of the benefits of risk reduction when population level exposure and mortality data are used. In addition to risk factor analysis, estimates of HALE include large uncertainty, especially in countries with poor mortality and disease registration systems as estimated and discussed elsewhere (Mathers et al. 2001). Further implications of these findings for research, and for policies and programmes aimed at improving population health, are discussed in chapter 29.

## Chapter 28

# Effects of multiple interventions 

James Robins, Miguel Hernan and Uwe Siebert

## 1. Introduction

The purpose of this chapter is (i) to describe some currently available analytical methods for using individual level epidemiological data to estimate the impact of multiple risk factor interventions on health and (ii) to carefully review the conditions under which these methods deliver unbiased estimates of impact. The chapter is organized as follows. In sections 2 and 3, we discuss estimation of effects of short-term, timeindependent interventions. Specifically, we discuss estimating the effect of a single risk factor intervention on life expectancy or quality-adjusted life expectancy over a specified period of follow-up in a single population, when essentially ideal epidemiological data are available. That is, we assume a random sample of the population is randomly assigned to different levels of the risk factor and followed prospectively for a fixed time period. Second, we consider the same study design, except now we are interested in the joint effect of interventions on several risk factors. Third, we consider the problem of extrapolation of the results to longer periods of follow-up and to other populations for which no primary epidemiological data are available. Sections 2 and 3 serve to indicate the possibilities and limitations of even ideal epidemiological data for estimating the effects of multiple time-independent risk factor interventions. In sections 4 and 5 we turn to the main topic of this chapter: the estimation of the effect of multiple time-dependent interventions from observational data, possibly plagued by confounding, selection bias, measurement error, information bias and ill-defined interventions. In sections 6 to 8 , we illustrate our methods by attempting to estimate the effects of various time-varying interventions on subjects entered in the Framingham Offspring cohort study. Finally, in section 9 we offer some conclusions.

## 2. Time-independent interventions

### 2.1 An ideal intervention

We suppose we have data from a randomized trial of the effect of a onetime short-term intervention (say, an anti-smoking intervention involving one week of intense study of literature on the health consequences of smoking) initiated at calendar time, say 1983. We suppose the subjects in the trial constitute a random sample of the population of a given country, say the United States of America, and these subjects are followed for twenty years. Let $S_{0}(t)$ and $S_{1}(t)$ be the survival curves of the exposed and unexposed respectively at $t$ years from the beginning of the trial for $t \leq 20$ years. Thus $S_{0}(t)$ and $S_{1}(t)$ are both equal to one at time $t=0$ and decrease as $t$ increases. Suppose there is no sharing of information in the sense subjects who receive the anti-smoking intervention do not pass on (i.e. infect or contaminate) others in the trial or in the general population with their acquired knowledge. Then it is well known that the area between the survival curves is equal to the expected years of life saved over the first twenty years of the trial due to the intervention. If we are interested in quality-adjusted years of life lost, we use subject-yearspecific health and interview data to associate with each year a subject lives a quality measure (taking values between 0 and 1 where 1 indicates optimal quality) and compare expected quality-adjusted years of life lost.

### 2.2 MUlTiple ideal interventions

Turn now to estimating the effect of simultaneous interventions on $k$ time-independent risk factors $A=\left(A_{1}, \ldots, A_{k}\right)$, such as smoking, alcohol, blood pressure, cholesterol, etc., where for the moment we assume all interventions were randomly assigned at the same moment in time and only once. Here $A$ is the $k$-vector of all risk factors. Each risk factor $A_{m}$ has some number $\left|A_{m}\right|$ of possible levels $a_{m 1}, \ldots, a_{m\left|A_{m}\right|}$. Then $A$ has $|A|=\left|A_{1}\right| \times\left|A_{2}\right| \times \ldots \times\left|A_{k}\right|$ possible joint levels. Let the set $\mathcal{A}=$ $\{a\}$ of size $|A|$ denote the set of possible values $a$ of the vector $A$. Let $S_{a}(t)$ be the survival curve for the random sample of subjects assigned to joint level $a$ of the various risk factors. Let $S(t)$ denote the survival curve for a random subset of the population on which no interventions were made. Then the expected years of life gained by intervening and setting each subject's level of the $k$ risk factors to $a$ compared to no intervention is precisely the area between the survival curves $S_{a}(t)$ and $S(t)$. The optimal intervention $a^{*}$ is the value of $a$ for which the area under $S_{a}(t)$ is largest. Further, the loss in life expectancy under intervention a compared to the optimal is simply the difference in area under $S_{a^{*}}(t)$ and $S_{a}(t)$. In principle, we need make no assumptions concerning necessary and sufficient causes, multiplicative or additive interactions, or the fraction of deaths attributable to any particular cause to order the health benefits of various joint interventions on life expectancy from such ideal
epidemiological data. All we need is a way to accurately estimate $S_{a}(t)$ for each joint intervention $a$ in $\mathcal{A}$. Due to random sampling variability, in order to obtain reliable estimates of each of the $|A|$ curves $S_{a}(t)$ would require an inconceivably large randomized trial if $|A|$ was at all large, since a large number of subjects would need to be randomly assigned to each of the $|A|$ possible levels of $A$. In practice such large trials are infeasible. As a consequence, we can randomize subjects to only a subset of the possible interventions. In that case we would need to make modelling assumptions as to the nature of the interactions between the risk factors on survival (e.g. by assuming no interaction between risk factors on the mortality rate on a particular scale such as multiplicative or additive) both in order to obtain estimates of the $S_{a}(t)$ that are not too variable and to extrapolate to values of $a$ outside the range of the data (i.e. to values of $a$ to which no one was randomized). In the final analysis it is the area under the curves $S_{a}(t)$ that remains of interest. If our models are misspecified (e.g. we assume no interaction on an additive scale when in fact such interaction is present), the resulting estimates of $S_{a}(t)$ will be biased. Thus we would like to avoid use of models as much as possible. However the use of models cannot be done away with because of our inability to conduct a sufficiently large study.

In the randomized experiment of the previous paragraph, we can also estimate the effects of conditional (or dynamic) interventions. Let $L=$ $\left(L^{(1)}, \ldots L^{(p)}\right)$ denote a $p$-vector of measured baseline (pretreatment) covariates such as age, sex and measures of baseline health status. Let $d(l)$ be a function that assigns to each value of the vector $L$ a value of $a$ in the set $\mathcal{A}$ of possible joint risk factor interventions. If a regime $d$ assigns the same value $a$ to each $L$, we refer to the regime $d$ as nondynamic. Otherwise, we refer to $d$ as a conditional or dynamic treatment regime, strategy or plan as it individualizes the treatment (i.e. joint risk factor intervention) a subject receives based on the subject's value of $L$. A wise choice of $d$ should allow us to optimize therapy for individuals and thus should be a better strategy than even the optimal non-dynamic intervention $a^{*}$ discussed above. Let $S_{d}(t)$ be the survival curve that would result if we randomly assigned individuals to plan $d$. For subjects with a given value $l$ of $L$, the conditional survival curve $S_{d}(t \mid L=l)$ given $L=l$ under regime $d$ equals $S_{a}(t \mid L=l)$ for the value $a=d(l)$ that they receive under the plan. Thus for the population as a whole $S_{d}(t)=\Sigma_{l} S_{a}(t \mid L=l) \operatorname{pr}(L=l)$ is weighted average of $S_{a}(t \mid L=l)$ with $a=d(l)$ and weights proportional to the fraction $\operatorname{pr}(L=l)$ of the population with $L=l$. Thus the survival curve $S_{d}(t)$ of a dynamic regime can be estimated from the data in the randomized trial wherein each subject is randomized to a non-dynamic regime. Define $d_{o p}(l)$ to be the treatment plan that minimizes the area under $S_{d}(t)$ over all possible dynamic and nondynamic treatment plans $d$. The loss in life expectancy under intervention $d$ compared to the optimal is the difference in area under $\mathrm{S}_{d_{o p}}(t)$ and $S_{d}(t)$. In an ideal world, we would estimate $d_{o p}(l)$ from a large ideal
randomized study and, after analysing the trial, treat a new individual with $L=l$ with treatments $d_{o p}(l)$.

## 3. Some limits of ideal data

In this section, we return to the simple randomized trial of section 2.1.

### 3.1 Extrapolation

Although we have a precise estimate of the effect of this intervention on twenty year mortality of United States citizens in the calendar period 1983-2003, the trial provides no direct evidence concerning the following more relevant policy questions. What would be the continuing effect of this intervention on the United States population through 2013 or 2023? What would be the effect of this same intervention, if it began now in 2003 rather than in 1983? What would be the effect of a similar intervention on a population that differs from the United States population on both measured and unmeasured determinants of mortality including smoking, age, cholesterol, high blood pressure, lifestyle pattern, access to state-of-the-art health care, etc? Obviously any of these questions can only be addressed by assuming a model that extrapolates beyond the observed data. A common simple approach to extrapolation is to first statistically test from the available data whether the relative risk (equivalently, mortality ratio, hazard ratio, rate ratio) in the exposed compared to the non-exposed remains nearly constant both over the 20 years of follow-up and within levels of measured covariates such as age, ethnicity, socioeconomic status and smoking. If the test accepts the constant relative risk hypothesis then we extrapolate by assuming the same will be true if follow-up was continued past 2003, if the intervention was in 2003, and if the intervention was applied to a population with different smoking and risk factor distribution than the United States. In most studies, however, the power to detect deviations from a constant rate ratio is fairly small and there is rarely any strong biological reason to believe that rate ratios rather than other effect measures (such as rate differences) should be constant over time and location. Further, we have no way to test whether the effect of an intervention on a rate ratio scale is the same across groups that differ in unmeasured factors. Finally, even if we assume the relative risk to be constant, nevertheless, to estimate the effect of intervention on life expectancy, we still require a method to estimate covariate-calendar yearspecific baseline rates in various populations in future years, since the effect on life expectancy depends both on the relative risk and on these baseline rates.

### 3.2 Contamination

In the discussion so far, we have assumed that the exposed do not "infect" or "contaminate" the unexposed with their exposure. This
assumption would not hold if subjects given, say, the aforementioned anti-smoking intervention distribute their anti-smoking materials to the control group. In that case, the beneficial effect of the intervention will be underestimated by the difference in the exposed and unexposed survival curves because a number of the unexposed will actually have been exposed. The difficulty is that the trial suffered from noncompliance in the sense that, contrary to our wishes, some of those assigned to no treatment actually received treatment. Certain analytic methods, referred to as instrumental variable methods, can partially adjust for this type of noncompliance if a randomly selected (possibly stratified) subsample of the trial population is interviewed to determine how much treatment they received as measured, say, by the fraction of the anti-smoking articles provided to the treatment group the controls actually read. This approach to correction for noncompliance is useful when the mechanism by which treatment exerts its effects is directly through access to the anti-smoking materials (Robins and Greenland 1996).

However, there are types of contamination that operate in quite different ways. For example, suppose that an effect of the treatment was that one of the treated subjects became so motivated that she started a public health campaign that resulted in the legal prohibition of smoking in public, leading to additional decreases in the cigarette consumption in both the exposed and unexposed. Then the difference in the treatmentarm specific survival curves would underestimate the total effect of the intervention (which should include the indirect effect through the legal prohibition) and correction by instrumental variable methods would not be possible. In this case a different design would be necessary. For example, one could use a cluster randomization design wherein different cities, counties or states are the experimental units and are randomly assigned as a whole to either treatment or control. The goal of the design is to have the experimental units sufficiently isolated from one another that one can be reasonably certain that between-unit contamination of treatment will not occur. If data from an appropriate cluster randomized design are not available, other different, and less reliable approaches to estimating the effect of the intervention on life expectancy must be used. Examples of such approaches include the following: (i) assume death rates would have remained unchanged had the intervention not occurred; (ii) specify and fit complex stochastic models for the mechanism by which the intervention reduced deaths, say, by assuming any decrease in the population exposure to cigarettes was wholly due to the intervention and modelling the effect on mortality of the observed decrease in smoking based on past or current data on changes in smoking and mortality; and (iii) create the observational equivalent of a cluster randomized design by assuming mortality and/or smoking data from other communities can be used to estimate what would have happened in the study population had no intervention taken place. A well known example of the type of contamination we are considering in this paragraph occurs in random-
ized trials studying the effect of vaccines on infectious disease and is the basis for the so-called phenomenon of "herd immunity" wherein an epidemic can be prevented in the unvaccinated (untreated) by vaccinating a sufficiently large fraction of the entire community.

The considerable difficulties caused by contamination and the need for extrapolation will not be considered further in this chapter due to space limitations and to the fact that the main goal of this chapter lies elsewhere. Manton et al. (1992) describe some models that may be used for extrapolation. We now turn to observational settings in which ideal epidemiologic data with which to estimate the effect of various treatments or risk factors even on the population under study may not be available.

## 4. Observational data and time-Independent and time-dependent interventions

For financial, ethical or logistical reasons, randomized trial evidence concerning the effectiveness of many if not most interventions is lacking and data from observational studies must be utilized. In this section we will use a hypothetical observational study of the effect of antiretroviral therapy on the progression of HIV-related disease as a specific example. It is well understood that causal effects can be estimated from observational studies only when data on all relevant time-independent and timedependent confounding factors have been obtained. What is less well known is that for time-varying treatments, standard approaches to confounder control can be biased, even when the causal null hypothesis of no treatment effect is true and there are no unmeasured confounding factors. Specifically, the standard approach to the estimation of the causal effect of a time-varying treatment on survival has been to model the hazard of failure at $t$ as a function of treatment history with a timedependent proportional hazards model. Robins et al. (1986) have shown that, even in the absence of unmeasured confounding factors or model misspecification, the usual approach may be biased even under the causal null hypothesis, whether or not one further adjusts for the past history of measured covariates in the analysis, when (i) there exists a timedependent risk factor (say CD4 lymphocyte count and/or Pneumocystis carinii pneumonia [PCP] history) for survival that also predicts subsequent treatment, and (ii) past treatment history predicts subsequent risk factor level. Specifically, condition (i) implies that the analysis that does not adjust for covariates is biased due to confounding by time-dependent risk factors such as CD4 count and/or PCP. Condition (ii) implies that the analysis that includes current CD4 count and/or PCP history as a regressor is biased since it adjusts for a variable (CD4 count and/or PCP history) affected by past treatment. In contrast to standard methods, estimation methods based on marginal structural models (MSMs), the parametric g-computation formula, and structural nested models provide
consistent estimates of causal effects whenever unmeasured confounding and model misspecification are absent (see the article, discussion and rejoinder in Robins et al. 1999, for additional details). To describe difficulties with standard approaches and the basis for the effectiveness of these three alternatives, it will be useful to informally introduce causal directed acyclic graphs (DAGs) as discussed by Spirtes et al. (1993), Pearl (1995), and Greenland et al. (1999).

