# Comparative Quantification of Health Risks 

Global and Regional Burden of Disease Attributable to Selected Major Risk Factors

Volume 1

## Edited by

Majid Ezzati, Alan D. Lopez, Anthony Rodgers and Christopher J.L. Murray

World Health Organization
Geneva

Comparative quantification of health risks : global and regional burden of disease attributable to selected major risk factors / edited by Majid Ezzati . . . [et al.].
$2 \mathrm{v} .+\mathrm{v} .3$ in 1 CD-ROM.
Contents: vol. 1, Childhood and maternal undernutrition-Other nutrition-related risk factors and physical activity-Addictive substancesvol. 2, Sexual and reproductive health-Environmental and occupational risks-Other selected risks-Distribution of risks by poverty-Data analysis and results-Multi-risk assessment.-Annex tables CD-ROM, Population attributable fractions, mortality and disease burden for selected major risk factors.

1. Risk factors 2. Cost of illness 3. Risk assessment
2. Comparative study I. Ezzati, Majid. II. Title: Global and regional burden of disease attributable to selected major risk factors.

ISBN 9241580313
(NLM Classification: WA 105)

## Contents

Volume 1
List of authors ..... vii
Foreword ..... xvii
Richard Peto
Preface ..... xix
Majid Ezzati, Alan D. Lopez, Anthony Rodgers and Christopher J.L. Murray

1. Comparative quantification of health risks: conceptual framework and methodological issues ..... 1
Christopher J.L. Murray, Majid Ezzati, Alan D. Lopez, Anthony Rodgers and Stephen Vander Hoorn
Childhood and maternal undernutrition
2. Childhood and maternal underweight ..... 39
Steven M. Fishman, Laura E. Caulfield, Mercedes de Onis, Monika Blössner, Adnan A. Hyder, Luke Mullany and Robert E. Black
3. Iron deficiency anaemia ..... 163
Rebecca J. Stoltzfus, Luke Mullany and Robert E. Black
4. Vitamin A deficiency ..... 211
Amy L. Rice, Keith P. West Jr. and Robert E. Black
5. Zinc deficiency ..... 257
Laura E. Caulfield and Robert E. Black
Other nutrition-related risk factors and physical inactivity
6. High blood pressure ..... 281
Carlene M.M. Lawes, Stephen Vander Hoorn, Malcolm R. Law, Paul Elliott, Stephen MacMahon and Anthony Rodgers
7. High cholesterol ..... 391
Carlene M.M. Lawes, Stephen Vander Hoorn, Malcolm R. Law and Anthony Rodgers
8. Overweight and obesity (high body mass index) ..... 497
W. Philip T. James, Rachel Jackson-Leach, Cliona Ni Mburchu, Eleni Kalamara, Maryam Shayeghi, Neville J. Rigby, Chizuru Nishida and Anthony Rodgers
9. Low fruit and vegetable consumption ..... 597
Karen Lock, Joceline Pomerleau, Louise Causer and Martin McKee
10. Physical inactivity ..... 729
Fiona C. Bull, Timothy P. Armstrong, Tracy Dixon, Sandra Ham, Andrea Neiman and Michael Pratt
Addictive substances
11. Smoking and oral tobacco use ..... 883
Majid Ezzati and Alan D. Lopez
12. Alcohol use ..... 959
Jürgen Rehm, Robin Room, Maristela Monteiro, Gerhard Gmel, Kathryn Graham, Nina Rehn, Christopher T. Sempos, Ulrich Frick and David Jernigan
13. Illicit drug use ..... 1109
Louisa Degenhardt, Wayne Hall, Matthew Warner-Smith and Michael Lynskey
Volume 2
Sexual and reproductive health
14. Unsafe sex ..... 1177
Emma Slaymaker, Neff Walker, Basia Zaba and Martine Collumbien
15. Non-use and use of ineffective methods of contraception ..... 1255
Martine Collumbien, Makeda Gerressu and John Cleland
Environmental and occupational risk factors
16. Unsafe water, sanitation and hygiene ..... 1321
Annette Prüss-Üstün, David Kay, Lorna Fewtrell and Jamie Bartram
17. Urban air pollution ..... 1353
Aaron J. Cohen, H. Ross Anderson, Bart Ostro, Kiran Dev Pandey, Michal Krzyzanowski, Nino Künzli, Kersten Gutschmidt, C. Arden Pope III, Isabelle Romieu, Jonathan M. Samet and Kirk R. Smith
18. Indoor air pollution from household use of solid fuels ..... 1435
Kirk R. Smith, Sumi Mehta and Mirjam Maeusezabl-Feuz
19. Lead exposure ..... 1495
Annette Prüss-Üstün, Lorna Fewtrell, Philip J. Landrigan and José Luis Ayuso-Mateos
20. Global climate change ..... 1543
Anthony McMichael, Diarmid Campbell-Lendrum, Sari Kovats, Sally Edwards, Paul Wilkinson, Theresa Wilson, Robert Nicholls, Simon Hales, Frank Tanser, David Le Sueur, Michael Schlesinger and Natasha Andronova
21. Selected occupational risk factors ..... 1651
Marisol Concha-Barrientos, Deborah Imel Nelson, Timothy Driscoll, N. Kyle Steenland, Laura Punnett, Marilyn Fingerhut, Annette Prüss-Üstün, James Leigh, Sang Woo Tak and Carlos Corvalan
Other selected risk factors
22. Contaminated injections in health care settings ..... 1803
Anja M. Hauri, Gregory L. Armstrong and Yvan J.F. Hutin
23. Child sexual abuse ..... 1851
Gavin Andrews, Justine Corry, Tim Slade, Cathy Issakidis and Heather Swanston
Distribution of risk factors by poverty
24. Distribution of risks by poverty ..... 1941
Tony Blakely, Simon Hales, Charlotte Kieft, Nick Wilson and Alistair Woodward
Data analysis and results
25. Estimating attributable burden of disease from exposure and hazard data ..... 2129
Stephen Vander Hoorn, Majid Ezzati, Anthony Rodgers, Alan D. Lopez and Christopher J.L. Murray
26. Mortality and burden of disease attributable to individual risk factors ..... 2141
Majid Ezzati, Anthony Rodgers, Alan D. Lopez, Stephen Vander Hoorn and Christopher J.L. Murray
Multi-risk factor assessment
27. Potential health gains from reducing multiple risk factors ..... 2167
Majid Ezzati, Stephen Vander Hoorn, Anthony Rodgers, Alan D. Lopez, Colin D. Mathers and Christopher J.L. Murray
28. Effects of multiple interventions ..... 2191
James Robins, Miguel Hernan and Uwe Siebert
29. Conclusions and directions for future research ..... 2231
Alan D. Lopez, Majid Ezzati, Anthony Rodgers, Stephen Vander Hoorn and Christopher J.L. Murray
Index ..... 2235
CD-ROM
Annex tables
Population attributable fractions, mortality and disease burden forselected major risk factors

## List of AUTHORS

H. Ross Anderson, St George's Hospital Medical School, University of London, London, England (randerso@sghms.ac.uk).

Gavin Andrews, WHO Collaborating Centre for Evidence in Mental Health Policy, St Vincent's Hospital, Sydney, Australia (gavina@crufad.unsw.edu.au).

Natasha Andronova, Department of Atmospheric Sciences, University of Illinois at Urbana-Champaign,Urbana, IL, USA (natasha@uiatma.atmos.uiuc.edu).

Gregory L. Armstrong, Division of Viral Hepatitis, Centers for Disease Control and Prevention, Atlanta, GA, USA (GArmstrong@cdc.gov).
Timothy P. Armstrong, Chronic Diseases and Health Promotion, World Health Organization, Geneva, Switzerland (armstrongt@who.int).

José Luis Ayuso-Mateos, Servicio de Psiquiatria, Hospital Universitario de la Princesa, Madrid, Spain (joseluis.ayuso@uam.es).

Jamie Bartram, Protection of the Human Environment, World Health Organization, Geneva, Switzerland (bartramj@who.int).

Robert E. Black, Department of International Health, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, USA (rblack@jhsph.edu).

Tony Blakely, Department of Public Health, Wellington School of Medicine and Health Sciences, University of Otago, Wellington, New Zealand (tblakely@wnmeds.ac.nz).

Monika Blössner, Nutrition for Health and Development, World Health Organization, Geneva, Switzerland (bloessnerm@who.int).

Fiona C. Bull, School of Sport \& Exercise Sciences, Loughborough University, Loughborough, Leicestershire, England (F.C.L.Bull@lboro.ac.uk).

Diarmid Campbell-Lendrum, Protection of the Human Environment, World Health Organization, Geneva, Switzerland (campbelllendrumd@who.int).

Laura E. Caulfield, Department of International Health, Center for Human Nutrition, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, USA (lcaulfie@jhsph.edu).

Louise Causer, European Centre on the Health of Societies in Transition, Department of Public Health and Policy, London School of Hygiene and Tropical Medicine, European London, England.

John Cleland, Centre for Population Studies, London School of Hygiene and Tropical Medicine, London, England (john.cleland@lshtm.ac.uk).

Aaron J. Cohen, Health Effects Institute, Boston, MA, USA (acohen@healtheffects.org).

Martine Collumbien, Centre for Population Studies, London School of Hygiene and Tropical Medicine, London, England (martine.collumbien@bigfoot.com).

Marisol Concha-Barrientos, Asociación Chilena de Seguridad, Gerencia de Salud, Santiago, Chile (gsamcb@gw.achs.cl).

Justine Corry, WHO Collaborating Centre for Evidence in Mental Health Policy, St Vincent's Hospital, Sydney, Australia (j.corry@unsw.edu.au).

Carlos Corvalan, Protection of the Human Environment, World Health Organization, Geneva, Switzerland (corvalanc@who.int).

Mercedes de Onis, Nutrition for Health and Development, World Health Organization, Geneva, Switzerland (deonism@who.int).

## Acknowledgements

This book is the product of more than four years of collaborative effort involving a large group of scientists across the world. This collaboration, led by the World Health Organization (WHO) and known as the comparative risk assessment (CRA) project, is one of the largest and most comprehensive research projects ever undertaken by WHO. The successful completion of the project, and this book, would not have been possible without great effort from a number of individuals and organizations.

More than 150 scientists, experts on the various risk factors and methodological aspects, reviewed the chapters in this book with great care, many of them multiple times, to ensure the scientific integrity, completeness and plausibility of the material and the conclusions. Many individuals and organizations donated their unpublished data to the project to fill some of the existing data gaps. Stephen Vander Hoorn played a key role in the design of the conceptual and methodological framework for the analysis. The literally millions of calculations leading to the disease burden estimates reported in these volumes are the result of his invaluable technical and statistical abilities and perseverance. Our colleagues David Evans, Emmanuela Gakidou, Mie Inoue, Carlene Lawes, Rafael Lozano, Doris Ma Fat, Susan Piccolo, Chalapati Rao, Joshua Salomon, Kenji Shibuya and Niels Tomijima, provided substantial motivational and intellectual support and assistance with the Global Burden of Disease databases. We are especially grateful to Marie-Claude von Rulach for her extraordinary efforts in helping to manage the network of contributors and the collaborators meetings, and for secretarial support. Technical discussions on burden of disease methodology with Colin Mathers and Claudia Stein contributed greatly to improving the scientific basis of the estimates.

The final editing and production of a book of this magnitude, with contributions from numerous authors, is a challenging and complex task. Kaarina Klint and Kai Lashley have managed that process with great care and commitment. Editorial assistance from Stanislava Nikolova, Anna Moore and Margaret Squadrani is highly appreciated. Our thanks also to our technical and copy editors Andrew Colborne, Heidi Mattock, Gillian Stanbridge and Frank Theakston for their efforts to ensure consistency of style across chapters originally written with varied disciplinary and personal styles. Colin Mathers, David Evans
and Ties Boerma generously and efficiently coordinated the production process in its final stages.

The initial concept of the cover artwork was developed by Saied Ezzati; the final arrangement of the cover design was done by Mark Forrest and Emmanuela Gakidou.

The research published in this book forms part of the larger Global Burden of Disease 2000 project, funded by a grant from the National Institute on Aging (PO1-AG17625). Their support is gratefully acknowledged.

## Foreword

During the twentieth century reliable cause-specific mortality statistics became available for many countries, culminating in the Global Burden of Disease project which, during the 1990s, provided estimates for different regions of the world (with, obviously, varying degrees of reliability) of the numbers of deaths due to major diseases, and of the amounts of "disability-adjusted" loss of healthy life from those diseases. The present study goes further, and seeks to estimate the amounts of death and disability due to the main avoidable causes of those diseases. Its preliminary conclusions underlay the 250-page World Health Organization report on "Reducing Risks" (2002), the aim of which was to summarize, for the first time, the amount of death and disability in each of 14 subregions of the world that is attributable not to particular diseases, but to particular avoidable risk factors.

Such attributions of causality throw up, of course, many more difficulties than were encountered in the previous studies of the Global Burden of Disease, which merely tried to classify deaths by the one main disease (or type of accident or violence) that underlay them. For, one death may have several avoidable causes. For example, if a poorly nourished child dies of measles, should "the cause" be thought of as exposure to the virus, or as the lack of measles vaccination (in that child or in the community), or as the poor diet (low in protein, energy and certain micronutrients) that prevented recovery from the illness? The most appropriate answer, if we want to prevent such deaths, is that each of these factors should be thought of as "a cause" of a certain proportion of the childhood deaths from measles. That is what the authors of the World bealth report 2002 tried to do, and in the present much more detailed series of monographs they explain to the interested (or disputative) reader much more about their main conclusions, and about how they reached those conclusions. This is important, because over the years some of the conclusions may need to be revised, as more detailed studies are undertaken or as exposure and disease patterns evolve.

For many decades it has been recognized increasingly clearly by those concerned with global health that much can affordably be achieved even in relatively poor countries if resources are directed to the major diseases of childhood and early adult life, and more recently the affordable avoidability of much other adult mortality and morbidity has been recognized
(see The Health of Adults in the Developing World). Ten years ago, the 1993 World Bank report, Investing in health (together with its companion volume, Disease Control Priorities in Developing Countries) was extremely influential in consolidating these ideas and getting them accepted, and acted upon, by the major international economic institutions.