A causal graph is a DAG in which the vertices (nodes) of the graph represent variables, the directed edges (arrows) represent direct causal relations between variables, and there are no directed cycles, since no variable can cause itself. For a DAG to be causal, the variables represented on the graph must include the variables and additional unmeasured variables, such that if any two measured variables on the graph have a cause in common, that common cause is itself included as a variable on the graph.

A variable is a cause of a second variable if there is a directed path from the first variable to the second consisting solely of arrows pointing towards the second variable. As an example consider a follow-up study of AIDS patients. Let $A(t)=A_{t}$ be the dose of the treatment or exposure of interest, say an antitetroviral therapy, at $t$ with time measured in months since start of follow-up. The time $t$ at which a treatment occurs will either be placed in parentheses or subscripted, depending on the context. Let $Y$ be a dichotomous outcome of interest (e.g. $Y=1$ if HIV RNA is not detectable in the blood and is 0 otherwise) measured at end of follow-up at time $K+1$. Our goal is to estimate the causal effect of the time-dependent treatment $A(t)$ on the outcome $Y$.

Figure 28.1 is a causal graph that represents our study with $K=1$. In Figure 28.1, $L(t)=L_{t}$ represents the value at time $t$ of the vector of all measured causal risk factors for the outcome, such as CD4 count, white blood count (WBC), red blood count (RBC), the presence or absence of various opportunistic infections such as PCP, age and weight. We assume that $L(t)$ is temporally prior to $A(t)$ since physicians commonly obtained data recorded in $L(t)$ such as CD4 count before deciding on a treatment $A(t)$ to be given in month $t$. Similarly, $U(t)=U_{t}$ represents the value at time $t$ of all unmeasured causal risk factors for Y. Figure 28.1(b) differs from Figure 28.1(a) only in that the arrows from the unmeasured risk factors into the treatment variables have been removed. When, as in Figure 28.1(b), there are no arrows from unmeasured risk factors directly into treatment variables, we say that there are no unmeasured confounders given data on the measured confounders $L(t)$. Figure 28.1(c) differs from Figures 28.1(a) and 28.1(b) in that none of the causal risk factors for $Y$ (measured or unmeasured) has arrows into any treatment variable. Note, however, that earlier treatment $A(0)$ can causally affect later treatment $A(1)$. When, as in Figure 28.1(c), there are no arrows from any (non-treatment) risk factor into any treatment variable, there

Figure 28.I Causal graphs for a time-dependent exposure
(a)

(b)

(c)

is no confounding by either measured or unmeasured factors, in which case we say that treatment is unconfounded or, equivalently, causally exogenous.

The distinctions drawn above apply equally to more familiar point treatment studies where the treatment is not time-dependent. As indicated in Figure 28.2, a point treatment study is a special case of the general set-up in which $K=0$. Figures 28.2(a)-28.2(c) are the analogues of Figures 28.1(a)-28.1(c) for a point treatment study.

Our causal DAGs would be of no use without an assumption linking the causal structure represented by the DAG to the statistical data obtained in an epidemiological study. Recall that if a set of variables $X$ is statistically independent of (i.e. unassociated with) another set of

Figure 28.2 Causal graphs for a point exposure $A_{0}$
(a)

(b)

(c)

variables $Y$ conditional on a third set of variables $Z$, then within joint strata defined by the variables in $Z$, any variable in $X$ is unassociated with any variable in $Y$. For example, suppose all variables are dichotomous and the set $Z$ consists of the two variables $Z_{1}$ and $Z_{2}$. Then conditional independence implies that the population odds ratio and population risk ratio between any variable in $X$ and any variable in $Y$ is 1 within each of the $4=2^{2}$ strata of $Z:\left(Z_{1}, Z_{2}\right)=(0,0),\left(Z_{1}, Z_{2}\right)=(0$, 1), $\left(Z_{1}, Z_{2}\right)=(1,0)$ and $\left(Z_{1}, Z_{2}\right)=(1,1)$. We use the symbol $\amalg$ to indicate statistical independence, e.g. $X \amalg Y \mid Z$ means $X$ is conditionally independent of $Y$ given $Z$. The following so-called causal Markov assumption links the causal structure of the DAG with the various statistical independencies.

### 4.1 Causal Markov assumption (CMA)

On a causal graph any variable that is not caused by a given variable $V$ will be independent of (i.e. unassociated with) $V$ conditional on (i.e. within joint strata defined by) V's direct causes. Thus, in Figure 28.1(c), $A(t)$ being causally exogenous implies that $A(0) \coprod L(0), U(0)$ and $A(1) \coprod\{L(0), L(1), U(0), U(1)\} \mid A(0)$.

As in any observational study, we cannot determine from the observed data whether there is confounding by unmeasured risk factors. We can only hope that whatever residual confounding there may be due to the $U_{1}<y$ is small. However, as discussed further below, under the untestable assumption that there is no unmeasured confounding given the $L_{k}$, we
can empirically test from the data whether treatment is causally exogenous. Specifically, a sufficient condition for treatment to be unconfounded is that, at each time $k$, among subjects with the same past treatment history $A_{0}, \ldots, A_{k-1}$, the treatment $A_{k}$ is unassociated with (i.e. statistically independent of) the past history of measured covariates $L_{0}, \ldots, L_{k}$. In particular, in our point treatment study, treatment will be causally exogenous if $A_{0}$ is unassociated with $L_{0}$.

### 4.2 Inverse probability of treatment weighted estimation

In this section, our goal is to estimate using MSMs the causal effect of the time-dependent treatment $A(t)$ on the mean of $Y$, which for a dichotomous $(0,1)$ response is just the probability that $Y=1$. In this section, we assume that there is no loss to follow-up so $Y$ is observed on each study subject. For any time-dependent variable we use overbars to denote the history of that variable up to and including $t$. For example, $\bar{L}(t)=$ $[L(0), L(1), L(2), \ldots, L(t)]$ is the covariate process through $t$. Consider first the association (i.e. regression) model that states that the mean of Y, given treatment history $\bar{A} \equiv \bar{A}(K)$, is a linear logistic function of a subject's duration of antiretroviral therapy. That is,

$$
E[Y \mid \bar{A}]=g(\bar{A} ; \gamma)
$$

where

$$
\begin{equation*}
g(\bar{A} ; \gamma)=\frac{\exp \left[\gamma_{0}+\gamma_{1} \operatorname{Dur}(\bar{A})\right]}{1+\exp \left[\gamma_{0}+\gamma_{1} \operatorname{Dur}(\bar{A})\right]} \tag{1}
\end{equation*}
$$

$\operatorname{Dur}(\bar{A})=\sum_{k=0}^{K} A(k)$ is the subject's duration of treatment in months, and $A(k)$ equals 1 if the subject is on treatment in month $k$ and is 0 otherwise. That is, we are assuming a linear logistic regression model

$$
\begin{equation*}
\text { logit } \operatorname{pr}(Y=1 \mid \bar{A})=\gamma_{0}+\gamma_{1} \operatorname{Dur}(\bar{A}) \tag{2}
\end{equation*}
$$

The logistic regression maximum likelihood estimator (MLE) of $\gamma=\left(\gamma_{0}\right.$, $\gamma_{1}$ ) that is computed by all standard packages maximizes $\prod_{i=1}^{n} L i k_{i}(\gamma)$ with $\operatorname{Lik}_{i}(\gamma)=g\left(\bar{A}_{i} ; \gamma\right)^{\gamma_{i}}\left[1-g\left(\bar{A}_{i} ; \gamma\right)\right]^{1-\gamma_{i}}$ being the likelihood contribution for a single subject and $n$ the sample size.

Assuming the association model (1) is correct, when does $\gamma_{1}$ and $\gamma_{2}$ have a causal interpretation? To answer this question, imagine that the decision to administer treatment at each time $t$ was made totally at random by the treating physician. In that hypothetical randomized trial, treatment at time $t$ is not expected to be associated with the history up
to $t$ of any measured or unmeasured prognostic factors (i.e. there is no confounding). In the absence of confounding, association implies causation and we would expect $\gamma_{1}$ to represent the effect of antiretroviral therapy on the mean of Y. More generally, the marginal association between treatment and response represents causation whenever the treatment is causally exogenous, that is, the conditional probability of receiving a treatment $A(t)$ at time $t$ given past treatment and prognostic factor history for $Y$ (measured and unmeasured) depends only on past history of treatment $\bar{A}(t-1)$ as in Figures 28.1(c) and 28.2(c). A more technical definition is provided below after we define counterfactual outcomes. It is well-recognized in the social sciences, econometrics, epidemiological, and biostatistical literature that the treatment parameters of a correctly specified association model will have a causal interpretation if treatment is causally exogenous.

To help assess whether antiretroviral therapy may be causally exogenous, we introduce the concept of "statistical exogeneity". We say that treatment $A(t)$ is a "statistically exogenous or ancillary" process if the probability of receiving treatment at time $t$ does not depend on the history of measured time-dependent prognostic factors up to $t$, conditional on treatment history prior to $t$, i.e.

$$
\bar{L}(t) \mathrm{C} A(t) \mid \bar{A}(t-1)
$$

Note that a nearly necessary condition for $A(t)$ to be "causally exogenous" is for it to be "statistically exogenous". However, that a process is "statistically exogenous" does not imply it is "causally exogenous", because there may be unmeasured prognostic factors $\bar{U}(t)$ for the outcome (i.e. confounders) that predict the probability of treatment $A(t)$ at time $t$ given past treatment history. Thus we can test from the data whether $A(t)$ is statistically exogenous as it is a relationship between observed variables, but are unable to test whether a statistically exogenous process is causally exogenous. However, as mentioned above and discussed further below, if we make the untestable assumption that there are no unmeasured confounders, then statistical exogeneity will imply causal exogeneity.

Suppose $A(t)$ is discrete and we can correctly model both the probability $f[a(t) \mid \bar{l}(t), \bar{a}(t-1)]$ of taking treatment $a(t)$ on day $t$ as a function
of past treatment $\bar{a}(t-1)$ and measured prognostic factor history $\bar{l}(t)$, and the probability $f[a(t) \mid \bar{a}(t-1)]$ of taking treatment $a(t)$ in month $t$ as a function only of past treatment $\bar{a}(t-1)$ history. Here we use the convention that random variables (i.e. variables whose values can differ from subject to subject) are denoted by upper case letters. Lower case letters denote possible values of the corresponding random variables. Thus, for example, $f[a(t) \mid \bar{a}(t-1)]$ is the proportion of subjects in the target population with treatment $A(t)$ equal to $a(t)$ among subjects with past treat-
ment history $\bar{A}(t-1)$ equal to $\bar{a}(t-1)$. We could measure the degree to which the treatment process is statistically non-exogenous through time $t$ by the time $t$-specific random variable

$$
\begin{equation*}
S W(t)=\prod_{k=0}^{t} \frac{f[A(k) \mid \bar{A}(k-1)]}{f[A(k) \mid \bar{A}(k-1), \bar{L}(k)]} \tag{3}
\end{equation*}
$$

where $\prod_{k=0}^{t} z(k)$ is the product $z(0) \times z(1) \times \ldots \times z(t), f[A(k) \| \bar{A}(k-1)$, $\bar{L}(k)]$ is, by definition, the conditional probability mass function $f[a(k) \mid \bar{a}(k-1), \bar{l}(k)]$ with $(a(k), \bar{a}(k-1), \bar{l}(k))$ evaluated at a subject's data $(A(k), \bar{A}(k-1), \bar{L}(k))$ and $f[A(k) \mid \bar{A}(k-1)]$.

For example, if for a given subject $A(k)$ is zero and there are 55 other subjects with the same $\bar{A}(k-1), \bar{L}(k)$ history of whom 25 have $A(k)$ of zero and 70 subjects with the same $\bar{A}(k-1)$ history of whom 32 have $A(k)$ of zero, then $f[A(k) \mid \bar{A}(k-1), \bar{L}(k)]$ is $20 / 55$ and $f[A(k) \mid \bar{A}(k-1)]$ is $32 / 70$ for the subject. Informally, the denominator in each term in $S W(t)$ is the probability that a subject received his own observed treatment, $A(k)$, at time $k$ given his past antiretroviral treatment and measured prognostic factor history. Informally, the numerator is the probability that a subject received his observed treatment conditional on his past antiretroviral treatment history, but not further adjusting for his past prognostic factor history. Note that the numerator and denominator of $S W(t)$ are equal for all $t$ with probability 1 if and only if the treatment process is statistically exogenous, i.e. $\bar{L}(t) \amalg A(t) \mid \bar{A}(t-1)$. In practice $S W(t)$ will have to be estimated from the data but, for pedagogical purposes, assume for now that it is known.

When $A(t)$ is statistically non-exogenous, we shall consider estimating $\gamma$ by a weighted logistic regression in which a subject is given the weight $S W \equiv S W(K)$. Standard software packages for logistic regression will allow the user to specify the subject-specific weight $S W$. The weighted logistic regression estimator, which we will refer to as an inverse-probability-of-treatment-weighted (IPTW) estimator, is the maximizer of $\prod_{i=0}^{n}\left[L i k_{i}(\gamma)\right]^{s W_{i}}$. This weighted logistic regression would agree with the usual unweighted analysis described above just in the case in which $A(t)$ were statistically exogenous. The IPTW estimator is an extension to longitudinal causal inference models of estimators proposed by Horvitz and Thompson (1952).

If the vector of prognostic factors recorded in $\bar{L}(t)$ constitutes all relevant time-dependent prognostic factors (i.e. confounders) so that there are no unmeasured confounders (as in Figures 28.1(b) or 28.2(b)), then,
whether or not the treatment process is statistically exogenous, the weighted logistic regression estimator of $\gamma_{1}$ will converge to a quantity $\beta_{1}$ that can be interpreted as the causal effect of antiretroviral therapy on the mean of $Y$ (on the log odds ratio scale). In contrast, when $A(t)$ is statistically non exogenous, the usual unweighted logistic regression estimator will still converge to $\gamma_{1}$, but now $\gamma_{1}$ will have no causal interpretation. We now give a formal mathematical meaning to the informal concepts of the causal effect of antiretroviral therapy on the mean of $Y$.