But, any such cost-effectiveness calculations require, among other things, reliable estimates of effectiveness, and the present report goes further than any other in providing estimates of just how much mortality and morbidity could be avoided by addressing particular causes of disease. In many parts of the world (the main exceptions being where political disruption or HIV predominate) the risk of premature death has been reduced by more than half over the past few decades, and premature death can be halved again over the next few decades if the major intervention options are pursued to control disease and injury, and their causes.

This book will greatly facilitate such progress. It is well organized, stimulating and is an important part of a political and scientific process that is already preventing many millions of deaths a year, and will prevent many more millions of deaths a year in the future.

Sir Richard Peto
Professor of Medical Statistics and Epidemiology
University of Oxford, England

## Preface

A clear understanding of the role and relative magnitude of diseases, injuries and their underlying causes-and effective and affordable interventions to reduce them-should guide policies and programmes for health development. Over the centuries, the health of populations has improved because science has helped us understand the main causes of disease affecting large populations, and how technologies or programmes can be delivered to reduce hazards among those affected or at risk.

While the monitoring and analysis of diseases and mortality in populations has been largely undertaken by actuaries and demographers, much of the work on causes of disease has emanated from research in fields such as epidemiology, toxicology and physiology, which focus on micro-level analysis. By its very nature, this research has quantified hazards in the study population, with its specific characteristics. This body of knowledge has had tremendous application in reducing the established causes of disease, from smoking to iodine deficiency, in many populations. The broader, policy-relevant issue of population effects of exposure to risks, however, has remained under-explored relative to our documentation of established diseases. Thus, while there has been decades of epidemiological research into the leading causes of many major diseases, from childhood diarrhoea to ischaemic heart disease, there have been few attempts to estimate the population-level effects of various exposures, either for specific countries and groups of countries, or for the world and its major regions.

During the last quarter of the twentieth century, a number of works have addressed both the methodological and empirical aspects of population-wide effects of major causes of diseases. Examples include the development of cancer risk models and methods to forecast the health of ageing populations based on their causal determinants, and the estimates of mortality due to risk factors such as smoking, asbestos and childhood malnutrition. This gradual establishment of "risk assessment" or "risk quantification" has been driven partly by the academic curiosity of individual researchers and partly by the demands of regulatory agencies and public policy for better quantitative evidence on the health implications of certain risk exposures.

This book provides a comprehensive assessment of the health effects caused by a range of exposures that are known to be hazardous to human
health. Its origins lie in the expressed need by policy and advocacy groups for comparable data on risk factor exposure and effects in populations. The only previous attempt to quantify risk factor burden worldwide, the Global Burden of Disease (GBD) 1990 project, was affected by a lack of conceptual and methodological comparability across risk factors; the analysis of each risk was constrained by its own disciplinary tradition. It nonetheless stimulated debate about the crucial role of risk factor assessment as a cornerstone of the evidence base for public health action: for instance, the leading risk factor in 1990, malnutrition, accounted for substantially more disease burden worldwide than the leading cause of disease at that time, acute lower respiratory infections.

A key concern of the current work on risks to health is to provide a degree of conceptual and methodological consistency and comparability across risk factors. The results reported in this book, therefore, differ in a number of important ways from those of GBD 1990: a new analytical framework and consistent set of definitions on "risk factor exposure" have been used to enhance comparability; the number of exposures assessed has more than doubled; and the analyses have benefited from more recent and thorough research into causality and geographical variations in population exposures and health effects.

The scope of risks to health studied in this book covers many of the most important hazards to health addressed by various fields of scientific enquiry. Arguably, there are hundreds of risk exposures that are harmful to health; and there are important implications for better understanding the disease burden they cause across the world. We have selected only a relatively small number of exposures for quantification in this book, largely determined by the availability of scientific research about their prevalence and health effects in different parts of the world. It was also important to make choices about the definition of each risk factor. Given the close interrelationships among diet, exercise and physiological risks on the one hand, or among water, sanitation and personal hygiene on the other, the exact definition of what a "risk factor" is, itself requires careful attention. That a particular risk factor like dietary fat intake does not appear in this book does not, of course, imply that it is of limited relevance; or that exposure to lead has been assessed separately from urban air pollution does not override their close linkages. Rather, we have limited ourselves to risk factors for which there was good potential for satisfactory quantification of population exposure distributions and health effects using the existing scientific evidence and available data, and for which intervention strategies are available or might be envisioned to modify their impact on disease burden.

The chapters in Volumes 1 and 2 of this book fall into two broad categories: those that address specific risk factors, and those that provide conceptual, methodological or empirical links across risks. The book begins with a description of some of the important conceptual and methodological issues in quantifying risk factor burden in a consistent
and comparable framework. This is followed by twenty-two chapters, organized under six broad sections, each of which present the background and the scientific evidence and empirical findings for individual risks. These are followed by an attempt to quantify the distributions of some risks by poverty levels. While much is known about the relationship between poverty and health, it is undoubtedly too complex and population-specific to be adequately assessed in a single quantification effort. The research reported here is therefore limited to a simple mapping of risks by poverty, based on existing data. Following the risk factor chapters, the calculus of estimating the burden of disease attributable to each risk factor from exposure and hazard data is presented, followed by a chapter that summarizes the results for individual risk factors.

Many policies and programmes affect multiple risks simultaneously, motivating an assessment of the disease burden from multiple risk factors. The focus on joint exposures and hazards is particularly important because diseases and injuries are almost always caused by multiple risk factors, which may act together on disease processes, or have effects mediated through each other. We have therefore included two chapters on the joint effects of multiple risk factor exposures. The final chapter of the book provides conclusions and recommendations for future research, based on the analytical findings presented in the book, as well as the gaps in data and scientific knowledge that increased uncertainty in quantifying risk factor burden reported here.

The specific risk factor chapters have been grouped according to clusters of exposures likely to be of similar scientific or policy interest. Volume 1 begins with four chapters on childhood and maternal undernutrition, which collectively cause a significant proportion of the childhood infectious disease burden worldwide. With substantial reductions in child mortality over the past few decades in many countries, the focus of scientific enquiry has progressively moved to improving our understanding of the causes of disease and injury among adults. The next five chapters address the various distal (e.g. exercise), more proximal (e.g. overweight and obesity), and physiological (e.g. suboptimal cholesterol levels) risks that are clustered together under the label of nutrition and physical activity. The last section in Volume 1 and the first section in Volume 2, addictive substances and sexual and reproductive health, include the major lifestyle and behavioural risks that are widespread in many societies and, despite being the subject of scientific enquiry and public health intervention for decades, present a range of complexities in risk quantification.

The risk factors that are a part of the physical environment of households (e.g. indoor air pollution from household solid fuel use), communities (e.g. urban air pollution), or specific subgroups (e.g. occupational risk factors) are the next group of risks assessed in Volume 2. The next two chapters, childhood sexual abuse and contaminated medical injec-
tions, do not fall into any of the above broad categories and are presented independently. These two chapters, each representing a risk factor that affects multiple important diseases, illustrate the potential for risk assessment as an analytical tool for improving the public health evidence base across a wide spectrum of health concerns.

In each of the specific risk factor chapters, the authors have provided a definition of the risk factor and introduced an "exposure variable" that best reflects the distribution of hazards in the population. The complexity of disease causation mechanisms (e.g. sexual behaviour and sexually transmitted infections), and the limitations posed by available data and epidemiological studies (e.g. physical inactivity or indoor smoke from solid fuels) have been important factors in the choice of exposure variable. Coupled with this is the choice of a "theoretical-minimum-risk population exposure distribution", which can serve as a consistent baseline for assessing attributable disease burden across difference risks. For some risks such as smoking or childhood abuse, the theoretical-minimum-risk population exposure distribution is obviously zero exposure for the whole population; for others the choice of baseline exposure distribution is less obvious, either because zero exposure is not definable (e.g. blood pressure) or because it may not lead to the lowest risk level in some populations (e.g. alcohol). Each chapter includes current estimates of exposure distributions by age and sex for 14 epidemiological subregions. The chapters also examine in detail the evidence for health outcomes, including the evidence for causality and the estimates of hazard (disease-specific) associated with each level of exposure. Each chapter then concludes with summary results of the burden of disease and injury in 2000 attributable to the risk factor, and when possible using existing evidence and knowledge, estimates of projected future exposure to the risk.

The CD-ROM attached contains detailed tables on the various components of disease burden (i.e. deaths, years of life lost [YLL] due to premature mortality, and disability-adjusted life years [DALYs]) attributable to each risk factor by age, sex and the 14 epidemiological subregions of the world used by the World Health Organization (WHO) in the World health report 2002. The 191 Member States of WHO were divided into five mortality strata on the basis of their levels of child mortality (under five years of age) and 15-59-year-old male mortality. When these mortality strata are applied to the six WHO regions, they produce 14 epidemiological subregions, which are used throughout this book (Table 1).

This book is the culmination of over four years of scientific enquiry and data collection, collectively known as the comparative risk assessment (CRA) project, coordinated by WHO and involving over 100 scientists worldwide. The book is also one of the several planned outputs of the GBD 2000 project which includes multiple analytical and empirical perspectives on global population health. The importance of the collaborative effort in the CRA project goes beyond having leading

## Table I The 14 GBD epidemiological subregions

| WHO region | Mortality stratum ${ }^{\text {a }}$ | Countries |
| :---: | :---: | :---: |
| AFR | D | Algeria, Angola, Benin, Burkina Faso, Cameroon, Cape Verde, Chad, Comoros, Equatorial Guinea, Gabon, Gambia, Ghana, Guinea, GuineaBissau, Liberia, Madagascar, Mali, Mauritania, Mauritius, Niger, Nigeria, Sao Tome and Principe, Senegal, Seychelles, Sierra Leone, Togo |
|  | E | Botswana, Burundi, Central African Republic, Congo, Côte d'lvoire, Democratic Republic of the Congo, Eritrea, Ethiopia, Kenya, Lesotho, Malawi, Mozambique, Namibia, Rwanda, South Africa, Swaziland, Uganda, United Republic of Tanzania, Zambia, Zimbabwe |
| AMR | A | Canada, Cuba, United States of America |
|  | B | Antigua and Barbuda, Argentina, Bahamas, Barbados, Belize, Brazil, Chile, Colombia, Costa Rica, Dominica, Dominican Republic, El Salvador, Grenada, Guyana, Honduras, Jamaica, Mexico, Panama, Paraguay, Saint Kitts and Nevis, Saint Lucia, Saint Vincent and the Grenadines, Suriname, Trinidad and Tobago, Uruguay, Venezuela |
|  | D | Bolivia, Ecuador, Guatemala, Haiti, Nicaragua, Peru |
| EMR | B | Bahrain, Cyprus, Iran (Islamic Republic of), Jordan, Kuwait, Lebanon, Libyan Arab Jamahiriya, Oman, Qatar, Saudi Arabia, Syrian Arab Republic, Tunisia, United Arab Emirates |
|  | D | Afghanistan, Djibouti, Egypt, Iraq, Morocco, Pakistan, Somalia, Sudan, Yemen |
| EUR | A | Andorra, Austria, Belgium, Croatia, Czech Republic, Denmark, Finland, France, Germany, Greece, Iceland, Ireland, Israel, Italy, Luxembourg, Malta, Monaco, Netherlands, Norway, Portugal, San Marino, Slovenia, Spain, Sweden, Switzerland, United Kingdom |
|  | B | Albania, Armenia, Azerbaijan, Bosnia and Herzegovina, Bulgaria, Georgia, Kyrgyzstan, Poland, Romania, Serbia and Montenegro, Slovakia, Tajikistan, The former Yugoslav Republic of Macedonia, Turkey, Turkmenistan, Uzbekistan |
|  | C | Belarus, Estonia, Hungary, Kazakhstan, Latvia, Lithuania, Republic of Moldova, Russian Federation, Ukraine |
| SEAR | B | Indonesia, Sri Lanka, Thailand |

[^0]researchers for multiple risk factors working simultaneously on the same project. Rather, the interactions of these researchers, with a core network of scientists applying a common analytical framework and methods, has ensured greater consistency and comparability in using and evaluating scientific evidence across risks. As a result, our understanding of the comparative extent of disease burden caused by various exposures worldwide has advanced, and key areas of scientific enquiry necessary to better inform policies to reduce risks have been elucidated. Health advocates and those entrusted with policy and programme development to promote better health now have a more comparable empirical assessment of the hazards to health worldwide, and thus a firmer basis for public health action. We hope that the methodological and empirical findings reported in these volumes will indeed serve as the stimulus for global, regional and national policy action to reduce key hazards to health for decades to come.

## Chapter I

# Comparative quantification <br> OF HEALTH RISKS: CONCEPTUAL <br> FRAMEWORK AND <br> METHODOLOGICAL ISSUES 

Christopher J.L. Murray, Majid Ezzati, Alan D. Lopez, Anthony Rodgers and<br>Stephen Vander Hoorn

## 1. Introduction

Detailed description of the level and distribution of diseases and injuries, and their causes are important inputs to strategies for improving population health. Data on disease or injury outcomes alone, such as death or hospitalization, tend to focus on the need for palliative or curative services. Reliable and comparable analysis of risks to health, on the other hand, is key for preventing disease and injury. A substantial body of work has focused on the quantification of causes of mortality, and more recently, the burden of disease (Murray and Lopez 1997; Preston 1976). Analysis of morbidity and mortality due to risk factors, however, has frequently been conducted in the context of methodological traditions of individual risk factors and in a limited number of settings (Kunzli et al. 2000; Leigh et al. 1999; McGinnis and Foege 1993; Peto et al. 1992; Single et al. 1999; Smith 2000; Smith et al. 1999; Willet 2002). The principal conclusions of this body of work are as follows:

- Causal attribution of morbidity and mortality to risk factors has been estimated relative to zero or some other constant level of population exposure. This single, constant baseline, although illustrating the total

Population Health Metrics, 2003, 1:1.
magnitude of the risk, does not provide visions of population health under other alternative exposure distribution scenarios.

- Intermediate stages and interactions in the causal process have not been considered in the causal attribution calculations. As a result, attributable burden could be calculated only for those risk factor-disease combinations for which epidemiological studies had been conducted (often limited to individual risks).
- Causal attribution has often taken place using exposure and/or outcome at one point in time or over an arbitrary period of time (for notable exceptions see the works of Manton and colleagues [Manton et al. 1993b, 1994; Yashin et al. 1986] and Robins [Robins 1986, 1987, 1999a, 1999b; Robins and Greenland 1991; Robins et al. 1999]). Such "counting" of adverse events (such as death) has not been able to clearly distinguish between those cases that would not have occurred in the absence of the risk factor and those where occurrence would have been delayed. More generally, this approach is unable to consider the accumulated effects of time-varying exposure to a risk factor-in the form of years of life lost prematurely or lived with disability.
- The outcome has been morbidity or mortality due to specific disease(s) without conversion to a comparable unit, making comparison among different diseases and/or risk factors difficult.

To allow the assessment of risk factors in a unified framework while acknowledging risk-factor specific characteristics, the comparative risk assessment (CRA) module of the Global Burden of Disease (GBD) 2000 study is a systematic evaluation of the changes in population health which would result from modifying the population distribution of exposure to a risk factor or a group of risk factors (Murray and Lopez 1999). This unified framework for describing population exposure to risk factors and their consequences for population health is an important step in linking the growing interest in the causal determinants of health across a variety of public health disciplines from natural, physical, and medical sciences to the social sciences and humanities. In particular, in the CRA framework:

- The burden of disease due to the observed exposure distribution in a population is compared with the burden from a hypothetical distribution or series of distributions, rather than a single reference level such as the non-exposed population.
- Multiple stages in the causal network of interactions among risk factor(s) and disease outcome are considered to allow making inferences about combinations of risk factors for which epidemiological studies have not been conducted, including the joint effects of changes in multiple risk factors.
- The health loss due to risk factor(s) is calculated as a time-indexed "stream" of disease burden due to a time-indexed "stream" of exposure.
- The burden of disease and injury is converted into a summary measure of population health, which allows comparing fatal and non-fatal outcomes, also taking into account severity and duration.

It is important to emphasize that risk assessment, as defined above, is distinct from intervention analysis, whose purpose is to estimate the benefits of a given intervention or group of interventions in a specific population and at a specific time. Rather, risk assessment aims at mapping alternative population health scenarios to changes in distribution of exposure to risk factors over time, irrespective of whether exposure change is achievable using existing interventions. Therefore, while intervention analysis is a valuable input into cost-effectiveness studies, risk assessment contributes to assessing research and policy options for reducing disease burden by changing population exposure to risk factors.

Summary measures of population health (SMPH) and their use in burden of disease analysis are discussed elsewhere (Murray 1996; Murray et al. 2002). The next three sections of this chapter address the conceptual basis and methodological issues for the remaining three points above. We then discuss the sources and quantification of uncertainty.

## 2. Causal attribution of SMPH to

 RISK FACTORSMathers et al. (2002) describe two traditions for causal attribution of health determinants, outcomes, or states: categorical attribution and counterfactual analysis. In categorical attribution, an event such as death is attributed to a single cause (such as a disease or risk factor) or group of causes according to a defined set of rules (hence $100 \%$ of the event is attributed to the single cause or group of causes). The International Classification of Disease system's (ICD) attribution of causes of death (WHO 1992) and attribution of some injuries to alcohol or occupational conditions are examples of categorical attribution. In counterfactual analysis, the contribution of one or a group of diseases, injuries or risk factors to a summary measure of population health is estimated by comparing the current or future levels of the summary measure with the levels that would be expected under some alternative hypothetical scenario, including the absence of or reduction in the disease(s) or risk factor(s) of interest. This hypothetical scenario is referred to as the counterfactual (see Maldonado and Greenland 2002 for a discussion of conceptual and methodological issues in the use of counterfactuals).

In theory, causal attribution of a summary measure to risk factors can be done using both categorical and counterfactual approaches. For
example, categorical attribution has been used in attribution of diseases and injuries to occupational risk factors in occupational health registries (Leigh et al. 1999) and attribution of motor vehicle accidents to alcohol consumption. In general however, categorical attribution of SMPH to risk factors overlooks the fact that many diseases have multiple causes (Rothman 1976). The epidemiological literature has commonly used the counterfactual approach for the attribution of a summary measure to a risk factor, and compared mortality or disability from the current distribution of exposure to the risk factor to that expected under an alternative exposure scenario.

The dominant counterfactual exposure distribution in these studies has been zero exposure for the whole population (or a fixed non-zero level where zero is not possible such as the case of blood pressure when defined as presence or absence of hypertension). The basic statistic obtained in this approach is the population attributable fraction (PAF) defined as the proportional reduction in disease or death that would occur if exposure to the risk factor were reduced to zero, ceteris paribus (Cole and MacMahon 1971; Eide and Heuch 2001; Greenland 1984; Levin 1953; MacMahon and Pugh 1970; Miettinen 1974; Ouellet et al. 1979; Rockhill et al. 1998; Uter and Pfahlberg 2001). ${ }^{1}$ The attributable mortality, incidence or burden of disease due to the risk factor, $A B$, is then given as $A B=P A F \times B$ where $B$ is the total burden of disease from a specific cause or group of causes affected by the risk factor with a relative risk of $R R$ :

$$
\begin{equation*}
P A F=\frac{P(R R-1)}{P(R R-1)+1} \tag{1a}
\end{equation*}
$$

The exposed population may itself be divided into multiple categories based on the level or length of exposure, each with its own relative risk. With multiple ( $n$ ) exposure categories, the PAF is given by the following generalized form:

$$
\begin{equation*}
P A F=\frac{\sum_{i=1}^{n} P_{i}\left(R R_{i}-1\right)}{\sum_{i=1}^{n} P_{i}\left(R R_{i}-1\right)+1} \tag{1b}
\end{equation*}
$$

Although choosing zero as the reference exposure may be useful for some purposes, it is a restricting assumption for others. The contribution of a risk factor to disease or death can alternatively be estimated by comparing the disease burden due to the observed exposure distribution in a population with that from another distribution (rather than a single reference level such as non-exposed) as described by the generalized
"potential impact fraction" equation (Drescher and Becher 1997; Eide and Heuch 2001; Walter 1980).

$$
\begin{equation*}
P I F=\frac{\int_{x=0}^{m} R R(x) P(x) d x-\int_{x=0}^{m} R R(x) P^{\prime}(x) d x}{\int_{x=0}^{m} R R(x) P(x) d x} \tag{2a}
\end{equation*}
$$

where $R R(x)$ is the relative risk at exposure level $x, P(x)$ is the population distribution of exposure, $P^{\prime}(x)$ is the counterfactual distribution of exposure, and $m$ the maximum exposure level. The first and second terms in the numerator of Equation 2a therefore represent the total exposureweighted risk of mortality or disease in the population under current and counterfactual exposure distributions. The corresponding relationship when exposure is described as a discrete variable with $n$ levels is given by:

$$
\begin{equation*}
\text { PIF }=\frac{\sum_{i=1}^{n} P_{i} R R_{i}-\sum_{i=1}^{n} P_{i}^{\prime} R R_{i}}{\sum_{i=1}^{n} P_{i} R R_{i}} \tag{2b}
\end{equation*}
$$

In addition to relaxing the assumption of the no-exposure group as the reference, analysis based on a broader range of distributions has the advantage of allowing multiple comparisons with multiple counterfactual scenarios. Equation 2a can be further generalized to consider counterfactual relative risks (i.e. relative risk may depend on other risks, new technology, medical services, etc.). For example the relative risk of injuries as a result of alcohol consumption may depend on road conditions and traffic law enforcement. Similarly, people employed in the same occupation may have different risks of occupational injuries because of different safety measures. Therefore, a more general form of Equation 2 a is given by:

$$
\begin{equation*}
P I F=\frac{\int_{x=0}^{m} R R(x) P(x) d x-\int_{x=0}^{m} R R^{\prime}(x) P^{\prime}(x) d x}{\int_{x=0}^{m} R R(x) P(x) d x} \tag{2c}
\end{equation*}
$$

### 2.1 Counterfactual exposure distributions

Various criteria may determine the choice of the counterfactual exposure distributions. Greenland (2002) has discussed some of the criteria for the choice of counterfactuals, arguing that the counterfactuals should
be limited to actions that can be implemented (e.g. anti-smoking campaigns), rather than the effects of removing the outcomes targeted by those actions (e.g. smoking cessation) because, in practice, the implementation of counterfactuals for one risk factor or disease may affect other risks. The solution to Greenland's concern, however, is better analytical techniques for estimating joint risk factor effects, rather than abandoning non-intervention-based counterfactuals which, as argued by Mathers et al. (2002), is a limiting view. Estimating the contributions of risk factors to disease burden and the benefits of their removal, even in the absence of known interventions, can provide an understanding of their role in population health and visions of population health under different scenarios of risk factor exposure. This knowledge of risk factor effects can provide valuable input into public health policies and priorities, as well as research and development.

Murray and Lopez (1999) introduced a taxonomy of counterfactual exposure distributions that, in addition to identifying the size of risk, provides a mapping to policy implementation options. These categories include the exposure distributions corresponding to theoretical minimum risk, plausible minimum risk, feasible minimum risk and cost-effective minimum risk. Theoretical minimum risk refers to the exposure distribution that would result in the lowest population risk, irrespective of whether currently attainable in practice. Plausible minimum refers to a distribution which is imaginable, and feasible minimum is one that has been observed in some population. Finally, cost-effective minimum considers the cost of exposure reduction (through the set of known costeffective interventions) as an additional criterion for choosing the alternative exposure scenario.

In addition to illustrating the total magnitude of disease burden due to a risk factor, the theoretical-minimum-risk distribution (or the current difference between theoretical and plausible or feasible risk levels) can guide research and development resources towards those risk factors for which the mechanisms of reduction (i.e. interventions) are currently underdeveloped. For example, if the reduction in the burden of disease due to improved medical injection safety is high and the methods for risk reduction are well-known, so that plausible/feasible and theoretical minima are identical, then current policy may have to be focused on the implementation of such methods. On the other hand, if there are large differences between plausible/feasible and theoretical minima risk levels for blood lipids or body mass index (BMI) (Powles and Day 2002), then research on reduction methods and their implementation should be encouraged. For this reason the total magnitude of the burden of disease due to a risk factor, as illustrated by the theoretical minimum, provides a tool for considering alternative visions of population health and setting research and implementation priorities.

Biological principles as well as considerations of equity would necessitate that, although the exposure distribution for theoretical minimum
risk may depend on age and sex, it should in general be independent of geographical region or population. Exceptions to this are, however, unavoidable. An example would be the case of alcohol consumption, which in limited quantities and when drunk in certain patterns has beneficial effects on cardiovascular mortality, but is always harmful for other diseases such as cancers and accidents (Puddey et al. 1999). In this case, the composition of the causes of death as well as drinking patterns in a region would determine the theoretical-minimum-risk distribution. In a population where cardiovascular diseases are a dominant cause of mortality, the theoretical-minimum-risk exposure distribution may be nonzero with moderate drinking patterns, whereas in a population with binge drinking and a large burden from injuries the theoretical minimum would be zero. Feasible and cost-effective distributions, on the other hand, may vary across populations based on the current distribution of the burden of disease and the resources and institutions available for exposure reduction.

The above categories of counterfactual exposure distributions are based on the burden of disease in the population as a whole. Counterfactual exposure distributions may also be considered based on other criteria. For example, a counterfactual distribution based on equity would be one in which the highest exposure group (or the group with the highest burden of disease) would be shifted towards low exposure values. Further, such equitable counterfactual distributions for each risk factor may themselves be categorized into theoretical (most equitable), plausible, feasible and cost-effective as described above. Similarly, a counterfactual distribution that focuses on the most susceptible groups in the population is one that gives additional weight to lowering the exposure of this group. Therefore, by permitting comparison of disease burden under multiple exposure distributions based on a range of crite-ria-including, but not limited to, implementation and cost, equity and research prioritization-relaxing the assumption of a constant exposure baseline provides an effective policy and planning tool.

### 2.2 EXPOSURE DISTRIBUTION FOR THEORETICAL MINIMUM RISK

In one taxonomy, risk factors such as those in the GBD project (Ezzati et al. 2002; see also the risk factor chapters in this book) can be broadly classified as physiological, behavioural, environmental and socioeconomic. Some general principles that guide the choice of theoretical-minimum-risk exposure distribution for each category are:

1. Physiological risk factors: This group includes those factors that are physiological attributes of humans, such as blood pressure or blood lipids, and at some level result in increased risk. Since these factors are necessary to sustain life, their "exposure-response" relationship is J-shaped or U-shaped, and the theoretical-minimum-risk distribution is non-zero. For such risk factors, the choice of optimal exposure
needs to be based on empirical evidence from different scientific disciplines. For example, epidemiological research on blood pressure and cholesterol have illustrated a monotonically increasing dose-response relationship for mortality even at low levels of these risk factors (Chen et al. 1991; Eastern Stroke and Coronary Heart Disease Collaborative Research Group 1998; MacMahon et al. 1990; Prospective Studies Collaboration 1995). But, given the role of these factors in sustaining life, this relationship must flatten and reverse at some level. In the blood pressure and cholesterol assessment, a theoretical-minimum-risk exposure distribution with a mean of 115 mmHg for systolic blood pressure and $3.8 \mathrm{mmol} / \mathrm{l}$ for total cholesterol (each with a small standard deviation) were used (Ezzati et al. 2002). This distribution corresponds to the lowest levels at which the dose-response relationship has been characterized in meta-analyses of cohort studies (Chen et al. 1991; Eastern Stroke and Coronary Heart Disease Collaborative Research Group 1998; MacMahon et al. 1990; Prospective Studies Collaboration 1995). Further, these levels of blood pressure and cholesterol are consistent with levels seen in populations which have low levels of cardiovascular disease, such as the Yanomamo Indians (Carvalho et al. 1989) and rural populations in China (He et al. 1991a, 1991b), Papua New Guinea (Barnes 1965; Carvalho et al. 1989), and Africa (Mann et al. 1964). Although meta-analyses of randomized clinical trials have indicated that blood pressure and cholesterol levels may be lowered substantially with no adverse effects (LaRosa et al. 1999; Pignone et al. 2000), it is difficult to justify an optimal exposure distribution lower than that measured in population-based studies, since lower levels in individuals may be caused by factors such as pre-existing disease. Arguments from evolutionary biology would also support the choice of a lower bound on the optimal distribution based on historical survival of populations who are not substantially exposed to factors that raise blood pressure or cholesterol.
2. Behavioural risk factors: The exposure-response relationship for this group of risk factors may be monotonically increasing or J-shaped. For risk factors with a monotonic exposure-response relationship, such as smoking, the optimal exposure would be zero unless there are physical constraints that make zero risk unattainable. For example in the case of blood transfusion, there may be a lower bound on the safety of the blood supply process even using the best monitoring technology. With a J-shaped or U-shaped exposure-response relationship, the minimum risk would occur at the turning point of the exposure-response curve. An example of this is alcohol consumption in adult populations with high cardiovascular disease rates, since moderate consumption may result in a reduction in ischaemic heart disease (IHD) in some age groups (Corrao et al. 2000). With a

J-shaped exposure-response curve, similar to physiological risk factors, empirical evidence would have to be used to determine the theoretical minimum risk.