### 4.3 COUNTERFACTUALS AND MARGINAL STRUCTURAL MODELS

To formalize our results, we use counterfactual or potential outcomes. Neyman (1923) introduced counterfactual outcomes to analyse the causal effect of time-independent treatments in randomized experiments. Rubin (1978) championed Neyman's idea and emphasized the usefulness of counterfactuals in the analysis of the causal effects of timeindependent treatments from observational data. Robins (1986, 1987) proposed a formal counterfactual theory of causal inference that extended Neyman's (1923) time-independent treatment theory to longitudinal studies with both direct and indirect effects and sequential timevarying treatments and confounders. In this theory, for any fixed history of antiretroviral therapy $\bar{a}, Y_{\bar{a}}$ is defined to be the random variable representing a subject's outcome had, possibly contrary to fact, the subject been treated with $\bar{a}$ rather than his observed treatment $\bar{A}$. Note that $\bar{a}$ is a possible value of the random variable $\bar{A}$. For each possible history $\bar{a}$ we are assuming a subject's response $Y_{\bar{a}}$ is well defined, although generally unobserved. Indeed we only observe $Y_{\bar{a}}$ for that treatment history $\bar{a}$ equal to a subject's actual treatment history $\bar{A}$, i.e. a subject's observed outcome $Y$ equals $Y_{\bar{A}}$. This identity is the fundamental "consistency" assumption that links the counterfactual data $Y_{\bar{a}}$ to the observed data (Y, $\bar{A})$.

Note that if, at each time $t, A(t)$ can take but one of two values ( 0 for untreated and 1 for treated) and the study duration is $K$ months, then there are $2^{K}$ different $Y_{\bar{a}}$ values associated with each subject as there are $2^{K}$ possible treatment patterns only one of which is actually observed for a given subject. Then, formally, the statement that the effect of treatment history on the mean of $Y$ is a linear logistic function of duration of antiretroviral therapy is the statement that, for each $\bar{a}$,

$$
E\left[Y_{\bar{a}}\right]=g[\bar{a} ; \beta]
$$

where

$$
\begin{equation*}
g[\bar{a} ; \beta]=\frac{\exp \left(\beta_{0}+\beta_{1} \operatorname{Dur}(\bar{a})\right)}{1+\exp \left(\beta_{0}+\beta_{1} \operatorname{Dur}(\bar{a})\right)} \tag{4}
\end{equation*}
$$

$\beta=\left(\beta_{0}, \beta_{1}\right)$, and $\operatorname{Dur}(\bar{a})=\sum_{k=0}^{K} a(k)$ is the subject's duration of treatment under the treatment history $\bar{a}$. We refer to this model as a MSM for the effect of antiretroviral therapy on the mean of $Y$, since it is a model for the marginal distribution of counterfactual variables and, in the econometric and social science literature, causal models (i.e. models for counterfactual variables) are often referred to as structural.

The parameter $\beta$ of our MSM encodes the magnitude of the average causal effects of the treatment on the outcome. By definition, the causal effect of treatment regime $\bar{a}$ on the outcome $Y$ for a given study subject is the difference $Y_{\bar{a}}-Y_{\bar{o}}$ between his outcome $Y_{\bar{a}}$ when treated with regime $\bar{a}$ and his outcome $Y_{\overline{\overline{0}}}$ when never treated. Thus the average causal effect of regime $\bar{a}$ is $E\left[Y_{\bar{a}}-Y_{\overline{\bar{o}}}\right]=E\left[Y_{\bar{a}}\right]-E\left[Y_{\overline{0}}\right]=g(\bar{a} ; \beta)-$ $g(\overline{0} ; \beta)$, which depends on $\beta$. If $\beta_{1}$ is zero, we say that there is no effect of treatment $\bar{a}$ on the outcome since $E\left[Y_{\bar{a}}\right]-E\left[Y_{\overline{0}}\right]$ is the same for all $\bar{a}$. In contrast, the association parameter $\gamma_{1}$ lacks a causal interpretation when treatment is not causally exogenous. Furthermore, the optimal non-dynamic intervention $\bar{a}^{*}$ is the value of $\bar{a}$ for which $E\left[Y_{\bar{a}}\right]=g(\bar{a} ; \beta)$ is the greatest if our goal is to maximize the probability that HIV will not be detected in the serum.

### 4.4 Formal definitions of causal exogeneity and no unmeasured confounders

We are now in a position to offer mathematically precise definitions of causal exogeneity and of no unmeasured confounders. Let $\left\{Y_{\bar{a}}\right\}$ be the set of all counterfactual outcomes $Y_{\bar{u}}$ as $\bar{a}$ varies. Formally, we say that the treatment process $A(t)$ is causally exogenous if,

$$
\begin{equation*}
\left\{Y_{\bar{a}}\right\} C \quad A(t) \mid \bar{A}(t-1) \tag{5}
\end{equation*}
$$

which is mathematically equivalent to the statement that $\left\{Y_{\bar{a}}\right\}$ is independent of $\bar{A}$. Note that even when $A(t)$ is "causally exogenous", if the treatment has an effect on the outcome, then the observed outcome $Y=Y_{\bar{A}}$ will not be independent of $\bar{A}$, since $Y_{\bar{A}}$ is a function of a subject's observed treatment history $\bar{A}$ itself. Given the covariates recorded in $L(t)$, following Robins (1987) we say there are no unmeasured confounders for the effect of $A(t)$ on $Y$ if

$$
\begin{equation*}
\left\{Y_{\bar{u}}\right\} C \quad A(t) \mid \bar{A}(t-1), \bar{L}(t) \tag{6}
\end{equation*}
$$

We shall also refer to the assumption of no unmeasured confounders as
the assumption that treatment $A(t)$ is sequentially randomized given the past. This assumption generalizes Rosenbaum and Rubin's (1983) assumption of ignorable treatment assignment to longitudinal studies with time-varying treatments and confounders. The assumption states that, conditional on treatment history and the history of all recorded covariates up to $t$, treatment at $t$ is independent of the counterfactual random variables $Y_{\bar{a}}$. This will be true if all prognostic factors for (i.e. predictors of) $Y$ that are used by physicians to determine whether treatment is given at $t$ are recorded in $\bar{L}(t)$ and $\bar{A}(t-1)$. That is, as in Figure 28.1(b), the causal graph generating the data has no arrows directly from any unmeasured causal risk factors for $Y$ directly into treatment. For example, since physicians tend to administer prophylaxis to subjects with previous bouts of PCP, and in untreated subjects PCP predicts $Y$, the assumption of no unmeasured confounders would be false if $\bar{L}(t)$ does not contain PCP history. It is the primary goal of the epidemiologists conducting an observational study to collect data on a sufficient number of covariates to ensure that the assumption of no unmeasured confounders will be at least approximately true.

In an observational study, the assumption of no unmeasured confounders cannot be guaranteed to hold even approximately and it is not subject to empirical test. Therefore, it may be useful to investigate the sensitivity to violations of the assumption through a formal sensitivity analysis. Robins et al. (1999, rejoinder) and Robins et al. (1999) provide details.

Robins (1999) proved that when there are no unmeasured confounders, (i) statistical exogeneity implies causal exogeneity, (ii) the weighted logistic regression estimator using the weights $S W$ converges to the parameter $\beta$ of the MSM (4) for $E\left[Y_{\bar{a}}\right]$, and (iii) the probability limit $\gamma$ of the usual unweighted logistic estimator generally differs from the causal parameter $\beta$ of the MSM unless the treatment process is statistically exogenous. Here we provide an informal heuristic argument for (ii). View each person as a member of a pseudo-population consisting of $S W$ copies of themselves. In this new pseudo-population, it can be shown that $\bar{L}(t)$ does not predict treatment at $t$ given past treatment history, and thus we have created a pseudo-population in which treatment is causally exogenous. Furthermore, the causal effect of treatment on $Y$ in the pseudo-population is the same as in the original population. That is, if $E\left[Y_{\bar{a}}\right]=g(\bar{a} ; \beta)$ in the true population, the same will be true of the pseudo-population. Hence, we would like to do ordinary logistic regression in the pseudo-population. But that is what our weighted logistic regression estimator is doing, since the weights create, as required, $S W$ copies of each subject.

We can generalize our MSM (4) slightly and model the marginal distribution of $Y_{\bar{a}}$ within levels of a subset $V$ of the pre-treatment (baseline) covariates $L(0)$. Then, our marginal structural logistic model (4) could
be modified to

$$
E\left[Y_{\bar{a}} \mid V\right]=\frac{\exp \left(\beta_{0}+\beta_{1} \operatorname{Dur}(\bar{a})+\beta_{2}^{\prime} V+\beta_{3}^{\prime} \operatorname{Dur}(\bar{a}) V\right)}{1+\exp \left(\beta_{0}+\beta_{1} \operatorname{Dur}(\bar{a})+\beta_{2}^{\prime} V+\beta_{3}^{\prime} \operatorname{Dur}(\bar{a}) V\right)}
$$

$\beta^{\prime}{ }_{3}$ measures how the magnitude of the effect of $\operatorname{Dur}(\bar{a})$ is modified by the pretreatment covariates $V$. An IPTW estimator of the parameter $\beta$ can be obtained by weighted logistic regression with weights $S W$ except now the logistic model includes $\operatorname{Dur}(\bar{A})$ and $V$ as regressors, and $S W(t)$ is redefined to be

$$
\begin{equation*}
S W(t)=\prod_{k=0}^{t} \frac{f[A(k) \mid \bar{A}(k-1), V]}{f[A(k) \mid \bar{A}(k-1), \bar{L}(k)]} . \tag{7}
\end{equation*}
$$

Note $V$ is already included in the denominator, since $V$ is a subset of the variables in $L(0)$.

Let $d(V)$ be a function (regime) that assigns to each value of the vector $V$ a value of $\bar{a}$ in the set $V$ of possible interventions. If a regime $d$ assigns the same value $\bar{a}$ to each $V$ we refer to the regime $d$ as non-dynamic. Otherwise, we refer to $d$ as a conditional or baseline-dynamic treatment regime, strategy or plan as it individualizes the treatment history a subject receives based on the subject's value of the baseline variables recorded in $V$, a subset of $L(0)$. A wise choice of $d$ should allow us to optimize therapy for individuals and thus should be a better strategy than even the optimal non-dynamic intervention $a^{*}$. Let $E\left[Y_{d}\right]$ be the probability of being without HIV in the serum if all subjects followed plan $d$. For subjects with a given value $v$ of $V$, the conditional expectation $E\left[Y_{d} \mid V=v\right]$ given $V=v$ under regime $d$ equals $E\left[Y_{\bar{a}} \mid V=v\right]$ for the value $\bar{a}=d(v)$ that they receive under the plan. Thus for the population as a whole $E\left[Y_{d}\right]=\Sigma_{v} E\left[Y_{\bar{a}} \mid V=v\right] \operatorname{pr}(V=v)$ is a weighted average of $E\left[Y_{\bar{a}} \mid V=v\right]$ with $a=d(v)$ and weights proportional to the fraction $\operatorname{pr}(V=v)$ of the population with $V=v$. Then $d_{o p}^{\text {baseline }}(v)$ is the treatment plan that maximizes $E\left[Y_{d}\right]$ over all possible baseline-dynamic and nondynamic treatment plans $d$. Now even $d_{o p}^{\text {baseline }}(v)$ only allows one to optimize treatment history $\bar{a}$ based on pretreatment (baseline) variables. However, with time-varying treatments it is usually important to dynamically choose the treatment at each time $t$ based on a subject's entire covariate history up to time $t$. For example, consider drug treatment for a chronic disease. When a drug becomes toxic to a subject, the optimal strategy is to stop the drug (or reduce the dose) at least temporarily. One cannot know when to stop the drug based on baseline covariates. Rather, the optimal treatment strategy must allow treatment decisons to be based on a subject's evolving covariate history. The best methods for estimating the effects of true dynamic regimes are not based on MSMs. Further discussion is provided in section 5.

### 4.5 Marginal structural Cox proportional hazards model

MSMs can easily be extended to failure time outcomes by specifying a marginal structural Cox proportional hazards model such as

$$
\begin{equation*}
\lambda_{T \bar{a}}(t \mid V)=\lambda_{0}(t) \exp \left(\beta_{1} a(t)+\beta_{2}^{\prime} V+\beta_{3}^{\prime} a(t) V\right) \tag{8}
\end{equation*}
$$

where $T_{\bar{a}}$ is the subject's time to death if he had followed anti-retroviral therapy history $\bar{a}, \lambda_{I_{\bar{a}}}(t \mid V)$ is the hazard (force of mortality) of $T_{\bar{a}}$ at $t$ conditional on having pretreatment variables $V, \lambda_{0}(t)$ is an unspecified baseline hazard function, $\exp \left(\beta_{1}+\beta_{3}^{\prime} V\right)$ is the causal rate ratio for the effects of treatment at level $V$ of a vector of baseline regressors including age, calendar year, CD4 count, CD8 count, WBC count, RBC count, platelets, etc. For variety, we have chosen a model which specifies that the hazard of death at time $t$ depends on current treatment status rather than the duration of treatment. Other dose-response models could be used.

Let $T$ be a subject's observed failure (i.e. death) time, so that $T=T_{\bar{A}}$. Arguing as above, Robins (1999) shows that, in the absence of censoring, a consistent estimator of the unknown parameter $\beta=\left(\beta_{1}, \beta_{2}^{\prime}\right.$, $\left.\beta_{3}^{\prime}\right)^{\prime}$ is obtained by fitting the ordinary time-dependent Cox model

$$
\begin{equation*}
\lambda_{T}(t \mid \bar{A}(t), V)=\lambda_{0}(t) \exp \left(\gamma_{1} A(t)+\gamma_{2}^{\prime} V+\gamma_{3}^{\prime} A(t) V\right) \tag{9}
\end{equation*}
$$

except that the contribution of a subject to a calculation performed on a subject $i$ at risk at time $t$ is weighted by $S W_{i}(t)$, as defined in (7) with $T>k$ added to the conditioning event. Note the subject-specific weights change with time. Few standard Cox proportional hazards software programs allow for time-varying weights. To avoid this software problem one can fit a weighted pooled logistic regression treating each personmonth as an observation and allowing for a time-dependent intercept. That is, one can fit, by weighted logistic regression using weights $S W(t)$, the model

$$
\begin{align*}
\text { logit } \operatorname{pr}[D(t) & =1 \mid D(t-1)=0, \bar{A}(t-1), V] \\
& =\gamma_{0}(t)+\gamma_{1} A(t-1)+\gamma_{2}^{\prime} V+\gamma_{3}^{\prime} A(t-1) V \tag{10}
\end{align*}
$$

where $D(t)=0$ if a subject was alive at time $t$ and 1 if the subject died at month $t$, and $\gamma_{0}(t)$ is a time-specific intercept. This method offers the advantage of being easily programmed in any standard statistical package. Under our assumptions we thereby obtain a consistent estimator of the parameter vector $\beta$ of the MSM

$$
\begin{align*}
\text { logit } \operatorname{pr}\left[D_{\bar{a}}(t)\right. & \left.=1 \mid D_{\bar{a}}(t-1)=0, V\right] \\
& =\beta_{0}(t)+\beta_{1} a(t-1)+\beta_{2}^{\prime} V+\beta_{3}^{\prime} a(t-1) V \tag{11}
\end{align*}
$$

When the death rate in any given month $t$ is small, the parameters of (11) and (8) closely approximate one another.