Finally, some behavioural risks are expressed as the absence of protective factors such as physical inactivity or low fruit and vegetable intake. In such cases, optimal exposure would be the level at which the benefits of these factors would no longer continue. With a monotonic exposure-response relationship or without detailed knowledge about a possible turning point, the theoretical-minimumrisk exposure distribution should be chosen based on empirical evidence about the highest theoretically sustainable levels of intake or exposure (for example very active life style or a purely vegetarian diet).
3. Environmental risk factors: The toxicity of most environmental risk factors is best described as a monotonically increasing function of exposure (potentially with some threshold). Therefore, the theoreti-cal-minimum-risk exposure distribution for this group would be the lowest physically achievable level of exposure, such as background particulate matter concentration due to dust.
4. Socioeconomic "risk factors": Socioeconomic status and factorssuch as income (including levels and distribution) and associated levels of poverty and inequality, education, the existence of social support networks, etc.-are important determinants of health, often through their effects on other risk factors. The effects of each of these factors on health are, however, highly dependent on other socioeconomic variables as well as the policy context, including accessibility and effectiveness of health and welfare systems. For this reason, the theoretical-minimum-risk exposure distribution, even if meaningfully defined, is likely to change over time and space depending on a large number of other factors. Given this heterogeneity, the effects of socioeconomic variables are best assessed relative to counterfactual distributions defined based on policy and intervention options in specific times and settings, as discussed by Greenland (2002).

## 3. Risk Quantification models

Prediction implicitly assumes the use of a conceptual model which infers the value of the variable of interest at a point in time or space based on knowledge from a different time, or another location. Predictive models can be divided along a continuum between aggregate and structural categories. A completely aggregate model uses the previous trend of the variable of interest as the basis for predicting its future value. A structural model, on the other hand, identifies the components-and the relationships among them-of the "system" that determines the variable of interest. It then uses the knowledge of the system for predicting the value of
the variable of interest. Most predictive models lie between the two extremes and use a combination of aggregate and structural modelling. ${ }^{2}$

Consider for example predicting the future population of a city or the future ambient concentration of a pollutant. An aggregate model would extrapolate the historical levels to predict future values. Even in this case the model may include some structural elements. For example, the model may use a specific functional form-linear, exponential, quadratic or logarithmic-for extrapolation which involves an assumption about the underlying system. A structural model, in the case of population prediction would consider the age structure of the population, fertility (which itself may be modelled using data on education and family planning programmes), public health variables and rural-urban migration (which itself can be modelled using economic variables). In the case of air pollution, a structural model may consider demographic variables (themselves modelled as above), the structure of the economy (manufacturing, agriculture or service), the current manufacturing and transportation technology and effects of research and development on new technology, the demand for private vehicles, the price of energy and the atmospheric chemistry of pollution. Once again, in both examples the models may include some aggregation of variables by using historical trends to predict the future values of individual variables in the system, such as funding for family planning or research and development of new technologies.

The comparative advantage of structural and aggregate models lies in the balance between theoretical precision and data requirement. Structural models offer the potential for more robust predictions, especially when the underlying system is complex and highly sensitive to one or more of its components. In such cases, a shift in some of the system variables can introduce large changes in the outcome, which may be missed by extrapolation (such as the discovery of antibiotics and infectious disease trends or the change in tuberculosis mortality after the HIV epidemic). Aggregate models, on the other hand, require considerably less knowledge of the system components and the relationships among them. These models can therefore provide more reliable estimates when such information is not available, especially when the system is not very sensitive to inputs.

### 3.1 Models for risk factor-disease RELATIONSHIP

Using the above aggregate, structural taxonomy, it is also possible to classify models that are used to predict changes in death or disease as a result of changes in exposure to underlying risk factors. Murray and Lopez (1999) described a "causal-web" which includes the various distal (such as socioeconomic), proximal (behavioural or environmental) and physiological and patho-physiological causes of disease, as shown in Figure 1.1. While different disciplinary traditions-from social sciences

Figure I.I Simplified schema for a causal-web illustrating various levels of disease causation

Note: Feedback from outcomes to preceding layers may also exist. For example, individuals or societies may modify their risk behaviour based on health outcomes.
and humanities, to the physical, natural and biomedical sciences-have focused on individual components or stages of these relationships, in a single multi-layer causal model with interactions the term "risk factor" can be used for any of the causal determinants of health (Mathers et al. 2002; Yerushalmy and Palmer 1959). ${ }^{3}$ For example, poverty, location of housing, lack of access to clean water and sanitation, and the existence of a specific pathogen in water can all be considered the causes of diarrhoeal diseases, providing a more complete framework for assessment of interventions and policy options. Similarly, education and occupation, diet, smoking, air pollution, physical activity, BMI and blood pressure are some of the risk factors at various levels of causality for cardiovascular diseases.

Compared to a causal-web, Equations 1 and 2 that use relative risk estimates from epidemiological methods (e.g. the Cox proportional hazard or other regression models) lie further towards aggregate modelling. In general, in such methods, relative risks are estimated so that they incorporate the aggregation of the various underlying relationship (ideally, but not always, controlling for the appropriate confounding variables $)^{4}$ without considering intermediate relationships as separate causal stages. On the other hand, if specified and estimated correctly, considering the complete set of causal pathways which include multiple

Figure I.2 A possible causal diagram based on established relationships for estimating the incidence of ischaemic heart disease

DBP Diastolic blood pressure.
Note: Other interactions may also be possible.
risk factors will allow making inferences about combinations of risk factors and risk factor levels for which direct epidemiological studies may not be available.

As discussed earlier, the appropriateness of the two approaches to estimation of attributable burden depends on the specific risk factor(s), outcomes and available data. For example, the relationship between smoking and lung cancer has been shown to be highly dependent on smoking intensity and duration which, with appropriate indicators of past smoking (Peto et al. 1992), can be readily estimated using the relative risk approach of Equations 1 and 2. Consider, on the other hand, the relationship among age, socioeconomic status and occupation, behavioural risk factors (such as smoking, alcohol consumption, diet, physical activity), physiological variables (such as blood pressure and cholesterol level) and IHD shown in Figure 1.2. Given the multiple complex interactions, IHD risk may be best predicted using a structural (causal-web) approach, especially when some risk factors vary simulta-
neously, such as smoking, alcohol and diet, requiring joint counterfactual distributions. Using a multi-risk model would also allow considering situations for which direct epidemiological studies may not have been conducted, such as the effects of physical activity on those people who have diets different from the study group or those who take medicine to lower blood pressure.

The health effects of global climate change provide another example where a structural approach to risk assessment may be appropriate. Economic activities (including manufacturing, agriculture and forest use, transportation and domestic energy use) affect the emissions of greenhouse gases (GHG). Changes in precipitation, temperature and other meteorological variables due to atmospheric GHG accumulation alter regional ecology, which in turn results in changes in agricultural productivity, quantity and quality of water, dynamics of disease vectors and other determinants of disease. All these effects are in turn modulated by local economic activities, land-use patterns and income (Patz et al. 2000; Reiter 2001; Rogers and Randolph 2000). A model based on the atmospheric physics/chemistry of GHG emissions and accumulation, climate models, plant and vector ecology and human activity might provide the optimal basis for the prediction of the health effects of climate change. ${ }^{5}$

## Specifying The CaUsal-WEB

Assuming for the moment no temporal dimension in the relationship between the different variables in the causal system (temporal aspects are discussed below), each layer of a causal-web may be characterized by the equation:

$$
\begin{equation*}
\mathbf{X}^{n}=f\left(\mathbf{B}\left(\mathbf{X}^{n-1}, \mathbf{X}^{n}\right), \mathbf{X}^{n-1}\right) \tag{3a}
\end{equation*}
$$

where $\mathbf{X}^{n}$ is the vector of the variables in the $n$th layer of the causal-web (which can be causal or output such as $\mathrm{D}, \mathrm{P}, \mathrm{PA}$, or O using the notation of Figure 1.1); $f$ is the functional form connecting the $(n-1)$ th layer to the $n$th layer; B is a matrix of coefficients for $f$ which itself may be dependent on the variables in the $(n-1)$ th and $n$th layers $\left(\mathbf{X}^{n-1} \text { and } \mathbf{X}^{n}\right)^{7}$ (as well as time as we discuss below).

The attributable fraction of disease or mortality due to a single risk factor in the causal-web is then obtained by integrating the outcome ( O ) over the current $(P(\mathbf{x}))$ and counterfactual $\left(P^{\prime}(\mathbf{x})\right)$ population distributions of exposure, as for Equation 2.

$$
\begin{equation*}
A F=\frac{\int_{P(x)} \mathrm{O}(\mathbf{x})-\int_{P(x)} \mathrm{O}(\mathbf{x})}{\int_{P(x)} \mathrm{O}(\mathbf{x})} \tag{4}
\end{equation*}
$$

### 3.2 JOINT RISK FACTOR CHANGES

The attributable fraction relationships described in Equations 1 and 2 are based on individual risk factors. Disease and mortality are however often affected by multiple, and at times correlated, risk factors (Rothman 1976; Walter 1980). Estimating the joint effects of multiple distal and proximal risks is particularly important because many factors act through other, intermediate, factors (Murray and Lopez 1999; Yerushalmy and Palmer 1959), or in combination with other risks. It is therefore important to consider how the burden of disease may change with simultaneous variations in multiple risk factors. Analysis of joint risk factor changes implicitly acknowledges that the disease causation mechanism involves multiple factors, and is therefore suited to a causalweb framework, with $P(\mathbf{x})$ and $P^{\prime}(\mathbf{x})$ in Equation 4 being the joint distributions of the vector of risk factors, $\mathbf{x}$. Alternatively, when using Equations 1 or 2, knowledge of the distribution of all relevant risk factors and the relative risk for each risk factor, estimated at the appropriate level of the remaining risk factors, ${ }^{8}$ is required. Therefore, in Equation $2 \mathrm{a}, R R$ and $P$ may represent joint risks and exposure distributions for multiple risk factors (Eide and Heuch 2001). In this case, the estimates from Equations 2a and 4 may in theory be identical.

## ADDITIVITY OF ATTRIBUTABLE FRACTION

Many users of risk assessment desire information characterized by additive decomposition. In other words, users would like to know what fraction of the disease burden is related to any risk factor or group of risk factors, independent of the changes in other risk factors. As discussed by Mathers et al. (2002), additive decomposition is a property of categorical attribution and, in general, not of counterfactual attribution because many diseases are caused by the interaction of multiple risk factors acting simultaneously and therefore can be avoided by eliminating any of these factors (Rothman 1976; Rothman and Greenland 1998; Yerushalmy and Palmer 1959). Consider for example infant and child mortality due to acute respiratory infections (ARI), which are especially high among malnourished children, as a result of exposure to indoor smoke from solid fuels (Rice et al. 2000; Smith et al. 2000). In this case, removal of either risk factor can reduce mortality, some of which can therefore be attributed to both factors. Similarly the risk of mortality due to cardiovascular diseases among some of those who are exposed to smoking, low physical activity and poor diet may be reduced by elimination of any combination of these risk factors. Counterfactual causal attribution of disease and injury to individual risk factors does not normally allow additive decomposition and the sum of attributable fractions or burdens for a single disease due to multiple risk factors is therefore theoretically unbounded.

Although epidemiologically unavoidable and conceptually acceptable, the lack of additivity presents additional policy complexity and implies great caution is necessary when communicating and interpreting the estimates of attributable fraction and burden. With multiple attribution, the reduction of one risk factor would seem to make other, equally important risk factors potentially irrelevant from the perspective with a limited scope on quantification. At the same time multi-causality offers opportunities to tailor prevention based on availability and cost of interventions. It also necessitates the development of methods to quantify the effects of joint counterfactual distributions for multiple risk factors.

## 4. Temporal dimensions of the risk FACTOR-DISEASE RELATIONSHIP

Both exposure to a risk factor and the health outcomes due to exposure include a time dimension. This can be described by a modified version of Equation 3 in which exposure and outcome as well as the model parameters (B) are dependent on time. In the following two sections we consider the temporal characteristics of exposure and health outcomes, respectively.

### 4.1 Temporal characteristics of exposure

With the exception of acute hazards (e.g. injury risk factors) exposure to a risk factor affects disease over a time period. As a result, the distributional transition between any two exposure distributions includes a temporal dimension as illustrated schematically in Figure 1.3. The transition path is of little importance if exposure changes over a short time interval, especially relative to the time required for the effect of exposure on disease. Over long time periods, however, there is sufficient time for contributions from the intermediate exposure values, and the actual path of transition may be as important as the initial and final distributions in determining the disease burden associated with change in exposure. For example, the effects of reducing the prevalence of smoking or exposure to an occupational carcinogen by half in a population would be markedly different if the change takes place immediately, gradually over a twenty-year period or after twenty years. Therefore, the health effects of exposure to many risk factors depend on the complete profile of exposure over time, and may be further accompanied by a time lag from the period of exposure. Also, for some risk factors there may be complete or partial reversibility, with the role of past exposure gradually declining.

To capture the effects of exposure profiles over time, we begin by considering the role of temporal dimensions of exposure at the level of individuals (or groups of individuals with similar exposure) before considering the whole population.

Figure I.3 A (three-dimensional) representation of a time-indexed distributional transition of population exposure to a risk factor, with a decreasing central tendency

Suppose that at time $T$ the relative risk of a disease, $R R$, for individuals exposed to a risk factor (compared to the non-exposed group) depends on the complete profile or stream of exposure between time $T_{0}$ and $T$, denoted by $x(t)$, with some lag, $L$, between exposure and effect. Then, there is some function, $f(x)$, which can be used to describe the contribution of exposure at any point in time between $T_{0}$ and $T$ to the relative risk ( RR ). In mathematical notation:

$$
\begin{equation*}
\left.R R(x(t))\right|_{T_{0}} ^{T}=R R\left(\int_{T_{0}}^{T} f(x(t-L)) d t\right) \tag{5}
\end{equation*}
$$

The quantity $\int_{T_{0}}^{T} f\left(x(t-L) d x\right.$ is an equivalent exposure ${ }^{10}$ between $T_{0}$ and $T$ and is dependent on: i) the profile of exposure (i.e. level of exposure at any point in time) described by $x(t)$; and ii) the contribution of previous exposure to current hazard characterized by $f(x)$, an accumulative risk function. ${ }^{11}$ Some common forms for the accumulative risk function, $f(x)$, are given in Table 1.1.
Table I.I Possible forms for the accumulative risk function, $f(x)$

| Accumulative risk function, $f(x)$ | Interpretation | Relative risk | Potential example |
| :---: | :---: | :---: | :---: |
| I. $f(x)=\left\{\begin{array}{lc}1 & \text { if } t=T \\ 0 & \text { otherwise }\end{array}\right.$ | RR depends only on current exposure, with no contribution from past exposure | $\left.R R(x(t))\right\|_{T_{0}} ^{T}=R R(x(T))$ | Instantaneous poisoning as a result of exposure to high levels of toxic chemicals; injuries or death in accidents due to binge drinking; infection with Hepatitis B or C as a result of an infected injection |
| 2. $f(x)=1$ | RR depends on the accumulated exposure (or average exposure if normalized with respect to exposure time), without any effects from the temporal distribution of exposure | $\left.R R(x(t))\right\|_{T_{0}} ^{T}=R R\left(\int_{T_{0}}^{T} x(t) d t\right)$ | Cancer risk from lifetime exposure to carcinogens which have no threshold level |
| 3. $f(x)=\left\{\begin{array}{cc}\frac{1}{K} & \text { if } t>T-K \\ 0 & \text { otherwise }\end{array}\right.$ | RR depends on current and past exposures. But the role of past exposure lasts for a limited time, $K$, and declines as a linear function of time | $\left.R R(x(t))\right\|_{T_{0}} ^{T}=R R\left(\int_{T_{0}}^{T} \frac{(t-T+K)}{K} x(t) d t\right)$ | Reduction in cardiovascular events after lowering blood pressure ${ }^{\text {a }}$ |
| 4. $f(x)=\mathrm{e}^{\alpha(t-T)}$ | RR depends on current and past exposures. But the role of past exposure decays as an exponential function of time | $\left.R R(x(t))\right\|_{T_{0}} ^{T}=R R\left(\int_{T_{0}}^{T} \mathrm{e}^{\alpha(t-T)} x(t) d t\right)$ | Reduction in cardiovascular events after lowering blood pressure ${ }^{\text {a }}$ |

[^1]The above framework can be extended from individuals to populations, by indexing the exposure profile $(x(t))$ to individuals (i.e. representing the exposure of the $i$ th individual as $x_{i}(t)$ ) and considering how the distribution of exposure in the population evolves over time. ${ }^{12}$ This in turn provides the population distributions of equivalent exposure (current or expected future and counterfactual) which form the basis of calculating attributable fractions (i.e. the terms in the numerator of Equations 2a, 2 b or 4 ).

It is reasonable to assume that if the exposure of one individual is greater than that of another over the whole exposure period (i.e. tracking) (Foulkes and Davis 1981), the equivalent exposure of the former is also greater than the latter. In other words, the accumulative risk function, $f(x)$, has the following property:

$$
\begin{equation*}
\int_{T_{0}}^{T} f\left(x_{i}(t)\right) d t>\int_{T_{0}}^{T} f\left(x_{j}(t)\right) d t \quad \text { if } \quad x_{i}(t)>x_{j}(t) \quad \forall t \in\left[T_{0}, T\right] \tag{6}
\end{equation*}
$$

With this property, if the ordering of individuals in the exposure distribution remains unchanged over time (i.e. the rank-order correlation of individual exposures equals 1 between different points in time), the equivalent exposure will also have a distribution with the same ordering of individuals.

The method used by Peto et al. (1992) for estimating mortality due to smoking implicitly uses such as framework. It is well known that the accumulated hazards of smoking depend on a number of variables including the age at which smoking began, number of cigarettes smoked per day and cigarette type. Such data however are extremely rare. To overcome this problem, Peto et al. (1992) used the smoking impact ratio, $S I R$, which uses population lung cancer rates as a marker for accumulated hazard of smoking, to estimate the relative risk of the accumulated smoking exposure corresponding to the population. In the above notation:

$$
\left.R R(\operatorname{smoking}(t))\right|_{T_{0}} ^{T}=R R\left(\int_{T_{0}}^{T} f(\operatorname{smoking}(t-L)) d t\right)=R R(S I R(T))
$$

The temporal profile of exposure for some risk factors may be more easily available than the range of indicators that are needed to estimate the accumulated hazards of smoking. For example, exposure to indoor smoke from solid fuels is likely to remain unchanged as long as household fuel and housing conditions remain the same. Therefore, estimating the effects of long-term exposure may require only knowledge of household fuel, housing and participation in cooking. Similarly, in the case of blood pressure, it is known that blood pressure follows a predictable age pattern (Tate et al. 1995; Yong et al. 1993), unless severely affected by a changes in social (stress), behavioral (diet or smoking)
or medical circumstances. In this case, the usual blood pressure of an individual reflects the history of the person's exposure. On the other hand, the patterns of fruit and vegetable consumption, smoking, or exposure to urban air pollution may change rapidly in countries with high rates of economic growth and urbanization, requiring more detailed data.

The above discussion is based on two implicit assumptions:

1. It considers the effects of exposure to a single risk factor over time. This approach may be appropriate for some risk factor-disease relationships (e.g. the effects of accumulated exposure to carcinogens with site-specific effects). But the single equivalent exposure cannot characterize other risk factor-disease relationships where risk factor interactions are important over time (e.g. physical activity, BMI, smoking and cardiovascular diseases). Extending this temporal dimension to multiple risk factors requires considering the accumulated effects of the vector of risk factors as well as their interactions. In this case, Equation 5 would be expressed in terms of the vector of risk factors of interest. Few epidemiological studies, however, have gathered the data needed for assessing accumulated interactive effects.
2. It considers exposure to each risk factor as an exogenous variable (i.e. intermediate exposure at any time, $x(t)$, is not affected by disease or other risk factors) whose accumulated effect can be captured in a single value using the risk accumulation function. For some risk factors, this assumption may not be valid since exposure to behavioural as well as environmental risk factors may be affected by knowledge of their current effects-individuals may change their diet or activity levels based on knowledge of their weight or blood pressure and governments may introduce regulations based on the level of various contaminants in air or water. ${ }^{13}$

Manton et al. (1993a, 1994) have relaxed these assumptions using a diffusion model for forecasting cardiovascular disease mortality in the United States of America. In this model, it is the change in the outcome at any time, $t$, that is modelled as a function of all the other variables in the system (i.e. other risk factors as well as outcomes) and their interactions. Using the notation of Equation 3:

$$
\begin{equation*}
d \mathbf{X}(t)=\mathbf{u}(\mathbf{X}(t), t) d t \tag{7}
\end{equation*}
$$

where $\mathbf{u}(\mathbf{X}(t), t)$ is a drift term whose value depends on the current value of all the variables in the system as well as their interactions (and can be described by a functional form similar to that in Equation 3). ${ }^{14}$ Methods for estimation of such models using longitudinal data are discussed by Robins (1997, 1999b).

### 4.2 Temporal characteristics of health outcomes

If the outcome variable used in causal attribution of disease and mortality to a risk factor only involves counting of adverse events (such as disease incidence or death), it is not possible to characterize those cases whose occurrence would have been delayed in the absence of the risk factor (Greenland and Robins 1988; Robins and Greenland 1989, 1991). A major shortcoming with this approach is that it does not take into account the accumulated effects of exposure-in the form of years of life lost prematurely or lived with disability. Parameterizing the above relationships by age (or birth cohort) would allow estimating the effects of exposure to a risk factor, not as an event without time dimension, but as an event at a certain age and time. More broadly, considering the timeindexed stream of health losses due to a risk factor requires using a timebased (and not event-based) SMPH.

Murray and Lopez (1999) have provided an additional temporal distinction for the burden of disease due to a risk factor by introducing the concepts of "attributable" and "avoidable" burden. Attributable burden is defined as the reduction in current and/or future burden of disease if past exposure to a risk factor had been equal to some counterfactual distribution. Avoidable burden is the reduction in the future burden of disease if the current or future exposure to a risk factor is reduced to a counterfactual distribution. Attributable and avoidable burden are shown graphically in Figure 1.4. While attributable burden is easier to measure and more certain, avoidable burden is more useful for policy purposes. The distinction between attributable and avoidable burden becomes less significant as the time between exposure to risk factor and effects on disease burden decreases. In this case, attributable burden is a good predictor of avoidable disease burden.

Figure 1.4 also illustrates a conceptual complexity in defining and estimating avoidable burden. Attributable burden is defined based on the difference between (accumulated) current exposure and a counterfactual. Measuring current exposure, while difficult and uncertain, is conceptually well defined. Avoidable burden, on the other hand, depends on the expectation of future exposure and a counterfactual, with the former being analogous to current exposure. Consider for example a population exposed to rising levels of air pollution or rates of obesity. In this setting, interventions that would maintain pollutant concentrations or BMI at their current levels would result in avoiding disease and mortality; they reduce exposure from what it would be in their absence. Therefore, avoidable burden (i.e. how much of future burden could be prevented) by definition requires estimates of future exposure (i.e. how much of future burden there is). Projecting future exposure in turn raises the need to provide a projection framework. To provide visions of public health under various intervention and policy scenarios we suggest that the future exposure level, with respect to which avoidable burden is

Figure I.4 Attributable and avoidable burden

estimated, be the expectation of exposure if the current policy and technological context were to continue, referred to as the "business-as-usual" exposure trend. Therefore avoidable burden is the burden of disease averted due to reduction in exposure to a risk factor beyond its expected trends. We emphasize that with this definition, avoidable burden is the difference between two exposure scenarios: the expectation of future trends (business-as-usual) and a reduction with respect to this trend towards theoretical minimum.

### 4.3 Cumulative vs period estimates of attributable and AVOIDABLE BURDEN

Although analytically inconsequential, the starting point and the duration of the time interval over which attributable or avoidable burden is reported has policy implications because reductions in various risk factors may provide health benefits that occur after short or long delays and last for different periods. Consider for example the health benefits of reductions in binge alcohol consumption, smoking and GHG emissions. Reducing binge drinking would result in immediate health benefits from a drop in alcohol-related accidents and injuries (as well as medium- and long-term benefits from reduction in other diseases). Lowering smoking will have some short- and medium-term benefits from reduction of acute respiratory diseases and cardiovascular disease as well as longer-term benefits from lowering cancers and chronic obstructive pulmonary disease (COPD). The benefits of policies that reduce climate change as a result of GHG emissions are likely to be heavily concentrated in the future.

Consider these examples of health benefits in terms of duration: the distribution of a drug that lowers blood pressure, or food aid to reduce malnutrition; and programmes that promote and sustain increased physical activity, the introduction of a new agricultural technology which results in higher food yields, or automotive technology which eliminates the use of leaded gasoline. While the benefits of all these interventions may be equally large and important for the current cohort, the first two actions have one-time health benefits (unless repeated) while the latter three are likely to last indefinitely.

The above discussion would suggest reporting the estimates of avoidable burden in multiple ways including both period (e.g. annual) and cumulative estimates, as well as over short and long time frames. The issue of future estimates and their policy relevance is further complicated by the growing uncertainty of estimates with increasing length of the estimation interval. Therefore, while it may be preferable to increase the prediction horizon, it is important to emphasize that long-term predictions are inherently more uncertain.

### 4.4 Discounting future risk and health effects

Individuals may discount consumption or welfare within their own lifespan and exhibit a preference for benefits today over the future. The theoretical and empirical arguments for and against individual discounting with specific emphasis on health, including the possibility of negative discount rates, are summarized elsewhere (Murray 1996; Murray and Acharya 2002) and are directly incorporated in the calculation of a summary measure of population health. In addition to individual discounting and discount rates, policies dealing with risk confront the issue of addressing benefits to different populations across time. As a result, these policies must address ethical and analytical dilemmas related to the valuation of current and future health and welfare, in the form of social discount rates (Kneese 1999). Discounting future risks, benefits and welfare has been a subject of great debate (Howarth 1996; Lind 1982; Portney and Weyant 1999; Schelling 1995; Toman 1999), motivating some economists to conclude that

> maybe the idea of a unitary decision-maker-like an optimising individual or a wise and impartial adviser-is not very helpful when it comes to the choice of policies that will have distant-future effects about which one can now know hardly anything. Serious policy choice may then be a different animal, quite unlike individual saving and investment decisions... "Responsibility" suggests something less personal (Solow 1999).

The arguments for and against discounting of future health and welfare, and their validity, have been discussed in detail elsewhere (Anand and Hansen 2002; Murray and Acharya 2002; Murray and Lopez 1996; Parfit 1984). According to one specific argument, "the disease eradication and health research paradox", not discounting future health would imply investing all of society's health resources in research programmes or programmes for disease eradication, which would result in an infinite stream of benefits, rather than in any programme that improves the health of the current generation. Such an excessive intergenerational "sacrifice" is a particularly powerful argument for discounting of future health (or more precisely for something that resembles discounting as we discuss shortly) (Parfit 1984). It is important to emphasize that this argument does not imply that future welfare or health is less valuable than current, but rather it uses discounting as a tool to avoid excessive sacrifice for the current generation, to the point of investing all resources in an infinite stream of future health. For this reason, Parfit (1984) argues that the issue of intergenerational distribution should be considered as an independent criterion, rather than explicitly discounting future benefits.