Because of the weights, the standard error estimates outputted by a standard logistic program are invalid and may be either too large or too small. To overcome this difficulty, model (10) should be fit using a generalized estimating equations (GEE) (Liang and Zeger 1986) program which outputs robust variance estimators. The robust variance GEE estimators provide a conservative confidence interval for the $\beta$ (Robins, 1999). That is, the $95 \%$ Wald confidence interval calculated as $\beta \pm 1.96$ $\times$ (robust) standard error is guaranteed to cover the true $\beta$ at least $95 \%$ of the time in large samples.

We now describe how to accommodate censoring in the analysis. We defined a subject as right censored at time $t$ (i.e. $C(t)=1$ ) if by time $t$ he either dropped out of the study or reached administrative end of followup alive.

We say that censoring is ignorable or non-informative if the conditional cause-specific hazard of being censored at $k$ among subjects alive and uncensored up to $k$ does not depend on the failure times $T_{\bar{a}}$ given $\bar{A}(k-1)$, and the time-dependent covariate $\bar{L}(k-1)$ history prior to $k$. Under the assumptions of ignorable censoring and no unmeasured confounding, Robins (1999) shows that we still obtain from fitting (10) consistent estimators of $\beta$ if we weight a subject alive and uncensored at month $t$ by $S W(t) \times S W^{\dagger}(t)$ where (i)

$$
S W^{\dagger}(t)=\prod_{k=0}^{t} \frac{\operatorname{pr}[C(k)=0 \mid \bar{C}(k-1)=0, \bar{A}(k-1), V, T>k]}{\operatorname{pr}[C(k)=0 \mid \bar{C}(k-1)=0, \bar{A}(k-1), \bar{L}(k), T>k]}
$$

is informally the inverse of the ratio of a subject's probability of remaining uncensored up to month $t$ divided by that probability calculated as if there had been no time-dependent determinants of censoring except past treatment history and $V$, and (ii) we modify our definition (7) of $S W(t)$ to add $C(k)=0$ to the conditioning events both in the numerator and the denominator. The denominator of $S W(t) \times S W^{\dagger}(t)$ is informally the probability that a subject would have his own observed treatment and censoring history through month $t$.

Hernan et al. (2000) describe how to estimate the weights $S W(t) \times\left(S W^{\dagger}(t)\right.$ from the data using pooled logistic regression models with treatment (censoring) at each time $k$ as the response variable. Substituting out estimated weights into our IPTW estimators allows us to estimate, under the assumption of no unmeasured confounders, logit $\operatorname{pr}\left[D_{\bar{a}}(t)=1 \mid D_{\bar{a}}(t-1)=0, V\right]=\beta_{0}(t)+\beta_{1} a(t-1)+\beta_{2}^{\prime} V+\beta_{3}^{\prime} a(t-1) V$ and thus the conditional survival curves $S_{\bar{a}}(t \mid V)=\prod_{k=0}^{t} \operatorname{pr}\left[D_{\bar{a}}(k)=0 \mid D_{\bar{a}}(k-1)\right.$ $=0, V]$ that would be observed if all subjects have followed regime $\bar{a}$.

Again let $d(V)$ be a function (regime) that assigns to each value of the
baseline vector $V$ a value of $\bar{a}$ in the set $V$ of possible interventions. Let $S_{d}(t)$ be the survival curve if all subjects followed plan $d$. For subjects with a given value $v$ of $V$, the conditional survival curve $S_{d}(t \mid V=v)$ given $V=v$ under regime $d$ is $\Sigma_{v} S_{\bar{a}}(t \mid V=v) \operatorname{pr}(V=v)$ is a weighted average of $S_{\bar{a}}(t \mid V=v)$ with $a=d(v)$ and weights proportional to the fraction $\operatorname{pr}(V=v)$ of the population with $V=v$. Then $d_{o p}^{\text {baseline }}(v)$ is the treatment plan that minimizes the area under $S_{d}(t)$ over all possible baselinedynamic and non-dynamic treatment plans $d$. Now even $d_{o p}^{\text {baseline }}(v)$ only allows one to optimize treatment history $\bar{a}$ based on pretreatment (baseline) variables. The best methods for estimating the effects of general dynamic regimes are not based on MSMs. Further discussion is provided in section 5 .

We have seen that under the assumption of no unmeasured confounders, IPTW estimation of a marginal structural Cox proportional hazards model can, in contrast with standard methods, be used to estimate the effect of time-varying treatments on survival.

The correctness of the resulting causal inferences is dependent on three key assumptions. First, we must assume that the covariates in $L(t)$ are sufficient to adjust for both confounding and for selection bias due to loss to follow-up. This implies that we have available, in each month, data recorded in $L(t)$ on the history of all time-dependent covariates that (i) are independent predictors of death and (ii) independently predict the probability of changes in treatment and/or of being censored in that month. As in all observational studies, this fundamental assumption cannot be empirically tested. In practice, this would never be precisely or sometimes even approximately true. As described earlier, methods have recently been developed which allow one to evaluate the sensitivity of one's estimates to increasing violation of this assumption.

Second, we must assume that our models for changes in treatment and censoring, given past covariate and treatment history, are correctly specified. Last, we need to assume that our MSM for the effect of antiretroviral therapy on mortality is correctly specified.

Even when estimating the effect of a time-independent treatment using standard statistical models, the same assumptions (no unmeasured confounders, non informative censoring, and no model misspecification) are required to endow the parameters with a causal interpretation. Furthermore, when estimating the effect of a time-varying treatment, our assumptions are less restrictive than those required by standard analyses: an approach based on IPTW estimation of MSMs does not require for validity the absence of confounding by time-dependent covariates.

## 5. Alternatives to MSMs

Before introducing MSMs, Robins and coauthors introduced two
other methods for estimation of the causal effect of a time-varying treatment in the presence of time-varying confounders: the parametric g-computation algorithm formula estimator (Robins 1986), and g-estimation of structural nested models (Robins et al. 1992). When (i) both treatment and the confounders are discrete variables, (ii) they are measured at only a few time points, and (iii) the sample size is large, then estimation can be carried out using fully saturated models (i.e. nonparametrically) and all three methods are precisely equivalent. They differ when, as in observational studies with sparse multivariate data, one must introduce modelling assumptions.

A major advantage of MSMs is that they resemble standard models. For example, the logistic MSM and the Cox proportional hazards MSM described above are the natural way to extend the ordinary logistic and time-dependent Cox models to allow for estimation of causal effects of time-dependent treatments. However a major advantage of the parametric g-computation algorithm formula estimator and g-estimation of structural nested models over MSMs is that these models are much more useful than MSMs for estimating both interactions between treatment and time-dependent covariates and the effect of dynamic treatment regimes (Robins 1999). Due to space limitations, we will focus in this chapter on the parametric g-computation algorithm formula estimator, and we will not consider g-estimation of structural nested models.

Now for any variable $Z$, let $Z$ be the support (i.e. the possible values) of $Z$. Define a treatment regime or plan $d$ to be a collection of $K+1$ functions $d=\left\{d_{0}, \ldots, d_{K}\right\}$ where $d_{m}: \overline{\mathcal{L}}_{m} \rightarrow \mathcal{A}_{m}$ maps histories $\bar{l}_{m} \in \overline{\mathcal{L}}_{m}$ into a treatment $d_{m}\left(\bar{l}_{m}\right) \in \mathcal{A}_{m}$. If $d_{m}\left(\bar{l}_{m}\right)$ is a constant, say $a_{m}$, not depending on $\bar{l}_{m}$ for each $m$, we say regime $d$ is non-dynamic and write $d=\bar{a}, \bar{a} \equiv\left(a_{0}, \ldots, a_{K}\right)$. Otherwise, $d$ is dynamic. We let $\mathcal{D}$ be the set of all regimes $d$. Let $f(o)$ and $F(o)$ represent the density and distribution function of the observed data $O=\left(\bar{A}_{K}, \bar{L}_{K+1}\right)$.

Associated with each regime $d$ is the distribution $F_{d}(o)$ with density $f_{d}(o)$ that represents the distribution of the observed data had, contrary to fact, all subjects in the population been treated with regime $d$. Suppose the assumption of no unmeasured confounders holds for the joint outcomes $\bar{L}_{\bar{a}}=\bar{L}_{\bar{a}, K+1}$ [i.e. Equation 6 holds with $\left\{\bar{L}_{\bar{a}}\right\}$ replacing $\left\{\bar{Y}_{\bar{a}}\right\}$. Then given a regime $d=\left(d_{0}, d_{1}, \ldots, d_{K}\right)$ and the joint density

$$
\begin{equation*}
f(o)=f\left(l_{0}\right) \times f\left(a_{0} \mid l_{0}\right) \times \ldots \times f\left(a_{K} \mid \bar{l}_{K}, \bar{a}_{K-1}\right) \times f\left(l_{K+1} \mid \bar{l}_{K}, \bar{a}_{K}\right), \tag{12}
\end{equation*}
$$

of the observed data (written as a Markov factorization in temporal order), $f_{d}(o)$ is the density $f(o)$ except that, in the factorization (12), $f\left(a_{0} \mid l_{0}\right)$ is replaced by a degenerate distribution at $a_{0}=d_{0}\left(l_{0}\right), f\left(a_{1} \mid l_{1}, a_{0}, l_{0}\right)$ is replaced by a degenerate distribution at $a_{1}=d_{1}\left(l_{0}, l_{1}\right)$, and, in general, $f\left(a_{k} \mid \bar{l}_{k}, \bar{a}_{k-1}\right)$ is replaced by a degenerate distribution at $a_{k}=d_{k}\left(\bar{l}_{k}\right)$. That
is the density $f_{d}(o)$ is given by

$$
\begin{equation*}
f_{d}(o)=f\left(l_{0}\right) \times f_{d}\left(a_{0} \mid l_{0}\right) \times \ldots \times f_{d}\left(a_{K} \mid \bar{l}_{K}, \bar{a}_{K-1}\right) \times f\left(l_{K+1} \mid \bar{l}_{K}, \bar{a}_{K}\right), \tag{13}
\end{equation*}
$$

where $f_{d}\left(a_{k} \mid \bar{l}_{k}, \bar{a}_{k-1}\right)$ is equal to 1 if $a_{k}=d_{k}\left(\bar{l}_{k}\right)$ and $f_{d}\left(a_{k} \mid \bar{l}_{k}, \bar{a}_{k-1}\right)$ is equal to 0 otherwise.

Again suppose the outcome of interest is $L_{K+1}$ which is assumed to be univariate and shall be denoted by $Y$. In the following, let $d\left(\bar{l}_{k}\right) \equiv$ $\left(d_{0}\left(\bar{l}_{0}\right), \ldots, d_{k}\left(\bar{l}_{k}\right)\right)$ and $d_{k}\left(\bar{l}_{k}\right)$ denote values of $\bar{A}_{k}$ and $A_{k}$ respec-
tively. Then the chance of having history $\left(y, \bar{l}_{K}\right)$ under the distribution $F_{d}(o)$ is $f_{d}\left(y, \bar{l}_{K}\right)=f_{d}\left(y \mid \bar{l}_{K}, d\left(\bar{l}_{K}\right)\right) \prod_{j=0}^{K} f\left(l_{j j} \bar{l}_{j-1}, d(\bar{l}\right.$
$\left.{ }_{j-1}\right)$ ) since the
terms
$f_{d}\left(a_{j} \bar{l}_{j}, \bar{a}_{j-1}\right)$ are equal to 1 in expression (13) for $f_{d}(o)$. Thus the chance $f_{d}(y)$ of having $Y=y$ under $f_{d}(\cdot)$ is

$$
\begin{align*}
f_{d}(y) & =\int f_{d}\left(y, \bar{l}_{K}\right) d \mu\left(\bar{l}_{K}\right) \\
& =\int\left\{f\left(y \mid \bar{l}_{K}, d\left(\bar{l}_{K}\right)\right) \times \prod_{j=0}^{K} f\left(l_{j} \bar{l}_{j-1}, d\left(\bar{l}_{j-1}\right)\right)\right\} d \mu\left(l_{j}\right) \tag{14a}
\end{align*}
$$

where $d \mu\left(\bar{l}_{K}\right)$ represents integration (or summation if $\bar{l}_{K}$ is discrete) over all possible $\bar{l}_{K}$ histories. That is if $\bar{l}_{K}$ is discrete we obtain

$$
\begin{align*}
f_{d}(y) & =\sum_{l_{K}} f_{d}\left(y, \bar{l}_{K}\right) \\
& =\sum_{\bar{l}_{K}}\left\{f\left(y \mid \bar{l}_{K}, d\left(\bar{l}_{K}\right)\right) \times \prod_{j=0}^{K} f\left(l_{j} \mid \bar{l}_{j-1}, d\left(\bar{l}_{j-1}\right)\right)\right. \tag{14b}
\end{align*}
$$

with $\bar{l}_{j}$ the initial segment of a given $\bar{l}_{K}$ history. Robins (1986) referred to this formula as the g -computation algorithm formula or functional for the effect of regime $d$ on outcome Y. Similarly, the marginal distribution function of $Y$ under $F_{d}(\cdot)$ is

$$
F_{d}(y)=\int \ldots \int p r\left[Y<y \mid \bar{l}_{K}, d\left(\bar{l}_{K}\right)\right] \times \prod_{j=0}^{K} f\left(l_{j} \bar{l}_{j-1}, d\left(\bar{l}_{j-1}\right)\right) d \mu\left(l_{j}\right)
$$

To estimate $f_{d}(y)$ from the observed data we specify parametric models $f\left(l_{j} \bar{l}_{i-1}, \bar{a}_{i-1}\right)$ and $f\left(y \mid \bar{l}_{K}, \bar{a}_{K}\right)$, fit the models to the observed data to obtain estimates $\hat{f}\left(l_{j} \bar{l}_{j-1}, \bar{a}_{j-1}\right)$ and $\hat{f}\left(y \mid \bar{l}_{K}, \bar{a}_{K}\right)$ and evaluate these estimates at $\bar{a}_{j-1}=d\left(\bar{l}_{j-1}\right)$ and $\bar{a}_{K}=d\left(\bar{l}_{K}\right)$, and substitute them into the above expression for $f_{d}(y)$. Details are given in section 6 below where we consider
estimating the effect of treatment on a survival outcome. Under certain additonal assumptions described in section 6 , one may consider the gformula as giving the overall effect of an intervention regime $d$ on $Y$ by summing up both its indirect effects on $Y$ mediated through the effect of the intervention on the non-intervened on variables $L_{j}$ (which in turn affect the outcome $Y$ ) and its direct effects on $Y$. In contrast, MSMs always model the overall effect of the intervention on $Y$ without any decomposition into direct and indirect effects.