Koopmans (1960), Dasgupta and Mäler (1994) and Dasgupta et al. (1999), however, have shown that any preference-ordering defined over
a set of well-being paths over time can be represented by a numerical function with an apparently utilitarian form ${ }^{15}$ and therefore includes what resembles positive discounting of future well-being. We emphasize that this notion is simply a consequence of considering the paths of wellbeing (or temporal distributions), rather than a statement about the value of current or future welfare. With this formulation, Dasgupta and Mäler (1994) and Dasgupta et al. (1999) consider the implications of the choice of discount rate as a "derived notion", as opposed to a value judgement. Dasgupta and Heal (1974) and Solow (1974b) have shown that if wellbeing is a result of consumption of an exhaustible resource, a zero discount rate would imply investing all available resources for the benefit of future generations, and hence no current consumption. This is because each unit sacrificed by the first generation would yield a finite loss to this generation, but an infinite stream of benefits to future generations (Arrow 1999) which, without discounting, would always be larger than the one-time sacrifice. Although the first generation cannot sacrifice everything, ${ }^{16}$ the logical conclusion of this situation would be that "given any investment [for future benefits], short of the entire income, a still greater investment would be preferred" (Arrow 1999), or a potentially excessive intergenerational sacrifice (Murray 1996).

On the other hand, a positive discount rate would imply that in the long run consumption of resources should become zero. In this case, however, the additional requirement that well-being should never fall below a certain threshold would in turn require downward adjustment of the discount rate (Solow 1974a). The stricter requirement of nondeclining consumption and well-being would require a discount rate lower than the productivity of capital (Dasgupta and Mäler 1994). ${ }^{17}$ Based on these arguments, we suggest discounting of future attributable or avoidable disease burden due to risk factors, but with a low discount rate, to include the welfares of both current and future generations as described above.

## 5. Uncertainty

Quantitative risk assessment is always affected by uncertainty about the existence, magnitude and distribution of risk (Graham et al. 1988). Quantitative analysis of uncertainty greatly adds to the usefullness of the results because it shows not only the "best-estimate" of the magnitude and distribution of exposure to a risk factor, and the resulting burden of disease, but also the range of potential outcomes.

### 5.1 Sources of uncertainty in attributable fractions

Population distribution of Exposure
An important source of uncertainty in risk assessment is characterizing population distribution of exposure. Due to complexity and cost, for
most risk factors, exposure is measured only in small samples and in a limited number of settings. As discussed earlier, because a risk factor can be represented in different layers of causality, variables for which data are more readily available can be used as exposure proxies. The use of exposure proxies is sometimes also necessary because epidemiological studies have used such proxies in estimating hazard size. For example, anthropometric variables such as height-for-age or weight-for-age are used as indicators of childhood nutritional status; the presence of clean water sources or sanitary latrines as indicators of faecal-oral transmission of pathogens; concentration of particles as the measure of exposure to the various pollutants in ambient air, and so on. In addition to reduced data requirements, the use of such indirect indicators of exposure (or exposure scenarios [Kay et al. 2000]) may provide direct mapping to existing interventions. At the same time, these indicators, which are often more distal than actual exposure, do not capture the variability of exposure within each scenario, unless combined with other indicators which affect this variability (Ezzati et al. 2000). For example people using the same water source may experience different levels of faecal-oral transmission of pathogens due to different storage and hygiene behaviours. Therefore, the use of indirect exposure proxies results in additional uncertainty in exposure characterization.

Even with the choice of exposure proxies, extrapolation of exposure between different populations or age groups is often necessary. Such extrapolation (or spatial prediction) can be based on models as simple as using the average of subgroups with data for a whole population, or more complex prediction models. For example, urban air quality monitoring systems provide data on particle concentrations in some but not all cities in each region. Models to predict ambient concentrations of particulate matter based on energy consumption, number of vehicles and level of industrialization can be used to predict ambient air pollution levels for cities where data are not available. Similarly, the level of physical (in)activity in a population may be predicted from a model that uses rural-urban population distribution, income, education, distribution across occupational categories and available transportation modes in each geographical region. Each such extrapolation adds to the uncertainty of exposure distributions.

Finally, as we discussed earlier, for many risk factors, hazards are associated with accumulated effects of sustained exposure. Indicators of accumulated hazard for those risk factors with changing exposure such as smoking, urban air pollution or BMI, are needed but not always available. Further, few epidemiological studies have considered the role of a temporal profile of exposure on disease (see Peto 1986 for an example of an exception). Therefore even if longitudinal data on exposure prevalence were available, they could not always be used together with epidemiological studies that consider a single exposure variable-at the beginning or end of the follow-up period, for example. At the same time,
if the ordering of individuals in the exposure distribution remains unchanged over time (see above), risk estimates from epidemiological studies with similar ordering may be applicable, but result in additional uncertainty. ${ }^{18}$

## RISK FACTOR-DISEASE RELATIONSHIP

At the most fundamental level, quantifying the hazards associated with exposure to a risk factor requires identifying the diseases and injuries that are caused by a risk factor. The criteria for establishing disease causality have been the subject of interest and debate for over a century (summarized in Evans 1976, 1978; Hill 1965; National Research Council 1994; Yerushalmy and Palmer 1959). Epidemiological studies have successfully provided the basis for establishing causality between some risk factor-disease pairs. For other risk factor-disease combinations, where the measurement of exposure or disease has been difficult or the delay between exposure and health effects is very long, observational or experimental epidemiology has had less success in establishing causality (Evans 1976; Robins 1999a). For this reason, epidemiological evidence must often be complemented with inferences from other disciplines such as toxicology, physiology, parasitology and, increasingly, biophysics, in establishing disease causation.

Even when causality is established, the magnitude of the hazard due to a risk factor needs to be quantified. Although the statistical issues around establishing causality and estimating the effect size are similar (lack of causality is equivalent to zero excess risk) (Robins 1999a; Robins and Greenland 2000), in practice, with knowledge from multiple disciplines in establishing causality, it is often the latter that is the source of increased uncertainty in risk assessment. For example, the collectivity of scientific knowledge from disciplines such as economics and behavioural sciences, vector biology, physiology and bio-mechanics and epidemiology would confirm the possibility that climate change or socioeconomic inequality would increase disease, or whether the relationships between occupational factors or physical inactivity and lower back pain are causal. At the same time, risk assessment would require estimating the hazard magnitude for each of these relationships. Therefore, the complexity of the causal relationship, or lack of detailed data, would shift the debate from causality to hazard size.

Epidemiological studies that quantify hazards are often conducted in a limited number of settings, with emphasis on estimating the average effect size in the whole study group. While the robustness of relative risk measures has been confirmed for more proximal factors in studies across populations (Eastern Stroke and Coronary Heart Disease Collaborative Research Group 1998; Law et al. 1994), their extrapolation is an important source of uncertainty for more distal risks (e.g. child sexual abuse) or for those whose effects are heterogeneous (e.g. alcohol and injuries vs alcohol and cancer) and has received less attention in the
epidemiological literature (Horton 2000). For some risk factors, it is likely that the magnitude of the hazard may depend on the levels of other variables (i.e. effect modifiers). Therefore, in extrapolating the results of individual epidemiological studies or meta-analyses, the very strength of the original study-applicability to the average person-would be the source of uncertainty if the population to whom the effect size is extrapolated has characteristics which would result in effect modification (Britton et al. 1999; Horwitz et al. 1990, 1996, 1998). The impact of alcohol drinking patterns on cardiovascular disease risk estimates (Britton and McKee 2000; Puddey et al. 1999) is an example of the importance of considering factors that modulate and modify hazards in risk extrapolation.

## RISK Factor and disease correlations

Because multiple risks and disease are correlated (e.g. higher malnutrition, unsafe water, sanitation and hygiene, indoor smoke and childhood mortality in poor rural households in developing countries; higher smoking, BMI and occupational risks in developed countries [Thun et al. 2000]), estimating attributable fractions would require stratified (e.g. by other risk factors) prevalence as well as disease data. Lack of stratified data is another source of uncertainty, in general leading to the underestimation of effects in the presence of positive risk factor correlations (Greenland 1984).

### 5.2 Characterizing and quantifying uncertainty

Various taxonomies of uncertainty have been used in risk assessment (National Research Council 1994) including:

1. classification based on information type such as uncertainty in hazard identification, exposure assessment, exposure-response assessment, as discussed above;
2. classification based on uncertainty type such as randomness, true variability, and bias; and
3. classification based on the approach to handling uncertainty which divides uncertainty into parameter uncertainty and model uncertainty. Parameter uncertainty includes the uncertainty quantifiable using random-variable methods such as the uncertainty due to sampling and measurement error. Model uncertainty is due to gaps in scientific theory, measurement technology and data (National Research Council 1994). It includes uncertainty in the knowledge of causal relationships or of the form of the exposure-response relationship (threshold vs continuous, linear vs non-linear, etc.), the level of bias in measurement, etc. Defined broadly, model uncertainty also includes extrapolation of exposure or hazard from one population to another. Uncertainty in risk assessment is overwhelmingly dominated by model
uncertainty, which arises due to a lack of direct studies on exposure, hazard and background disease burden.
We distinguish between uncertainty, which is due to gaps in knowledge, methods or data, and variability, which is a real property of the world and itself may be known with certainty or with uncertainty. Variability can nonetheless be a source of uncertainty in the absence of population-specific data on exposure or the exposure-response relationship. For many risk factors, data on exposure distributions are available for a limited number of populations or demographic groups. The exposure distribution for other populations are then extrapolated from the available data based on some model. As discussed earlier, the extrapolation model may be as simple as using the population-weighted average of the existing data or more complex (based on a number of predictors). In such cases, the statistical uncertainty of the estimator (e.g. the $95 \%$ confidence interval of the mean or regression coefficients) is an underestimation of true uncertainty in predicted values due to the unexplained variability in the data. More complex models can increase the predictive power and therefore reduce uncertainty but even the most sophisticated models are unlikely to fully explain the variability of the data, resulting in residual uncertainty. Variability can also be a source of uncertainty in the estimation and extrapolation of exposure-response relationships or relative risks that are measured in a limited number of settings. In the presence of multiple estimates of hazard, it is common to use metaanalytical approaches to obtain an overall estimate. At the same time, the differences between various estimates may reflect true variability in effect size, especially if obtained from different populations, resulting in uncertainty in hazard estimates.

Parameter uncertainty can be readily included in quantitative analysis using random-variable statistical methods (Morgan and Henrion 1990). While we have discussed the various sources of uncertainty, the important issue of extrapolation of exposure and hazard using models requires new approaches to quantifying uncertainty in the presence of limited data. Quantitative analysis of model uncertainty, by definition, would require considering the uncertainty of the models and assumptions used (including assumptions about disease mechanism or data/ parameter extrapolation) using the methods of Bayesian statistics.

## 6. Conclusions

We have described a framework for systematic quantification of the burden of disease due to risk factors that attempts to unify the growing interest in health risks across a number of health, physical and social sciences. The key attributes of the framework, along with the corresponding methodological issues that arise in its application, are:

- comparing the burden of disease due to the observed exposure distribution in a population with the burden from a hypothetical distribution or series of distributions, rather than a single reference level such as non-exposed;
- considering the multiple stages of causality and interactions between risk factor(s) and disease outcome to allow inferences about combinations of risk factors for which epidemiological studies have not been conducted, including the joint effects of changes in multiple risk factors;
- calculating the health loss due to risk factor(s) as a time-indexed "stream" of disease burden due to a time-indexed "stream" of exposure, including consideration of discounting; and
- describing the sources of uncertainty in the risk assessment process.

For each of the above aspects, we have outlined the important conceptual and methodological issues and their implications for risk assessment. While this framework provides a means for considering risk factors in different layers of causality, with multiple counterfactuals (Ezzati et al. 2002; see also the risk factor chapters in this book), its application is limited by the availability of data on risk factors and hazards (Powles and Day 2002). The availability and form of data on both exposure and hazard are often determined by disciplinary boundaries as well as measurement difficulties. Analysis of selected risks highlights data and monitoring needs for better quantification and intervention strategies, especially more detailed data on exposure, hazard accumulation over time, and heterogeneity of risk factor-disease relationships.

For more effective and affordable implementation of a prevention paradigm, policies, programmes and scientific research should acknowledge and take advantage of the interactive role of major risks to health, across and within causality layers. Despite the methodological complexity and empirical difficulties, especially in estimating time-based multi-risk exposures, this framework provides a consistent basis for better and more comparable information about the various causes of disease and injury. In the remaining chapters of this book, the burden of disease due to a diverse set of risk factors is assessed according to this conceptual framework, with a detailed description of data sources and risk factor-specific methodological issues.

## Acknowledgements

This work has been sponsored by the National Institute of Aging Grant 1-PO1-AG17625. The participants in the various CRA project collaborators meetings and two reviewers provided valuable comments. J. Powles and J. Barendregt provided extensive comments on an earlier draft.

## Notes

1 As discussed by Greenland and Robins (1988), attributable fractions without a time dimension are not able to characterize those cases whose occurrence would have been delayed in the absence of exposure. The authors recommend the use of etiologic fractions with a time dimension to account for this shortcoming. Time-based measures are discussed in more detail below.
2 At the extreme, a structural model would attempt to use chemical or physical principles as the unit of analysis and modelling. This would of course be currently impossible in studying any system that involves population health.
3 The "driving force, pressure, state, exposure, effect" (DPSEE) model of Corvalan et al. (1999) does consider the multiple layers of causality. This model however focuses on the risk evolution process, which is less suitable for multi-risk factor interaction within and between layers. More complete discussions of causality and multiple causes are provided by Yerushalmy and Palmer $(1959)$, Evans $(1976,1978)$ and Rothman and Greenland (Rothman 1976; Rothman and Greenland 1998).
4 The exception is those risk factors whose effects occur through intermediate variables which are themselves a risk factor for the outcome considered, such as the relationships between physical inactivity or obesity and IHD, which are mediated through blood pressure or cholesterol. In such cases, controlling for the intermediate risk factor would result in a bias (towards the null) in the estimation of total hazard of the distal factor (Greenland 1987).
5 There are no past studies on "climate change" as it is expected to take place in the future. For this reason, the relationship between climate change and health would always be based on a model which relates climate change to meteorological variables (e.g. temperature or rainfall). The relationship between these variables, disease vectors and disease could then be estimated from past data and vector biology (Craig et al. 1999; Martens et al. 1999; Rogers and Randolph 2000).
6 If the variables in the $n$th layer of the causal-web are affected directly by those in the $(n-2)$ th layer in addition to the $(n-1)$ th layer, or by variables within the $n$th layer itself (see Figure 1.2 for an example), Equation 3a can be expanded to include these links as well:

$$
\begin{equation*}
\mathbf{X}^{n}=f\left(\mathbf{B}_{0}\left(\mathbf{X}^{n}\right), \mathbf{X}^{n} ; \mathbf{B}_{1}\left(\mathbf{X}^{n-1}, \mathbf{X}^{n}\right) \mathbf{X}^{n-1} ; \mathbf{B}_{2}\left(\mathbf{X}^{n-2}, \mathbf{X}^{n}\right) \mathbf{X}^{n-2}\right) \tag{3b}
\end{equation*}
$$

This can be extended to interactions across multiple causal layers, and in general any variable in the system can be affected by any other one as the concept of causal layer becomes more flexible.

7 In this case when some of the variables affect not only the other variables in the causal system but also the relationship(s) between variables, they are equivalent to "effect modification" in epidemiological literature (Rothman 1976). Graphically, in Figure 1.1 they would be represented as links (arrows) not between two variables but as links from one of the variables (the effect modifier) to another link in the system.
8 In other words the $R R(x)$ in Equations (2a) and (2b) are functions of the other covariates, referred to as effect modification earlier. Epidemiological
studies that stratify relative risks based on covariates other than age and sex are however rare.

9 The notation $\left.\right|_{T_{0}} ^{T}$ denotes "estimated between $T_{0}$ and $T$ ".
10 Equivalent exposure is an analytical concept and need not be physically realizable. In fact for many risk factors, such as carcinogens, where the effects are from life-long exposure, the equivalent exposure would be so high that its occurrence at a single instant would be impossible.
11 Further, if there is threshold, $M$, below which exposure has no effect:

$$
\left.R R(x(t))\right|_{T_{0}} ^{T}=R R\left(\int_{T_{0}}^{T} f(x(t-L))(\operatorname{TRUE}(x(t-L) \geq M)) d t\right)
$$

where

$$
\operatorname{TRUE}(x(t) \geq M)= \begin{cases}1 & \text { if } x(t) \geq M \\ 0 & \text { if } x(t)<M\end{cases}
$$

This framework can be easily modified to include cases where exposure has different effects below and above threshold by using $\operatorname{TRUE}(x(t) \geq M)$ for the effect above the threshold and $\operatorname{TRUE}(x(t)<M)$ for the effect below the threshold.
12 In this manner, the evolution of the exposure distribution is analytically similar to a "random process" in which a probability density function (PDF) describes a random variable which is a function of time. Exposure to a risk factor is not a random variable in the strict sense. But since a timedependent exposure distribution has an accumulated distribution of 1.0, it has the same representation as a random process.
13 Robins (1999a) discusses this issue in the case of estimating the effects of a dynamic treatment regime whose dose is dependent on symptoms.
14 The diffusion model also includes a stochastic component to account for those interactive effects not described by the drift term.
15 The functional form is $\int_{0}^{\infty} W_{i} \alpha^{t}$ where $0<\alpha<1$ in Koopmans (1960) and $\int_{0}^{\infty} W_{i} \exp (-\delta t)$ where $\delta>0$ in Dasgupta and Mäler (1994) and Dasgupta et al. (1999); $\alpha$ and $\delta$ are the social rate of discount.
16 The last unit of sacrifice will have infinite marginal utility therefore matching the future infinite stream of benefits.

17 These two additional constraints are external to the economic efficiency arguments as defined by maximizing aggregate welfare. In fact, these additional constraints of minimum acceptable or non-declining welfare result in an "inefficient" outcome in order to achieve better distribution across generations (Montgomery 1999). See Weitzman (1999) for another argument for the choice of lower discount rates.
18 If exposure is sustained for a longer time in the risk assessment population than in the study population and if the whole exposure period contributes to hazards, this would result in an underestimation of risk (and vice versa). For example, in many cohorts in current epidemiological studies, BMI
increased when the subjects were in their twenties or thirties. There is however increasing child and adolescent overweight or obesity in many regions of the world. If this continues into adult life, the hazards may be higher than subjects in the current study cohorts.

## Chapter 2

# Childhood and maternal UNDERWEIGHT 

Steven M. Fishman, Laura E. Caulfield, Mercedes de Onis, Monika Blössner, Adnan A. Hyder, Luke Mullany and
Robert E. Black

## Summary

Undernutrition, as measured by underweight status, has been associated with substantially increased risk of childhood mortality worldwide, but the magnitude of its effect on specific causes of mortality and morbidity has been less well described. We reviewed extant data and conducted statistical meta-analyses in order to determine the relative risk of disease and death attributable to underweight status. We used these estimates in combination with estimates of underweight prevalence among children aged $0-4$ years and women of reproductive age (15-44 years) to calculate the global burden of disease attributable to undernutrition.

Underweight was defined for children aged $0-4$ years as low weight-for-age relative to the National Center for Health Statistics/World Health Organization (NCHS/WHO) reference median. The theoretical-minimum-risk distribution for this population was equivalent to the reference population distribution, wherein $2.3 \%$ of children have a weight-for-age below -2 standard deviations (SDs) (weight-for-age $<-2$ SDs, or weight-for-age $z$-score [WAZ] $<-2$ ) and are classified as underweight. The relationship between low weight-for-age among children and mortality was analysed as a multiple categorical variable having four levels of exposure: WAZ $<-3$, WAZ -3 to -2 , WAZ -2 to -1 and WAZ >-1 (reference category). Morbidity was analysed as a dichotomous variable, comparing WAZ $<-2$ to WAZ $>-2$ (reference category). Underweight was defined for women of reproductive age as prepregnant body mass index (BMI) below $20 \mathrm{~kg} / \mathrm{m}^{2}$. The outcomes chosen for review were major diseases and disabilities commonly associated with nutritional deficiencies. Sufficient prevalence and risk data were available to analyse childhood underweight status as a risk factor for mortality due to diarrhoeal disease, measles, malaria and pneumonia.

Childhood underweight status was also analysed as a risk factor for increased incidence of these infectious diseases. Maternal underweight was considered as a risk for increased risk of conditions arising during the perinatal period. The relationships were considered causal on the basis of consistent evidence observed across different populations and settings, and persistence of the association after adjustment for recognized confounders and effect modifiers such as age, breastfeeding status and prior morbidity. Current prevalence and risk data were not suitable for deriving burden estimates relating to other outcomes or older populations, although this does not imply the lack of risk in those populations. We therefore reviewed and summarized two major areas of undernutrition research without calculating burden estimates: (i) effects of maternal underweight status during pregnancy on maternal mortality and fetal death; and (ii) the association between undernutrition and cognitive function.

Prevalence of undernutrition among children aged 0-4 years was obtained from the WHO Global Database on Child Growth and Malnutrition, derived from a systematic analysis of raw data sets from 310 nationally representative nutritional surveys that collected data on child anthropometry in 112 countries. Categorical underweight estimates for most subregions ${ }^{1}$ were calculated using multilevel modelling that adjusted for variability between regions, countries and surveys. Prevalence of underweight status was highest in SEAR-B (25.8\%), SEAR-D ( $45.9 \%$ ), AFR-D ( $32.2 \%$ ), AFR-E ( $31.1 \%$ ) and EMR-D ( $25.1 \%$ ). Projections based on national trends suggested declining prevalence in most subregions over the next 30 years but increasing prevalence in the African subregions.

Cause-specific mortality was estimated by extending the methods of Pelletier et al. (1994) to data obtained from the investigators of 10 cohort studies in which both weight-for-age category ( $<-3$ SDs; -3 to -2 SDs; -2 to -1 SDs; and $>-1$ SD) and cause-of-death information were available. All studies contributed information on weight-for-age and risk of diarrhoea, pneumonia and all-cause mortality. However, only six studies contributed information on deaths due to measles, and only three studies contributed information on deaths due to malaria or, in some cases, fever. By calculating the logarithm of the mortality rates by cause and anthropometric status in each country and utilizing weighted random effects models, we estimated the relation between weight-for-age and risk of death and calculated the relative risk of dying for each cause and allcause mortality from these models. The relative risks of mortality due to low weight-for-age were elevated for each cause of death. The attributable fractions of mortality associated with weight-for-age below-1 SD were $44.8 \%$ for measles, $57.3 \%$ for malaria, $52.3 \%$ for pneumonia and $60.7 \%$ for diarrhoea.

Estimation of cause-specific morbidity was based on statistical metaanalysis of published data identified through systematic literature
searches of Medline and other databases. We selected longitudinal studies that compared incidence data according to past anthropometric status. Underweight status among preschool-age children was significantly associated with subsequent risk of diarrhoea and pneumonia episodes, but the association with malaria was not statistically significant. There was no evidence that underweight status influenced susceptibility to measles infection. The overall attributable fractions of morbidity associated with weight-for-age below -2 SDs were $16.5 \%$, $5.3 \%$ and $8.2 \%$ for pneumonia, diarrhoea and malaria, respectively.

Mortality due to perinatal conditions was calculated by estimating the attributable fraction of neonatal mortality due to intrauterine growth retardation (IUGR) and then multiplying the value by the estimated attributable fraction of IUGR due to low maternal pre-pregnancy BMI for each subregion. Attributable fractions were based on prevalence and risk estimates from available published and unpublished sources.

Overall, undernutrition in children aged $0-4$ years, as reflected in underweight or low weight-for-age, caused 3599800 deaths, including 815900 diarrhoea deaths, 1042900 pneumonia deaths, 261300 measles deaths and 549200 malaria deaths. There were an additional 148400 low-birth-weight neonatal deaths associated with low maternal prepregnancy BMI. The total number of child deaths associated with maternal or child underweight status, 3748200 , represented $34.7 \%$ of all child deaths in the age group 0-4 years. The loss in disability-adjusted life years (DALYs) associated with these deaths was over 126 million. An additional 879900 DALYs were lost due to increased morbidity from pneumonia, diarrhoea and malaria. Of the total DALYs associated with undernutrition, 44 million ( $32.0 \%$ ) were lost in SEAR-D, 30 million ( $21.7 \%$ ) in AFR-D, 33 million ( $23.9 \%$ ) in AFR-E, 16 million ( $11.5 \%$ ) in EMR-D and 8 million ( $5.8 \%$ ) lost in WPR-B. Altogether, these five subregions accounted for $95 \%$ of the total DALYs lost due to undernutrition.

The true burden of disease associated with undernutrition extends beyond the narrow focus of this analysis. In addition to the effects of poor pre-pregnancy BMI, inadequate weight gain during pregnancy can lead to IUGR. Fetal growth retardation, in turn, may be associated with impaired immunocompetence, as well as increased risk of chronic disease in later life. Chronic undernutrition, especially in conjunction with poor environmental stimulation, is associated with impaired cognitive development, and severe undernutrition during infancy may contribute to lasting intellectual deficits. Chronic undernutrition among adults can contribute to diminished work capacity. Additional research is necessary into the prevalence and impact of undernutrition throughout the life cycle.

## 1. Introduction

Child undernutrition-measured as poor anthropometric status-is internationally recognized as an important public health indicator for monitoring nutritional status and health in populations. Young children are most vulnerable to undernutrition and face the greatest risk of its adverse consequences. Those who suffer from growth retardation as a result of poor diets and/or recurrent infections tend to have more frequent episodes of severe diarrhoea and are more susceptible to several infectious diseases, such as meningitis and pneumonia (Man et al. 1998; Tomkins and Watson 1989; Victora et al. 1994). A number of studies have demonstrated the association between increasing severity of anthropometric deficits and mortality, and undernutrition is thought to be a contributing factor in over half of all child deaths in developing countries (Pelletier 1994; Pelletier et al. 1993; Rice et al. 2000; Schroeder and Brown 1994). There is strong evidence that poor growth is associated with delayed mental development (de Onis 2001; Mendez and Adair 1999; Pollitt et al. 1993; WHO 1999a), and several studies have shown a relationship between impaired growth status and poor school performance as well as reduced intellectual achievement (Martorell et al. 1992; PAHO 1998). In addition, growth retardation in early childhood is associated with significant functional impairment in adult life (Martorell et al. 1992) and reduced work capacity (Spurr et al. 1977), which in turn has an impact on economic productivity.

The purpose of this chapter is to describe our review and analysis of existing data in order to calculate relative risks of specific causes of death and morbidity attributable to undernutrition (defined by low weight-forage or "underweight"), and to use the estimates, in combination with estimates of underweight prevalence from a comprehensive WHO database, to calculate the global burden of disease associated with underweight status.

### 1.1 Determinants of childhood undernutrition

Undernutrition has several levels of determinants. Poverty is a strong underlying determinant that leads to household food insecurity, poor childcare, maternal undernutrition, unhealthy environments and poor health care. These factors then lead to the immediate determinants of childhood undernutrition, that is, low birth weight, inadequate dietary intake of nutrients and frequent infectious diseases (Baqui and Black 2002). Low birth weight, primarily due to IUGR in developing countries, is a consequence of maternal undernutrition prior to and during pregnancy and subsequently contributes to undernutrition in infancy and childhood (Villar and Belizan 1982). This is especially important in areas such as South Asia, where there is a very high prevalence of low birth weight. The diets of many children in developing countries are inadequate, and children in the first two years of life are at particular risk.

During this period, children have a high rate of growth and demand for calories, protein, essential fats, vitamins and minerals. Breastfeeding provides excellent nutritional support for six months (Kramer and Kakuma 2002), but unfortunately many children in such settings are given fluids and other foods before this age, resulting in reduction of breast milk intake and exposure to infectious agents causing diarrhoea (Lutter 2000). After six months of age, even when breastfeeding is continued, children frequently lack sufficient dietary intake, or consume a diet that is of poor nutritional content (WHO 1998). Again, these dietary deficiencies may involve not only the macronutrients, but also the socalled micronutrients, that is, vitamins and minerals. In young children, the frequently contaminated environments and poor childcare practices cause high rates of infectious disease. These infections result in a reduction in nutrient intake, as well as increased utilization and loss of nutrients, such as vitamin A and zinc.