## 6. Analysis of the framingham OFFSPRING STUDY

In this section we describe the use of the parametric $g$-computation algorithm formula estimator of section 5 and IPTW MSM estimator of section 4 to estimate what the cumulative incidence of coronary heart disease mortality in the Framingham Offspring Study would have been

| Content | Time after follow-up | Sample size |
| :--- | :---: | :---: |
| Exam 1 | Year 0 | 5 I24 |
| Exam 2 | Year 8 | 3863 |
| Exam 3 | Year 12 | 3873 |
| Exam 4 | Year 16 | 4019 |

under various hypothetical intervention strategies. The Framingham Offspring public use file contained data on 5124 subjects ( 2483 male and 2641 female subjects). Subjects were examined five times over 20 years. Exam 1 occured in year 0 , exam 2 in year 8 , exam 3 in year 12, exam 4 in year 16 and exam 5 in year 20. The table below shows the number of subjects attending each of the first four exams. Mortality follow-up was essentially complete through exam 5 at year 20. By year 20, 891 subjects were known to have developed coronary heart disease (CHD), including those with pre-existing CHD at exam 1.
For reasons explained below, the follow-up period for our analysis began at exam 2 (which we will refer to as the baseline exam). Each subject contributed person-time from exam 2 to the date of CHD diagnosis, death from any cause, loss to follow-up, or exam 5 , whichever occurred first. Subjects with pre-existing CHD at exam 2 or with missing risk factor values at exam 1 were excluded from all calculations.

In the Framingham public use file, CHD was defined as one of the following events: (i) recognized or unrecognized myocardial infarction (using diagnostic ECG or transaminase/history/autopsy evidence), (ii) angina pectoris (first episode), (iii) coronary insufficiency, or (iv) death from CHD. The following (time-dependent) risk factors were used in various analyses: age at exam (years); sex (male/female); body mass index
$\left(\mathrm{kg} / \mathrm{m}^{2}\right)$; cigarette smoking (current smoker/non-current smoker); alcohol consumption (calculated alcohol index in ounces per week); diabetes mellitus (defined diabetes/no defined diabetes); LDL-cholesterol (mg/dl); HDL-cholesterol ( $\mathrm{mg} / \mathrm{dl}$ ); and systolic blood pressure ( mmHg ).

Missing values of risk factors in later exams were carried forward from the previous exam. Fat intake was not used in our analyses, because the Framingham public use file did not contain that information. Physical activity was also not used, because it was not measured at exams 1 and 4.

### 6.1 INTERVENTIONS

We estimated with the parametric g-computation algorithm formula estimator the cumulative incidence (i.e. risk) of CHD between exam 2 and exam 5 that would have been observed under the following hypothetical intervention strategies.

1. A random half of smokers at baseline (i.e. exam 2) quit smoking forever (no intervention on those who were not current smokers at baseline but started smoking later).
2. All smokers at baseline quit smoking forever (no intervention on those who were not current smokers at baseline but started smoking later).
3. Subjects who were drinkers at baseline were randomly assigned a non-time-varying level of alcohol consumption at baseline drawn at random from a truncated normal distribution with a mean of $20 \mathrm{~g} /$ day for males and $10 \mathrm{~g} /$ day for females, a maximum of $30 \mathrm{~g} /$ day for males and $15 \mathrm{~g} /$ day for females, and a minimum of $10 \mathrm{~g} /$ day for males and $5 \mathrm{~g} /$ day for females (with the sex-specific variance of the normal equal to the sex-specific variance of alcohol consumption at baseline among drinkers in study population). Alcohol consumption was not intervened on thereafter.
4. Body mass index (BMI) was lowered
a) by $10 \%$ at each visit BMI exceeded 22
b) to 22 at each visit BMI exceeded 22
5. The distribution of LDL at baseline was drawn at random from a normal distribution with mean of 90 and a SD of 30 (Chinese distribution both for males and females). LDL was not intervened on thereafter.
6. Interventions 1, 3 and 4a simultaneously.

### 6.2 Data analysis

## PARAMETRIC G-FORMULA

In this section we describe how we estimate the proportion of the Framingham Offspring Study population that would have developed CHD between exams 2 and 5 for each of the interventions mentioned above under the assumption of no unmeasured confounders. Specifically, we used the parametric g-formula (i.e. the g-formula evaluated at predicted values calculated under parametric regression models) to estimate the CHD risk in the Framingham Offspring data under each intervention. We remark that in this exercise we are estimating the cumulative incidence (probability of developing) CHD between exams 2 and 5 under each intervention rather than the expected life years and expected quality-adjusted life-years. Although these latter quantities are more relevant for public health decision-making, we decided to report the results in terms of cumulative incidences because this measure is more familiar to practising epidemiologists. It would be easy to use these same methods to estimate expected life measures. The g-formula to compute the CHD risk (i.e. cumulative incidences between exams 2 and 5) under a particular intervention (i.e. a possibly dynamic regime) $d$ is one minus the probability of "not developing CHD between exams 2 and 5 " which is given by the following g-formula for "survival without CHD."

$$
\begin{align*}
& \sum_{\bar{a}_{4}} \sum_{\bar{a}_{4}^{*}} \sum_{\bar{l}_{4}} \prod_{j=1}^{4} \operatorname{Pr}\left[C H D_{j+1}=0 \mid \bar{l}_{j}, \bar{a}_{j}, \overline{\mathrm{CHD}}_{j}=0, \bar{D}_{j}=0\right]^{I(j>2)} \\
& \quad \times f_{d}\left(a_{j} \mid \bar{l}_{j}, a_{j}^{*}, \bar{a}_{j-1}, \overline{C H D}_{j}=0, \bar{C}_{j}=0, \bar{D}_{j}=0\right)  \tag{15}\\
& \quad \times f\left(l_{j} \mid \bar{l}_{j-1}, \bar{a}_{j-1}, \overline{C H D}_{j}=0, \bar{C}_{j}=0, \bar{D}_{j}=0\right) \\
& \quad f\left(a_{j}^{*} \mid \bar{l}_{j}, \bar{a}_{j-1}, \overline{C H D}_{j}=0, \bar{C}_{j}=0, \bar{D}_{j}=0\right)
\end{align*}
$$

where $j$ denotes exam number for any $\bar{z}_{j}, \bar{z}_{0}$ is defined to be 0 since there is no exam 0 .
$C H D_{j+1}=1$ if CHD was diagnosed between exams $j$ and $j+1,0$ otherwise;
the overbar means history, i.e. $\overline{\mathrm{CHD}}_{j}=\left(\mathrm{CHD}_{1}, \ldots, \mathrm{CHD}_{j}\right)$;
the random variable $L_{j}$ with realized values $l_{j}$ is the set of risk factors not undergoing the intervention;
$a_{j}$ is the intervention value of the risk factors $A_{j}$ undergoing intervention at time $j$;
$\bar{l}_{j}$ is a history of (non-intervened on) risk factors through exam $j$ compatible with a particular $\bar{l}_{4}$ history in the sum;
$\bar{a}_{j}$ is a history of (intervened on) risk factors through exam $j$;
$a_{j}^{*}$ is the value of $A_{j}$ that would be observed at time $j$ if interventions were made through $j-1$ but no intervention was made at $j$ (see below); the sum is overall possible $\bar{l}_{4}, \bar{a}_{4}, \bar{a}_{\stackrel{*}{4}}$ histories;
$\bar{C}_{j}=0$ is the event that a subject remains uncensored through exam $j$;
$\bar{D}_{j}=0$ is the event that a subject has not died from other non-CHD causes through exam $j$;
$f(\cdot \cdot)$ is a conditional density function of the observed data distribution;
$f_{d}(\cdot \cdot)$ is the conditional density function of the exposure $A$ under the proposed intervention. Because we do not intervene until $j=2$, the "intervened on" value $a_{1}$ of $A_{1}$ must equal the "non-intervened on" value $a_{i}^{*}$. To accomplish this, we take for $j=1 f_{d}\left(a_{j} \mid \bar{l}_{j}, a_{j}^{*}, \bar{a}_{j-1}, \overline{\mathrm{CHD}}_{j}=0\right.$, $\left.\bar{C}_{j}=0, \bar{D}_{j}=0\right)=1$ if $a_{j}=a_{j}^{*}$ and 0 otherwise.

Formula (15) includes four generalizations of formula (14). First we allow the intervention treatment $a_{j}$ at time $j$ to depend on the value $a_{j}^{*}$ of $A_{j}$ that would be observed at time $j$ if the planned interventions were made through $j-1$ but no intervention was made at $j$. That is the intervention density $f_{d}\left(a_{j} \bar{l}_{j}, a_{j}^{*}, \bar{a}_{j-1}, \overline{\mathrm{CHD}}_{j}=0, \overline{\mathrm{C}}_{j}=0, \bar{D}_{j}=0\right)$ can be a function of $a_{j}^{*}$. This is meant to reflect the fact that when a subject arrives at visit $j$, his exposure $a_{j}^{*}$ could be noted and if it takes certain values it can, in principle, be intervened on and instantaneously changed to a new exposure labelled $a_{j}$. We assume it is $a_{j}$ that affects outcomes at the next visit $j+1$. For example, the BMI intervention 4 b was modelled in this way. This "instantaneous change" model might be a reasonable approximation to a real intervention in which BMI was reduced to 22 over 3 to 6 months, as the time between visits is four years. To determine at time $j$ the value of $a_{j}^{*}$ for a simulated subject, we need to generate $a_{j}^{*}$ from the non-intervention observed data density $f\left(a_{j}^{*} \mid \bar{l}_{j}, \bar{a}_{j-1}\right.$, $\overline{\mathrm{CHD}}_{j}=0, \overline{\mathrm{C}}_{j}=0, \bar{D}_{j}=0$ ), where it follows from the definition of $a_{j}^{*}$ that the arguments $\left(\bar{l}_{j}, \bar{a}_{j-1}\right)$ in the conditioning event are the values that would be seen had the planned intervention $d$ been made through $j-1$. Second, we now allow probabilistic (i.e. random) interventions so $f_{d}\left(a_{j} \bar{l}_{j}, a_{j}^{*}, \bar{a}_{j-1}, \overline{C H D}_{j}=0, \bar{C}_{j}=0, \bar{D}_{j}=0\right)$ need not take only the values 0 or 1 . For example, an intervention in which a subject who is a smoker at occasion $j$ (i.e. $a_{j}^{*}=1$ ) stops smoking with probability $1 / 2$ would have $f_{d}\left(a_{j} \bar{l}_{j}, a_{j}^{*}=1, \bar{a}_{j-1}, \overline{\mathrm{CHD}}_{j}=0, \bar{C}_{j}=0, \bar{D}_{j}=0\right)=1 / 2$ for both $a_{j}=1$ and $a_{j}=0$. Third, we now allow the interventions such as the alcohol intervention 3 and LDL intervention 5 to include active intervention at some times and no further intervention at other times. For example, in intervention $5, f_{d}\left(a_{j} \bar{l}_{j}, a_{j}^{*}, \bar{a}_{j-1}, \overline{\mathrm{CHD}}_{j}=0, \bar{C}_{j}=0, \bar{D}_{j}=0\right)$ is equal to a normal density with mean 90 and standard deviation 30 at the baseline visit $j=$ 2, but $f_{d}\left(a_{j} \mid \bar{l}_{j}, a_{j}^{*}, \bar{a}_{j-1}, \overline{\mathrm{CHD}}_{j}=0, \bar{C}_{j}=0, \bar{D}_{j}=0\right)=1$ if $a_{j}=a_{j}^{*}$ at visits $j$ $=3$ and $j=4$ in addition to visit $j=1$. Finally, the end-point is now survival to visit 5 , so the $g$-formula multiplies the probability of not failing at visits 3,4 and 5 .

## Caveats

As discussed above, the g-formula identifies the effect one would have
observed under a particular intervention under the assumption of no unmeasured confounders. But this assumption itself assumes that the counterfactual survival variables $\mathrm{T}_{\mathrm{d}}$ (the time to CHD under intervention d) are well defined. If the intervention is on smoking, it seems only mildly philosophically problematic to assume the existence of a welldefined counterfactual time of CHD had one received a different smoking history than one's actual history. However, for interventions $4 \mathrm{a}, 4 \mathrm{~b}$ or 5 , the counterfactual $\mathrm{T}_{\mathrm{d}}$ may be very poorly defined. For example, the effect on CHD of lowering LDL may possibly depend on the mechanism by which it is lowered. That is, the effect may be different depending on whether LDL were lowered by using drugs that decrease LDL production, drugs that increase its elimination or drugs that impair the absorption of fats from the gut. Similarly the effect on CHD of an intervention to lower BMI may be different depending on the degree of calorie restriction imposed, the foods allowed in the required diet, and the level of increased physical activity imposed. Thus for the interventions 4a, 4b and 5 d that are stated solely in terms of the level of BMI or LDL to be achieved (without further specifying the precise intervention that will be used to realize the reductions), it may be that the counterfactuals $\mathrm{T}_{\mathrm{d}}$ should not be regarded as well-defined. But if the counterfactulas are not well-defined, the assumption of no unmeasured confounders is vacuous (as the assumption is in terms of the counterfactuals). As a consequence, for such interventions, it is unclear what the counterfactual quantity one hopes the g -formula to estimate. However, if one correctly held the belief that LDL in the blood is a dominant cause of CHD and that all reasonable interventions that lowered LDL to a prespecified level would result in equal reductions in CHD risk, then $\mathrm{T}_{\mathrm{d}}$ would be well-defined even for an intervention d that, like intervention 5 , is stated only in terms of the level of LDL to be achieved. Evidence for this belief would be strenghtened if randomized experiments of various lipid lowering therapies that lowered average LDL by an identical amount showed the same improvement in CHD risk, regardless of the mechanism of action of the drug used to lower LDL.

Even when a counterfactual is well-defined, the g-formula only estimates the effect of an intervention under the assumption of no unmeasured confounders. Thus it is important for epidemiologists to try to obtain data on many potential confounders. The assumption of no unmeasured confounders will never exactly be true in observational studies and may not even be approximately true. A particular setting in which substantial unmeasured confounding may be present is when many of the confounders recorded in $L_{j}$ are measured with error. In that case, even if the correctly measured confounders would have served to fully control confounding, the mismeasured confounders may not. This could be the case even when the measurement error is random and nondifferential and the null hypothesis of no treatment effect is true. This
raises an important distinction between studies with time-varying treatments and studies with time-independent treatments. With time-varying treatments, past treatment history itself can be a confounder for the effect of current treatment on the outcome. Thus even when treatment is only subject to random (non-differential) measurement error, confounding bias can exist even under the null hypothesis of no treatment effect. This is in sharp contrast with the results for time-independent treatments in which random (non-differential) subject-specific measurement error does not lead to bias under the causal null hypothesis of no treatment effect. However, there is an additional subtlety in studies with time-varying treatments. If the decision to take a treatment at time $j$ depends on one's past measured treatment history (say as recorded in a pharmacy prescription database) and not on one's true past treatment history, then, under the null hypothesis, there is no bias introduced by the mismeasurement of treatment, even if the measurement error is differential. On the other hand, if the decision to take treatment at a given time depends on past true (but unrecorded) treatment history, then, by only controlling for past measured treatment history in the analysis, bias may exist under the null hypothesis of no treatment effect, even with random (nondifferential) measurement error.

In sections 4 and 5, we assumed the intervened on risk factors $A_{j}$ at time or visit $j$ occurred temporally after the non-intervened on risk factors $L_{j}$. We clearly cannot assume this to be the case in the Framingham Offspring Study for all 6 interventions of interest. Further, because the variables are generally measured but once every four years, each risk factor may potentially causally influence the others over the four years. In this setting, if we let $Z_{j}$ be the set of all measured risk factors at visit $j$ (regardless of whether one wants to consider intervening on any subset), let $D_{j}$ be the indicator variable for survival at visit $j$ with $D_{j}$ prior to $Z_{i}$, then a sufficient and nearly necessary condition for the g-functional (15) to identify the effect on the cumulative incidence of CHD under an intervention on any chosen subset of the measured timevarying risk factors is that (i) no risk factor causally influences any other risk factor over the four years between visits which we formalize as, for each visit $j$, no element of $Z_{j}$ is a cause of any other element of $Z_{j}$ on the causal DAG generating the data, (ii) the set of all measured risk factors $\bar{Z}_{K}$ are jointly causally exogenous for survival in the sense that on the causal DAG generating the data, for all combination of visit times $s$, $t, j$, there is no unmeasured $U_{s}$ that is a common cause of both $D_{j}$ and (an element of) $Z_{t}$ for which there exist directed paths from $U_{s}$ to $D_{j}$ and $U_{s}$ to $Z_{t}$ whose other vertices are all unmeasured variables, and (iii) any unmeasured common causes of variables in $Z_{j}$ are marginally independent of any unmeasured common cause of variables in $Z_{t}$ for $j \neq s$. That is, conditions (i)-(iii) guarantee that there are no unmeasured confounders for the effect of any possible intervention on survival, even without knowledge of time order among the variables $Z_{t}$ measured at
the same visit $t$ and even though there is substantial time (four years) between the visits at which data are recorded. Conditions (i)-(iii) are so restrictive that it seems unlikely that we would ever believe that the g formula will be exactly unbiased for the effect of all the various risk factor interventions in which we might have interest. If conditions (i)-(iii) did hold, then the g -formula gives the overall effect of an intervention regime $d$ on survival by explicitly summing up both its indirect effects on survival mediated through the effect of the intervention on the non-intervened on variables $L_{j}$ measured by the factors $f\left(l_{j} \mid \bar{l}_{j-1}, \bar{a}_{j-1}\right.$, $\overline{\mathrm{CHD}}_{j}=0, \overline{\mathrm{C}}_{j}=0, \bar{D}_{j}=0$ ) (which in turn affect the survival as measured by the dependence of the factors $\prod_{j=1}^{4} \operatorname{Pr}\left[C H D_{j+1}=0 \mid \overline{\bar{l}}_{i}, \bar{a}_{j}, \overline{C H D}_{j}=0, \bar{D}_{j}=0\right]$ on $\bar{l}_{j}$ ) and its direct effects on survival measured by the dependence of $\prod_{j=1}^{4} \operatorname{Pr}\left[C H D_{j+1}=0 \mid \bar{l}_{j}, \bar{a}_{i}, \overline{C H D}_{j}=0, \bar{D}_{j}=0\right]$ on $\bar{a}_{j}$.

## Details of estimation

Because the g -formula is a sum over all possible values of risk factor history $\bar{l}_{4}$ and each $l_{j}$ is a high-dimensional vector of covariates, a direct calculation based on (15) is computationally infeasible. Rather, we approximate the result of the g -formula under a given intervention by Monte Carlo simulation. To see how to conduct the simulation, first note that the g -formula (15) gives the probability of developing CHD between exams 2 and 5 based on a intervention-specific joint distribution of CHD and risk factors. Under the assumption of no unmeasured confounders, this is the joint distribution had all subjects followed the intervention.

Therefore we generate, for each intervention, a simulated population in which the joint distribution of CHD and risk factors is approximately equal to the joint distribution implied by the g -formula. Then the CHD risk in the simulated population (i.e. the expected fraction of subjects in the simulated population who develop CHD between exams 2 and 5) estimates the desired probability. Note that, if we simulate under no intervention (i.e. with $f_{d}\left(a_{j} \bar{l}_{i}, a_{j}^{*}, \bar{a}_{j-1}, \overline{C H D}_{j}=0, \bar{C}_{j}=0, \bar{D}_{j}=0\right)=1$ if $a_{j}=a_{j}^{*}$ for all $j$ rather than for just $j=1$ ), the expected CHD risk in the simulated population should equal that of the actual study population, because the joint distribution implied by the g -formula for the simulated population is precisely that of the study population.

Let $z_{j}=\left(l_{j}, a_{j}^{*}\right)$. To estimate

$$
\begin{aligned}
& f\left(z_{j} \mid \bar{l}_{j-1}, \bar{a}_{j-1}, \overline{C H D}_{j}=0, \bar{C}_{j}=0, \bar{D}_{j}=0\right) \\
& \quad=f\left(a_{j}^{*} \bar{l}_{j}, \bar{a}_{j-1}, \overline{C H D}_{j}=0, \bar{C}_{j}=0, \bar{D}_{j}=0\right) \\
& \quad f\left(l_{j} \mid \bar{l}_{j-1}, \bar{a}_{j-1}, \overline{C H D}_{j}=0, \bar{C}_{j}=0, \bar{D}_{j}=0\right)
\end{aligned}
$$

where $l_{j}$ includes all non-intervened on risk factors at exam $j$, we chose an arbitrary ordering of risk factors at exam $j$ : such as (i) body mass index, (ii) cigarette smoking, (iii) alcohol consumption, (iv) diabetes mellitus, (v) LDL, (vi) HDL and (vii) systolic blood pressure. The density (15) is invariant to the ordering of the variables in $z_{j}$. This invariance to ordering is one reason why (15) can only have a causal interpretation for all regimes $d$ under that assumption that no risk factor measured at $j$ causes any other risk measure at $j$, as in the above caveats. We then estimate (i) the conditional probability of BMI at $j$ given the past variables through $j-1$, (ii) the conditional probability of smoking given BMI at $j$ and past variables through $j-1$, (iii) the conditional probability of alcohol at $j$ given BMI, smoking at $j$ and past variables through $j-1$, and so on. We estimate each of these conditional densities by maximum likelihood from the observed data. Finally, we estimate $f\left(z_{j} \bar{l}_{j-1}, \bar{a}_{j-1}, \overline{\mathrm{CHD}}_{j}=0, \bar{C}_{j}=0, \bar{D}_{j}=0\right)$ as the product of these estimated conditional densities.

In detail, the algorithm used to simulate the simulated population exposed to an intervention was as follows:

## Part A: Modelling

1. We fit a pooled (over persons and time) linear logistic regression model to predict the risk of CHD given risk factor history. The outcome was CHD diagnosis between exams $j$ and $j+1$, and the covariates in the model were risk factors at exams $j$ and $j-1$. The model was restricted to those with no diagnosis of CHD at or before exam $j$. The parameters of this model define the estimated conditional probability of CHD risk given the entire past, and thus implicitly assume that risk factors more than 2 time periods previously do not predict CHD risk given risk factors in the past 2 periods.
2. For $j=3$ and $j=4$, we fit pooled regression models to predict each risk factor given past risk factor history, among those with no prior diagnosis of CHD. Risk factors at exam $j$ were the "outcome" in models that include other risk factors at exam $j$ (according to the arbitrary ordering explained above) plus all risk factors at exams $j-1$ and $j-2$ as covariates. We used linear regression for continuous risk factors, and logistic regression for dichotomous risk factors. Continuous risk factor variables with skewed distributions were log transformed. The parameters of these models define the estimated conditional distributions (Bernoulli or Normal or Log normal) of each risk factor.
3. Follow-up started at exam 2 in our analyses because two prior exams are used to predict CHD risk between exams $j$ and $j+1$. Thus, the CHD risk we estimate refers to the 12 -year period between exam 2 (year 8) and exam 5 (year 20).

## Part B: Data generation

4. We simulated a sample of 10000 individuals by sampling with replacement from the study population.
5. The risk factor values at exams 1 and 2 of these 10000 individuals were those actually observed (as interventions beginning at exam 2 could not affect these distributions so we were able to use the empirical distribution of the data).
6. The risk factor values $z_{j}=\left(l_{j}, a_{j}^{*}\right)$ at exams 3 and 4 were generated by sampling a value from the conditional distributions estimated in step 2 above.
7. $a_{j}$ was set equal to $a_{j}^{*}$ for each $j$.
8. The 12 -year probability $1-\prod_{j=1}^{4} \operatorname{Pr}\left[C H D_{j+1}=0 \mid \bar{l}_{i}, \bar{a}_{j}, \overline{C H D}_{j}=0, \quad \bar{D}_{j}=\right.$ 0 ] of CHD for each simulated individual was estimated, based on his/her simulated risk factor values, using the conditional distribution estimated in step 1 above. The population CHD risk is the average of each person's estimated risk.
9. The above procedure simulates the observed study population under no intervention.
10. To simulate a counterfactual population subject to a given intervention $d$ under the assumption of no unmeasured confounders, step 7 had to be modified by drawing $a_{j}$ for $j=2,3,4$ from the intervention density $f_{d}\left(a_{j} \bar{l}_{j}, a_{j}^{*}, \bar{a}_{j-1}, \overline{\mathrm{CHD}}_{j}=0, \bar{C}_{j}=0, \bar{D}_{j}=0\right)$ rather than setting $a_{j}$ to $a_{j}^{*}$ as under no intervention.

We used nonparametric bootstrap methods (sampling the observed study population with replacement 100 times) to estimate approximate confidence intervals (CI) of the counterfactual CHD risks and risk ratios. The size of each bootstrap sample was that of the original sample. To obtain standard errors and thus Wald-type confidence intervals, we re-applied all of steps $1-8$ to each of the 100 bootstrap samples. All analyses were performed separately by sex.

## MARGINAL STRUCTURAL MODEL

We also analysed the non-dynamic interventions on cigarette smoking using MSMs and compared the results to those obtained using the g-formula. Specifically our goal was (i) to estimate the (potentially time-
varying) hazard of CHD under pre-specified (i.e. non-dynamic) regimes or interventions, and (ii) to use this hazard to compute the 12-year CHD risk.

To estimate the hazard, we fit the discrete-time marginal structural Cox model

$$
\operatorname{logit} \lambda_{T_{\bar{a}}}(t)=\operatorname{logit} \lambda_{0}(t)+\beta a(t)
$$

where $\lambda_{T_{\bar{a}}}(t)=\operatorname{Pr}\left[\operatorname{CHD}_{\bar{a}}(t+1)=1 \mid\right.$ CHD $\left._{\bar{a}}(t)=0\right]$ is the discrete hazard of CHD between $t$ and $t+1$ under intervention $\bar{a}=[a(2), a(3), a(4)]$ at visits 2,3 and $4, \lambda_{0}(t)$ is the baseline hazard, $a(t)$ is smoking status (smoker or non-smoker) at study visit $t$ under regime $\bar{a}$, and, for dichotomous smoking exposure, $\beta$ is the $\log$ relative risk (i.e. odds ratio) for always exposed vs never exposed. Under the assumption of no unmeasured confounders, the parameters of this model can be estimated using inverse-probability-of-treatment weighting. The model used to predict smoking status was the same as the one used for the parametric g-formula. We fit the model by using a weighted pooled logistic model with a time-varying intercept.

To estimate the 12-year CHD risk when everybody quits smoking at baseline (and nobody initiates smoking thereafter), we could have computed one minus the survival probability

$$
\left[1-\lambda_{T_{\bar{a}}}(2)\right]\left[1-\lambda_{T_{\bar{\alpha}}}(3)\right]\left[1-\lambda_{T_{\bar{\alpha}}}(4)\right]
$$

with $\bar{a}=[0,0,0]$. However, this simple way of estimating the risk is potentially very inefficient (large variance) because the inverse-probabil-ity-of-treatment weights can be unstable. Therefore, to improve efficiency we used inverse-probability-of-treatment weighting to estimate the parameters of the model

$$
\operatorname{logit} \lambda_{T_{\bar{a}}}(t)=\operatorname{logit} \lambda_{0}(t)+\alpha^{T} V+\beta a(t)
$$

where $V$ is a vector of baseline (pre-intervention) covariates. The inclusion of $V$ allows us to use $V$-stabilized weights which result in much more efficient estimation.

We then simulated a sample of 10000 individuals by sampling with replacement from the study population and used the parameter estimates of the MSM above to compute the CHD risk between exams 2 and 5 for each simulated individual at each time based on the observed values of $V$ and $\bar{A}(t)$. We then computed the 12 -year CHD risk for each individual and averaged over all individuals to obtain an estimate of the risk under no intervention.

To estimate the 12 -year CHD risk when $50 \%$ of the subjects quit smoking at baseline (and nobody initiates or quits smoking thereafter),
we first assigned a random half of the smokers in our simulated sample to quitting smoking and then proceeded as above to compute each subject's 12 -year CHD risk under his/her smoking history (always smoking or never smoking).

## 7. Results

After exclusions, our analyses included 2230 men (47.8\%) and 2440 $(52.2 \%)$ women with 189 and 68 CHD events, respectively. Thus, the observed 12 -year risk of CHD in the study population was $8.48 \% ~(95 \%$ CI $7.37 \%-9.73 \%$ ) for males and $2.79 \%$ ( $95 \%$ CI $2.19 \%-3.54 \%$ ) for females.

The estimated 12-year risks of CHD (and 95\% CI) based on the parametric g-formula under several public health interventions are shown in Table 28.1. The simulated 12 -year risk of CHD under no intervention was $8.46 \%$ for males ( $95 \%$ CI $5.61 \%-11.30 \%$ ) and $2.82 \%$ for females ( $95 \%$ CI $2.15 \%-3.49 \%$ ). The risk ratios (and $95 \%$ CIs) for each intervention compared with no intervention are also shown in Table 28.1. For example, the estimated risk ratio among men is 0.81 ( $95 \%$ CI $0.73-0.90$ ) for all smokers quitting smoking at baseline vs no intervention. Note in row 6, we obtain the overall effect of combined interventions without explicitly imposing any particular functional form (e.g. multiplicative or additive) for the interaction of the individual interventions 1,3 and 4 a on the overall risk of CHD.

Table 28.2 displays the results when only one repeated measure of each risk factor (the most recent one) was included in the model for CHD risk. Results in Table 28.1 come from a model that includes the two most recent measures of each factor. The results in the two tables are compared and contrasted in the next section. Results of MSM analyses for the smoking intervention are given in Table 28.3 which displays the risk and risk ratio estimates from a MSM for two smoking interventions similar to interventions 1 and 2, respectively.

## 8. Discussion

We have presented two methods-parametric g-formula and MSMs-to estimate the causal effect of hypothetical public health interventions in the Framingham Offspring Study. In the absence of unmeasured confounders and model misspecification, these methods provide causal estimates from observational data that mimic the results of randomized experiments.

The dataset we used has two major limitations: (i) not all relevant confounders are available and (ii) the number of events, especially for women, is small. Because our methods are only valid when the assumption of no unmeasured confounders holds, we would not expect our estimates to be necessarily close to those of a randomized experiment.

Key: BS SE, bootstrap standard error; BS av. risk, bootstrap average risk.

However, our methods gave coherent results, i.e. when applied to similar interventions, both methods yielded similar estimates. Such coherent results are some evidence against model misspecification but constitute no evidence against confounding by unmeasured factors as even when such unmeasured confounders exist both the parametric g-formula and MSM approaches are estimating the same association parameter. We now discuss the relative advantages and disadvantages of the parametric g-formula and MSMs.

### 8.1 Model misspecification

When using the parametric g-formula, gross model misspecification can be detected by comparing the observed risk and the estimated risk under no intervention. In our example, both risks are similar ( $8.48 \%$ vs $8.46 \%$ in men, $2.79 \%$ vs $2.82 \%$ in women). Note that, whereas dissimilar risks indicate model misspecification, similar risks cannot rule out the existence of model misspecification.

Even in the absence of unmeasured confounding, (i) valid estimation of the effect of the smoking intervention (1) with the parametric g-

[^113]formula requires that one can correctly model both (a) the conditional probability of developing CHD conditional on risk factor history and (b) the conditional probability of current non-intervened on risk factors given past risk factor history; while (ii) valid estimation with MSMs requires that one (a) correctly model the conditional probability of the intervened on risk factor (smoking) given risk factor history and (b) the structural discrete time proportional hazard model. The parametric g-formula does not require that one correctly models the conditional probability of the intervened-on risk factor (smoking) given risk factor history because for the smoking intervention (1) the density $f_{d}\left(a_{j} \bar{l}_{i}\right.$, $a_{j}^{*}, \bar{a}_{j-1}, \overline{\mathrm{CHD}}_{j}=0, \bar{C}_{j}=0, \bar{D}_{j}=0$ ) does not actually depend on $a_{j}^{*}$; so no model for $f\left(a_{j}^{*} \mid \bar{l}_{i}, a_{j}^{*}, \bar{a}_{j-1}, \overline{C H D}_{j}=0, \bar{C}_{j}=0, \bar{D}_{j}=0\right)$ is required in (15) because the $a_{j}^{*}$ simply get summed out. Thus the models required for valid estimation of the effect of the smoking intervention (1) with the parametric $g$-formula have no overlap with the models required for valid estimation with MSMs. As a result, if estimates of the effect of the intervention agree under the two approaches, one can be somewhat confident that major model misspecification is absent. This represents a great advantage of having two independent methods of estimating the same intervention effect; each method can either reinforce or call into question the results obtained under the alternative method.

A subtle form of model misspecification when using the parametric gformula is due to collinearity among the repeated measures of the risk factors. Collinearity is not a problem for the prediction of CHD risk under no intervention but it may be a problem for predictions of CHD risk under certain interventions. For example, suppose that

1. in the logistic model for CHD risk at time 3, the odds ratio for log BMI at time 2 is 0.2 and the odds ratio for $\log$ BMI at time 1 is 5 , and because of collinearity among the repeated measures of BMI, neither estimate is significantly different from zero, but a chi-squared test on two degrees of freedom of the hypothesis that both coefficients are zero strongly rejects.
2. in the observed data, a subject has a quite elevated BMI of 29 at exams 1 and 2. Nonetheless, the predicted effect of the subjects BMI at exams 1 and 2 on CHD risk at exam 3 is null in the sense that the odds ratio comparing any level of BMI that is the same at the two exams with any other level of BMI also constant at the two exams on CHD risk at exam 3 is $0.2 \times 5=1.0$.

Under 1 and 2, the prediction of CHD risk for the subject under no intervention is quite stable (i.e. the confidence interval for the predicted probability is narrow). Now suppose we intervene to set BMI equal to 22 as soon as it is greater than 22 for times greater or equal than 2 (intervention 4 b ). The overall effect of BMI reduction is predicted to be
harmful since the odds ratio is $5^{\ln 29-\ln 22}=1.56$ compared to a subject with an observed BMI of 29 at both exams. However, in any given bootstrap sample, the odds ratios may be reversed due to sampling variability (because of the high correlation between BMI values over time). Therefore, in some bootstrap samples BMI would appear harmful, whereas in others BMI would appear to have a protective effect. The net result is the large variance we found for the risk (and risk ratio) of intervention $4 b$ and, to a lesser extent, of intervention 4 a (Table 28.1). The variance of the risk estimate for intervention 4 b was $39 \%$ greater than that of the risk estimate under no intervention.

To further assess issues of model misspecification, we conducted two separate sensitivity analyses: (i) we added a quadratic term to the linear term for $\log$ BMI in the CHD model, and (ii) we used cubic splines with 3 knots for log BMI in the CHD model. Both of these strategies slightly increased the variance of the estimates for intervention 4 a or 4 b (data not shown) and the risk ratio estimates did not change significantly.

The high variability arises because the correlation structure of the data is destroyed under the intervention. That is, there is no subject in the sample who has a BMI of 29 at occasion 1 and of 22 at occasion 2. Thus, it is not surprising and wholly appropriate that we are uncertain of what the result would be of an intervention that would create such subjects. Indeed, because there is no subject in the sample who has a BMI of 29 at occasion 1 and of 22 at occasion 2, the uncertainty we see in Table 28.1 for intervention 4 b is really an underestimate; it would have been more appropriate to admit that there was no data evidence with which to estimate the effect of such an intervention. Our apparent ability to estimate the intervention effect at all (albeit with great uncertainty) was wholly based on extrapolation under the, possibly incorrect, modelling assumption that the effect of BMI at the last 2 visits on CHD risk is linear on a logistic scale.

Some investigators, when faced with the problem of highly collinear repeated measures of exposures and the associated high variance of predicted interventions, decide to enter only one of the measures in their model, incorrectly arguing that the collinearity obscures the true exposure effect. To empirically examine some of the consequences of this flawed logic, we included only the most recent measure of each risk factor in the CHD model in Table 28.2 rather than the most recent two measures as in Table 28.1. The variance of the risk estimate for intervention 4 b was now only $24 \%$ greater than that of the risk estimate under no intervention. The difficulty, however, is that this estimate of the intervention effect can be badly biased if, in fact, the second most recent measure of BMI is in truth a risk factor for CHD controlling for the most recent BMI measure.

The lesson to be learned from the above discussion is that interventions that propose big and abrupt changes in the value of a risk factor that otherwise shows little variation over time (under no intervention)
will yield causal estimates with large variances and even these large variances will underestimate the actual uncertainty. This will be true regardless of the methodology used (i.e. MSMs or the parametric g-formula). Intervention involving these risk factors should be formulated in ways that do not imply big and abrupt changes. For example, reducing BMI by $10 \%$ (intervention 4 a ) resulted in a smaller variance than reducing BMI to the value 22 (intervention $4 b$ ).

### 8.2 Efficiency

The parametric g-formula yielded narrower confidence intervals for the risk ratios of interest than the MSM. This was expected based on underlying statistical theory.

### 8.3 Types of interventions

Marginal structural models are not useful to estimate risks under dynamic interventions (i.e. interventions that depend on the evolving values of time varying risk factors), such as interventions 4 a and 4 b . In those cases, the g-formula or structural nested models are needed.

A related subtle limitation of MSMs is that they cannot estimate the risk under no intervention in the presence of effect modification by time dependent non-intervened-on risk factors. This is so because IPTW estimation of a MSM effectively creates a pseudo-population in which the probability of receiving exposure does not depend on one's history of time dependent non-intervened-on risk factors. To clarify this point, we consider the following two scenarios:

1. Exposure is assigned to those who actually received it in the observed data.
2. Exposure is assigned to random subjects (in the same proportion as in the original population).

The proportion of CHD in both scenarios will be equal only in the absence of effect modification. A MSM provides estimates of CHD risk for scenario 2 but not for scenario 1. One consequence of this limitation is that, when using MSMs, we lack a way to detect gross model misspecification by comparing observed and estimated risk under no intervention. In our example, the observed and estimated risks under no intervention were close, so we assumed that effect modification was not an important issue and the relative risks in Table 28.3 are good approximations. Note that the no-intervention MSM results represent scenario 2 while the empirical CHD risk in the cohort represents scenario 1.

Because of these same reasons, we needed to slightly modify the meaning of interventions 1 and 2 when using a MSM. Rather than allowing non smokers to follow their own observed history after baseline (as was done in Tables 28.1 and 28.2), we forced them to remain as non-
smokers. This made little substantive difference as very few subjects initiated smoking after baseline.

### 8.4 Censoring

We defined as censored all subjects that were either lost to follow-up before the last study visit or died from competing causes (i.e. not CHD). Our causal estimates can be interpreted as the CHD risk under each intervention had censoring been abolished (i.e. had nobody been lost to follow-up or died from competing causes), provided there is no unmeasured confounding and censoring is ignorable in the sense that the conditional cause-specific hazard of being censored at $k$ among subjects alive and uncensored up to $k$ does not depend on the time $T$ to CHD given both $\bar{A}(k-1)$ and the time-dependent covariate $\bar{L}(k-1)$ history prior to $k$. However, one might be interested in the CHD risk had censoring by loss to follow-up, but not by competing causes of death, been abolished, especially because one may feel that the time $T$ to CHD were deaths from competing causes abolished is not a well-defined counterfactual quantity. For example, imagine a cohort of 100 people with 10 CHD cases, 20 deaths from other causes, and 70 subjects alive at the end of follow-up. If censoring from other causes was completely independent of failure and censoring by loss to follow-up, our CHD risk estimate would be $10 / 80=12.5 \%$ whereas the risk estimate had other causes of death not been abolished is $10 / 100=10 \%$. Of course, these two risks would only differ substantially if a large proportion of people died from competing causes, which is not the case in our data. We could easily adapt our methods to estimate the effect of interventions when deaths from other causes are included rather than eliminated.

In summary, estimation of non-dynamic interventions should be done both with MSMs and with the parametric g-formula, as agreement between the results is important evidence of lack of major model misspecification. MSMs are only useful to estimate the effect of non-dynamic interventions. The g-formula and structural nested models should be used to estimate the causal effect of dynamic interventions. In future work, we plan to compare $g$-formula and structural nested models based estimates of the effect of dynamic interventions in a manner similar to the comparisons of g-formula- and MSM-based estimates of nondynamic regimes reported here.

## 9. Conclusions

We have tried to show why it is that even with the high quality longitudinal data collected in the Framingham Offspring Study, valid estimation from observational data of the effect of considered interventions requires one to make a large number of unverifiable assumptions that will never hold exactly and may not even hold approximately. In most of the world and for many interventions of interest, relevant high quality
longitudinal data are unavailable, compounding the difficulties. Even if we succeeded in validly estimating the effect of simultaneous interventions on smoking, LDL, BMI and alcohol among the subjects in the Framingham Offspring Study, the question of how to extrapolate such results to other populations would remain unresolved. In this chapter we have stressed the large number of untestable assumptions that must be fulfilled to obtain valid estimates of causal effects and the improbability that all of them hold. We have not done so to discourage attempts to prioritize among potential interventions. Such prioritizing is, and will continue to be, done implicitly or explicitly every day. Our goal was simply to try to help the process by highlighting some of the central issues and potential biases that need to be carefully considered. It is a fact of life that deciding among potential interventions must be done-and must be done under great uncertainty. Methods for making decisions under uncertainty are well established, but the usefulness of such methods ultimately rests on an honest and comprehensive assessment of the uncertainties. It is our hope that this chapter will help in making such assessments.

## Chapter 29

# Conclusions and directions for FUTURE RESEARCH 

Alan D. Lopez, Majid Ezzati, Anthony Rodgers, Stephen Vander Hoorn and<br>Christopher J.L. Murray

The analyses of risk factors within a common analytical framework and using comparable methods as outlined in these volumes has ensured greater consistency and comparability in evaluating and using scientific evidence on major risks to health. At the same time, data and knowledge gaps identified in the analyses of these risks illustrate key areas of scientific enquiry necessary to better inform policies and programs that aim to prevent disease by reducing risk factor exposure. The principal findings were discussed in individual risk factor chapters, as well as in those that presented summary results for individual risk factors (chapter 26) and for the joint effects of multiple risks (chapter 27). In this chapter, we use these findings to describe broadly how the analyses might affect pubic health practice as well as research on risk factors.

The analyses of the selected risk factors considered in this work, based on comprehensive reviews of available evidence on exposure and hazards, suggest that a small number of risks, such as childhood and maternal underweight and unsafe sex, accounted for a very large contribution to global loss of healthy life. Further, several risks, such as high blood pressure, tobacco and alcohol, have relative prominence in regions at all stages of development. While reducing all of the above risks to their theoretical minima may not be possible using current interventions, the results illustrate that disease prevention by addressing known distal and proximal risk factors can provide substantial, and under-appreciated, public health gains.

Treatment of established disease will always have a role in public health, especially in the case of diseases such as tuberculosis where treatment contributes to prevention. At the same time, the current devotion of a disproportionately small share of resources to prevention by reducing exposure to major known risk factors, through personal and nonpersonal interventions, should be reconsidered in a more systematic way in the light of this evidence.

Beyond their total hazard, the distributions of risks in a population have major implications for prevention strategies. Risk typically increases along a continuum of exposures. Dichotomous labels such as "hypertensive" and "normotensive" are therefore not a description of the health consequences of risks, but rather an operational convenience. In fact, the "deviant minority" (e.g. hypertensives) who are considered to be at high risk are only part of a risk continuum, rather than a distinct group, leading to one of the most fundamental axioms in disease prevention across risk factors: "a large number of people exposed to a small risk may generate many more cases than a small number exposed to high risk". Rose (1992) pointed out that wherever this axiom applies (see chapter 26 for possible exceptions), a preventive strategy focusing on high-risk individuals will deal only with the margin of the problem and will not have any impact on the large proportion of disease occurring in the large proportion of people who are at moderate risk.

While a high-risk approach may be more appropriate to the individuals and their physicians at any point in time, treating prevention as managing individual, high-risk crises can only have a limited effect at the population level and over long time periods. This is particularly relevant in the context of efforts to improve global health by addressing multiple diseases and risk factors, many of which exhibit continuous associations with disease outcomes. Focusing on high-risk individuals does not alter the underlying causes of illness, relies on having adequate discriminative ability to predict future disease, and requires continued and expensive screening for new high-risk individuals. In contrast, population-based strategies that seek to shift the whole distribution of risk factors have the potential to control population incidence. Such strategies aim to make healthy behaviours and reduced exposures the social norm and thus lower risk in the entire population.

Our exploration of the joint contributions of multiple risk factors suggests that 20 leading risks contributed to considerable loss of healthy life in different regions of the world. In particular, for some of the leading global diseases (e.g. acute lower respiratory infections, diarrhoea, lung cancer, ischaemic heart disease and stroke), substantial proportions were attributable to these selected risk factors. Removing the leading 20 risk factors from among those studied here would not only have resulted in a 9.3 -year ( $17 \%$ ) gain in global healthy life expectancy in 2000 , but also accounted for some of the interregional healthy life expectancy (HALE) differences. The analysis showed that even populations with currently high healthy life expectancy (e.g. developed regions of the Western Pacific and Europe) could further benefit considerably from risk reduction. These results provide a guide for achieving potential gains in (healthy) life expectancy that have been estimated statistically from past trends (Oeppen and Vaupel 2002; Riley 2001) through disease prevention by reducing known risks. The results for multiple risk factors further emphasize that for more effective and affordable implementation of a
prevention paradigm, policies, programmes and scientific research should acknowledge and take advantage of the interactive and correlated role of major risks to health, across and within causality layers. This could be an important step in addressing health inequalities, many of which may arise from concentration of major risks among specific socioeconomic groups.

Health research has at times focused on topics which, while scientifically intriguing, have not always been motivated by broader population health consequences (Anonymous 2001; Gross et al. 1999; Horton 2003; Willet 2002). The collation of evidence on exposure and hazard for different risks in this book, and the existing data gaps have illustrated data and monitoring needs for better quantification of important risks.

Research needs include more detailed and better quality data on exposure to most risks, using exposure variables that capture the full distribution of hazards in the population. Important examples include detailed data on alcohol consumption volume and patterns, dietary and biological markers for micronutrients, and better indicators for physical activity, indoor air pollution and occupational risks, all of which were quantified using indirect measures with limited resolution.

Assumptions and extrapolations were also needed in quantifying risk factor-disease relationships because of gaps in knowledge about the impact of some important global risk factors, particularly in developing countries. Examples include limited quantitative assessment of the hazards of specific sexual behaviours for HIV/AIDS or other sexually transmitted diseases, alcohol drinking patterns (Puddey et al. 1999) or exposure to indoor smoke from solid fuels (Ezzati and Kammen 2002). Equally important are detailed exposure data for risks that have been traditionally studied in developed countries, but have global importance and require more detailed data and hazard quantification in developing regions (e.g. alcohol and obesity).

The limited evidence on the effects of multiple risk factors and risk factor interactions also points to important gaps in research on multirisk and stratified hazards as also discussed in chapters 27 and 28. Including multiple causes in epidemiological research and risk assessment would allow estimating the benefits of reduction in combinations of distal and proximal exposures using multiple interventions (e.g. using education and economic tools to: i) promote physical activity or healthier diet coupled with screening and lowering cholesterol; and ii) address overall childhood nutrition and environment instead of a focus on individual components). In such research, risk factor groups should be selected based on both biological relationships and socioeconomic factors that affect multiple diseases, as discussed in chapter 27. Examples include those risk factors that are affected by the same policies and distal socioeconomic factors (e.g. malnutrition, unsafe water, sanitation and hygiene, indoor smoke from solid fuels and rural development policies) or affect the same group of diseases (e.g. all of the above for child-
hood infectious diseases; smoking, diet and physical activity for cardiovascular diseases). Once risk factors have been selected, the emphasis on reducing confounding should be matched by equally important enquiry into independent and mediated hazard sizes that are stratified based on the levels of other risks.

This is a substantial research agenda, and one for which some progress has been made over the past decades. Yet public health policy needs demand that much greater priority is given to research that more reliably and relevantly identifies the potential for prevention in all countries, including information on exposures and risks among subpopulations, especially among the least well off. Such research will undoubtedly provide a more compelling basis for the massive increase in preventive efforts worldwide that is required if the potential for health gains identified in this book is to be realized.

High-mortality developing subregions: AFR-D, AFR-E, AMRD, EMR-D and SEAR-D. Low-mortality developing subregions: AMR-B, EMR-B, SEAR-B, WPR-B. Developed subregions: AMR-A, EUR-A, EUR-B, EUR-C and WPR-A. This classification has no official status and is for analytical purposes only.

[^1]:    Example is applicable in illustrating gradual reduction in risk after exposure is reduced. The exact functional form of risk reduction may not necessarily be linear or exponential.
    For simplicity of notation, in all these cases we assume that: i) $L=0$. Including a lag is straightforward and can be done by replacing $t$ with ( $t-L$ ) in the corresponding formulas; and ii) there is no threshold for exposure. Including the threshold level is also straightforward using the $\operatorname{TRUE}(x(z) \geq X)$ function.

    In scenarios I, 3 and 4, where the effects of past exposure are absent or decline over time, risk reversibility can take place if exposure is reduced or removed. In scenario I there is
    immediate risk reversibility; in scenario 3 , there is full reversibility after time $K$; in scenario 4 , risk reversibility asymptotically approaches $100 \%$. In scenario 2 there is no risk reversibility and the effects of past exposure remain for an indefinite period.

[^6]:    a AMR-A, EUR-A and WPR-A, comprising the developed countries, are estimated to move further towards overweight and thus the underweight levels are forecasted to decrease stepwise to reach $0 \%$ by 2030. In WPR-A the estimated trend is driven by Japan (comprising $77 \%$ of the population aged 0-4 years in this subregion) and a national survey from 1978-8I already resulted with a low prevalence of underweight (3.7\%). Similarly the 1996 national survey in Australia (contributing 16\% of the population aged $0-4$ years in this subregion) reported $0 \%$ underweight. Appendix $C$ lists by country in alphabetical order publications backing the estimated trend towards overweight in AMR-A, EMR-A and WPR-A.
    b There are very scarce empirical data on the nutritional status of children aged $<5$ years in EUR-B and EUR-C. Based on the little information available to date (see Appendix D) the estimated trends of underweight until 2030 for these two subregions are expected to stagnate and decline, respectively. These overall trend estimations for EUR-B and EUR-C, however, are to be taken with caution.

[^42]:    a The exposure variable is smoking impact ratio (SIR), divided into three categories: I) SIR = 0; 2) $0<S I R \leq 0.5 ; 3) 0.5<S I R \leq 1.0$ as described earlier.
    b No risk is estimated for those aged $<30$ years.

[^43]:    a Developing countries include those in AFR, AMR-B, AMR-D, EMR, SEAR and WPR-B subregions.
    b Industrialized countries include those in AMR-A, EUR and WPR-A.
    c Figures in parentheses indicate the proportion of overall disease burden in each category attributable to smoking.

[^44]:    a Independent of intoxication or dependence.

[^45]:    a Prevalences are rounded to full percentages. Thus, a value of zero does not necessarily indicate that there are no people in a certain category, but may indicate a prevalence of less than 0.005 or $0.5 \%$.
    b Drinking categories are defined as follows:

[^46]:    a Pattern values were defined as follows:
    Risk factor: alcohol—second dimension: patterns of drinking.
    Units: range between I and 4; originally derived from optimal scaling and then based on addition of values of each pattern component (see Appendix A for details); subregional averages are populationweighted country averages.

    ## Definitions of categories of risk factor levels

    Level I: based on score of initial pattern components, with values in the lowest quartile reflecting least detrimental patterns of drinking such as least heavy drinking occasions, drinking with meals, no fiesta drinking and least drinking in public places.
    Level 2: based on score of initial pattern components, with values in the second lowest quartile.
    Level 3: based on score of initial pattern components, with values in the second highest quartile.
    Level 4: based on score of initial pattern components, with values in the highest quartile reflecting detrimental patterns such as many heavy drinking occasions, drinking outside meals, high level of fiesta drinking and drinking in public places.

[^47]:    Unstandardized residuals are the raw residuals as indicated by formula I above.

[^48]:    a This corresponds to coefficient $\beta_{3}$ in the model shown in the footnote.
    Level-I model
    Mortality rate $=\beta_{0}+\beta_{1}{ }^{\text {a }}(\mathrm{YEAR})+\beta_{2}{ }^{\text {a }}$
    $\left(\mathrm{GNP}\right.$-PC) $+\beta_{3}{ }^{\text {a }}$ (PC_ALCOHOL) $+\varepsilon$
    Level-2 model
    $\beta_{0}=\gamma_{00}+\mu_{0}$
    $\beta_{1}=\gamma_{10}+\mu_{1}$
    $\beta_{2}=\gamma_{20}$
    $\beta_{3}=\gamma_{30}+\gamma_{31}{ }^{\mathrm{a}}$ (PATB) $+\gamma_{32}{ }^{\mathrm{a}}($ PATC $)+\gamma_{33}{ }^{\mathrm{a}}$ (PATD) $+\mu_{3}$
    where
    mortality $=$ age-standardized IHD mortality
    YEAR = year of observation
    GNP_PC = GNP per capita
    PC_ALCOHOL $=$ per capita adult ( $\geq 15$ years) alcohol consumption
    PATB = dummy variable for pattern 2
    PATC = dummy variable for pattern 3
    PATD = dummy variable for pattern 4.

[^49]:    a Patterns of drinking were entered grand-mean-centred into the equation. Thus, the effect of per capita consumption displayed here is the effect at the grand mean of pattern, which is 2.51 in this sample.

[^65]:    NA Not applicable.

[^66]:    a These projections only address changes in biomass use, i.e. for India and China, rates of coal use are not predicted to decline in the same manner. Indeed, recent trends in China indicate that coal is being substituted by gas in urban households, but is substituting for biomass in many rural households (Fridley et al. 2001).
    b Children's exposures differ from adult exposures at present in that they are modified by a different ventilation factor, since adults experience the health effects of exposures that took place before improvements in ventilation occurred. In the future, child and adult exposures will converge.
    c We assumed that the Chinese improved-stove programme would reach $90 \%$ penetration for biomass but that rates of coal use would not decrease (Goldemberg et al. 2000). When estimating exposure, the ventilation factor for China was therefore fixed at 0.25 for both adults and children, making the exposures of these two groups the same.

    c Summary of data from Ory et al. (1997) (India) and Toroptsova et al. (1995) (Russian Federation).

[^83]:    a Asbestos exposure is the most important cause of mortality from mesothelioma. Cause-of-death statistics coded in ICD-IO allow direct estimation of the total number of mesothelioma deaths. Using this method, recent studies suggest that each year there are about 700 malignant mesothelioma deaths in Australia (Leigh and Driscoll 2003), 700 in Japan (Furuya et al. 2003), 2600 in the United States (Price and Ware 2004), and 4000 in Europe (Peto et al. 1999). A large proportion of these deaths are undoubtedly caused by asbestos exposure, primarily work-related. Combining estimates of asbestos exposure in all 14 subregions with hazards obtained from these studies would result in an estimate of more than 40000 mesothelioma deaths caused by asbestos exposure in the world. Of these preliminary estimates, about 9000 occur in developed countries (AMR-A, EUR and WPR-A), 9000 in SEAR-D, and 16000 in WPR-B. These estimates are subject to uncertainty, especially in developing countries where ICD-IO cause-of-death data and detailed data on history of asbestos exposure are not available. These preliminary estimates are currently undergoing further refinement by authors. Preliminary estimates also indicate that there may have been approximately 9000 deaths from silicosis, 7000 deaths from asbestosis and 14000 deaths from coal workers' pneumoconiosis as a result of exposure to occupational dusts (silica, asbestos and coal dust) in 2000.