The relative importance of the three immediate determinants of undernutrition varies by setting. The percentage of growth faltering (compared with an international reference population) due to diarrhoea in developing countries in Latin America, Africa and Asia has been reported to range from $10 \%$ to $80 \%$ (Black 1991). A study in Bangladesh simultaneously examined the role of diarrhoea, other febrile illnesses and dietary intake on weight gain (Becker et al. 1991). In a model using data from this study, it was estimated that improving dietary intake to recommended levels would have a slightly greater effect than eliminating diarrhoea and febrile illness; however, doing both at the same time would be necessary to achieve growth equivalent to an international reference population. There are a number of factors specific to particular developing country settings that can moderate the effect of illness on growth (Black 1991). For example, the adverse effect of diarrhoea on growth is less in exclusively breast-fed children than in children after weaning. Furthermore, an adequate diet, such as that provided in supplementation programmes, may prevent the adverse effect of diarrhoea on growth in some (Lutter et al. 1989) but not all settings (Bhandari et al. 2001). Thus, undernutrition is due to a variety of determinants that act along a pathway from poverty to dietary deficiency and frequent infectious diseases of childhood.

### 1.2 OTHER AGE GROUPS

Undernutrition is not limited to young children. Over 815 million people of all ages are considered undernourished (FAO 2001), including roughly 243 million adults in developing countries who are considered severely underweight (ACC/SCN 2000a). Poor anthropometric status among adults and adolescents has been associated with maternal complications, diminished work capacity and increased risk of mortality (Martorell et al. 1992; Rotimi et al. 1999; Spurr et al. 1977; WHO 1995b). However, prevalence data for most adults, school-age children, adolescents and the
elderly are scarce, and understanding of the health effects of undernutrition in these populations is incomplete. There is a need for further research on undernutrition throughout the life cycle, especially as populations in developing countries go through demographic and epidemiological transitions.

### 1.3 Exposure variable

The internationally recommended way to assess undernutrition at the population level is to take body or anthropometric measurements (e.g. weight and height). Based on combinations of these body measurements anthropometric indices are constructed. These indices are essential for the interpretation of measurements, as the value for body weight alone, for example, has no meaning unless it is related to an individual's age or height (WHO 1995b). In children the three most commonly used anthropometric indices are weight-for-height, height-for-age and weight-for-age. These anthropometric indices can be expressed in terms of $z$-scores, percentiles, or percentage of median, which can then be used to compare a child or a group of children with a reference population.

Weight-for-age was chosen as the index of child nutritional status for this analysis because it is the most widely used in developing countries, allowing for the inclusion of the largest number of studies. Although it does not distinguish between wasting and stunting, low weight-for-age (underweight) represents a combination of both aspects and has a high positive predictive value as an indicator for child malnutrition in developing countries (WHO 1995b). Underweight is defined internationally as the proportion of preschool children falling below -2 SDs (weight-for-age $<-2$ SDs, or WAZ <-2) from the NCHS/WHO international reference median value for weight-for-age (de Onis and Blössner 1997; WHO 1995b). The burden of disease estimates for mortality were based on four weight-for-age categories: $<-3$ SDs; between -3 and -2 SDs; between -2 and -1 SDs; and the reference category of $>-1 \mathrm{SD}$. The estimates for morbidity were based on two categories: weight-for-age $<-2$ SDs and the reference category of $>-2$ SDs.

Although the terms are often used synonymously, "underweight" should be distinguished from the terms "malnourished" and "undernourished". "Undernourished" and "malnourished" refer to the internal, physiological state of nutriture. "Underweight" is an observable anthropometric marker for that state, while the internal process can only be inferred.

BMI was selected as the index of adult nutritional status recommended by the International Dietary Energy Consultative Group of the Administrative Committee on Coordination/Sub-Committee on Nutrition (Shetty and James 1994). BMI is less biased by height differences than other adult indicators, such as absolute weight, and correlates with
health-related outcome variables such as overall mortality risk. For evaluation of nutritional status in relation to pregnancy, only pre-pregnant BMI was considered. Unlike the classification of underweight status in children, there is no comparable international reference for BMI among adults. A BMI $<18.5 \mathrm{~kg} / \mathrm{m}^{2}$ represents chronic energy deficiency, and the Institute of Medicine recommends a BMI cut-off of $<19.8 \mathrm{~kg} / \mathrm{m}^{2}$ as the definition for underweight (Institute of Medicine 1990; Shetty and James 1994). The cut-off of $20 \mathrm{~kg} / \mathrm{m}^{2}$ is commonly used in studies of maternal risk, and, therefore, underweight status among women of reproductive age was defined as BMI $<20 \mathrm{~kg} / \mathrm{m}^{2}$ for this analysis. Further details on BMI can be found in the chapter on overweight and obesity (chapter 8).

### 1.4 Considerations in choice of child ANTHROPOMETRIC INDICATOR

Nutritional status can be assessed using clinical signs of malnutrition, biochemical indicators and anthropometry. Inadequacies in nutritional intake eventually alter functional capacity and result in many adverse health outcomes that are distinct expressions of malnutrition's different levels of severity. Initially, children adapt to inadequate diets through reduced physical activity and slowed rates of growth. At moderate degrees of malnutrition, activity and growth rates are affected to a greater degree, and in addition signs of wasting and some biochemical abnormalities (e.g. reduction in serum albumin), begin to show. At advanced stages of severity, all linear growth ceases, physical activity is severely curtailed, body wasting is marked and clinical signs (e.g. oedema, hair and skin changes) are noticeable. Anthropometry thus has an important advantage over other nutritional indicators: body measurements are sensitive over the full spectrum of malnutrition, whereas biochemical and clinical indicators are useful only at the extremes. In addition, anthropometric measurements are non-invasive, inexpensive and relatively easy to obtain. The main disadvantage of anthropometry is its lack of specificity, as changes in body measurements are also sensitive to several other factors, including infection, altitude, stress and genetic background (de Onis 2000).

A child's body responds to malnutrition in two ways that can be measured by anthropometry: (i) a deceleration or cessation of growth, which over the long-term results in low height-for-age or stunting; and (ii) body wasting, which is a short-term response to inadequate intakes, commonly assessed by weight relative to height. Height-for-age and weight-for-height thus discriminate between different biological processes, unlike weight-for-age, which could be low because of stunting (short stature) and/or wasting (recent weight loss). The current estimates relied exclusively on weight-for-age, which reflects body mass relative to chronological age. It is influenced by both the height of the child (height-for-age) and her weight (weight-for-height). Hence weight-
for-age cannot discriminate between short- and long-term forms of malnutrition given that children classified on its basis are a mixed group in terms of their nutritional status. In the 1990s weight-for-height emerged as a very important indicator (WHO 1995b) and, in fact, several authors have identified low weight-for-height as the indicator of choice for screening malnourished children who are at increased risk of dying (de Onis 2000).

### 1.5 Theoretical-minimum-exposure distribution

The prevalence of underweight status is defined as the proportion of preschool-age children falling below - 2 SDs indicated from the NCHS/ WHO international reference median value (de Onis and Blössner 1997; WHO 1995b). The theoretical-minimum-risk distribution is equivalent to this distribution, wherein $13.6 \%$ of children aged 0-4 years have weight-for-age between -1 to -2 SDs and $2.3 \%$ have a weight-for-age <-2SDs.

Anthropometric values are compared across individuals or populations in relation to a set of reference values based upon a healthy population. The choice of reference population to assess nutritional status has a significant impact on the proportion of children identified as being malnourished and, in turn, important implications for establishing relationships between nutritional status and functional outcomes (WHO 1995a). Much has been written about growth references, but unanswered questions remain about the many factors that determine human growth and indeed what constitutes "normal" growth. WHO has been recommending since the late 1970s the use of the NCHS/WHO international reference population $z$-scores for the comparison and presentation of child malnutrition data (Waterlow et al. 1977). A detailed account of the different growth references used prior to the current international reference is provided elsewhere (de Onis and Yip 1996). In the mid-1990s the NCHS/WHO international reference was found to have important technical and biological drawbacks (de Onis and Habicht 1996; de Onis and Yip 1996; WHO 1995a). Consequently, an international effort coordinated by WHO is under way to develop a new international growth reference for infants and young children (de Onis et al. 1997). The new international reference-which will be constructed from primary data collected for this purpose-includes a number of features that, taken together, will result in a reference population substantially different from the existing ones (de Onis et al. 2001). An important characteristic of this new reference is that it will be based on a truly international sample. Six countries, representing the major global geographic regions, are participating in this effort. Another notable feature is that it takes the breast-fed infant as the biological "norm", recognizing the health and nutritional benefits of breastfeeding. The extent to which the new curves differ from the current ones in shape and the spread of values around the mean will affect the relationship-established using the NCHS/WHO
reference values-between child anthropometry and functional outcomes such as morbidity and mortality.

Once a reference population has been selected, it is necessary to determine the limits of "normality". Current practice is to use a defined cutoff point using one of the three available classification systems for comparing a child, or a group of children, to the reference population: $z$-scores (SD scores), percentiles and percentage of median. The use of a statistically defined cut-off point (e.g. $-2 \mathrm{SD} z$-score) is not unique to anthropometry; indeed, it is widely applied in many fields of biology and medicine. Nevertheless, it is important to bear in mind that using a cut-off-based criterion to define what is "abnormal" is arbitrary. In reality, there are not two distinct populations-one well nourished and the other malnourished-but rather a continuous gradation of nutritional status (de Onis 2000). The risk of undesirable health outcomes such as mortality does not change dramatically by simply crossing the cut-off line; risks are continuous within the "normal" range. For many purposes, the best descriptor of a population's nutritional status is the mean $z$-score, which in less developed environments is usually shifted to the left. This concept is based on data from many different countries which showed a high consistency in the SD of weight-for-height among young children (de Onis and Blössner 1997). Even under extreme conditions, such as during famines, where the mean $z$-score is two or three units below the reference, the value of the SD of $z$-scores is very close to unity. This shows that the entire distribution is shifted so that all individuals, not only those below a given cut-off point, are affected (Rose 1985). Taking such a populationapproach resolves the problem of focusing solely on the severely malnourished subpopulation falling below a certain cut-off. In most instances, the mild and moderately malnourished subpopulations will be of greater importance from a public health perspective because there are many more children in these categories than in the severely malnourished one. For this reason, estimates are presented using low weight-for-age as both a dichotomous and multi-categorical variable when possible.

## 2. <br> Prevalence of underweight AMONG CHILDREN

Over the years the WHO Department of Nutrition has been monitoring trends in child malnutrition using anthropometric data. A major difficulty has been the lack of comparability of survey results. Although many nutritional surveys have been conducted since the 1970s, many of them had used distinct definitions of malnutrition (i.e. different anthropometric indicators, reporting systems, cut-off points and reference values) making comparison among studies difficult. This lack of comparable data prompted the beginning of WHO's systematic collection and standardization of data on the nutritional status of the world's population of children <5 years. Initial results of this effort, published in 1993 (de

Onis et al. 1993), were updated in 1997 and presented together with estimates of trends in child growth retardation in developing countries (de Onis and Blössner 1997). A more recent analysis using multilevel modelling updated these earlier estimates, describing trends in child malnutrition from 1980-2005 (de Onis et al. 2000).

### 2.1 DATA SOURCES AND QUALITY CONTROL

Cross-sectional data on the prevalence of underweight were obtained from nationally representative nutritional surveys that collected data on child anthropometry and are included in the WHO Global Database on Child Growth and Malnutrition. This database was initiated in 1986 to compile, standardize and disseminate the results of nutritional surveys performed in both developing and developed countries (de Onis and Blössner 1997). A distinct feature of this database is the systematic analysis of raw data sets in a standard format to produce comparable results. Only nationally representative data have been used for the present analysis. Three hundred and ten national nutrition surveys from 112 countries carried out from 1965 onwards were analysed to estimate the prevalence of underweight in children. The majority of surveys were conducted by either the relevant national ministry of the country concerned, by the Demographic and Health Surveys (DHS) programme of Macro International, or by the Multiple Indicators Cluster Surveys (MICS) carried out by the United Nations Children's Fund (UNICEF). Appendix A lists all national surveys included in the present analysis by country in alphabetical order.

Survey data for inclusion in the WHO Global Database on Child Growth and Malnutrition are identified by various ways and mechanisms.

- An automated Medline search provides results according to the established search history following the weekly online Medline updates. Selected abstracts are reviewed and relevant surveys with data searched for in the library. Data are extracted and frequently the principal investigators and/or data holders are contacted to complement the data provided in the article and/or give clarification on methodological issues.
- A wide network of collaborators, including international organizations (e.g. UNICEF, Food and Agriculture Organization of the United Nations [FAO]), nongovernmental organizations (NGOs) (e.g. Helen Keller International), Ministries of Health and National Institutes of Nutrition, as well as independent institutions (e.g. Macro International) and individual researchers provide their data directly to the WHO Global Database. In case of queries on the data the same procedure as above takes place to clarify any unclear issues.
- Principal investigators contact the WHO Global Database to enquire about possible inclusion of their data into the Global Database.
- Other WHO database managers within WHO headquarters share data sets and survey documents with the Global Database.

The sampling methods for each of the survey data used in this analysis were carefully reviewed to ensure national representativeness. Multistage random sampling methods were applied for sample selection in the majority of countries. Only a few countries, such as Argentina, Chile, Croatia, Uruguay and Venezuela based their estimates on well-established national nutritional surveillance systems with high population coverage (country-specific details on sampling procedures are available from the authors on request). Surveys generally followed standard procedures of measuring length up to 24 months of age and height from 24 months onwards. The anthropometric measurement techniques used in each survey are described in the comprehensive survey reports, which are available on request. Some surveys included information on reliability of the measurements while others did not.

Survey results were checked for inconsistencies between the estimates based on height-for-age, weight-for-age and weight-for-height. The observed SDs of the $z$-score distribution were used to assess the quality of the survey results. With accurate age estimates and anthropometric measurements, the SDs of the observed height-for-age, weight-for-age and weight-for-height $z$-score distributions should be relatively constant and close to the expected value of 1.0 for the reference distribution (ranging within approximately 0.2 units). This nearly constant SD in height-based and weight-based $z$-score distributions provides an opportunity to assess data quality (WHO 1995b). Surveys with a SD outside the expected ranges were subjected to closer examination because of possible problems related to age assessment and anthropometric measurements. Surveys with inaccurate data resulting from measurement error or incorrect age reporting were excluded from this analysis.

## $2.2 \quad$ Statistical analysis

The analysis followed three separate steps, which are described below. The number of countries and percentage of population aged $<5$ years covered by data for each subregion are listed in Appendix B. The population aged <5 years derived from the 1998 revision of the UN population estimates (UN 1999) for the particular survey year were added as population weights. As there were no significant differences observed between male and female child underweight prevalence, the model exercise included data only for sexes combined, and estimates were assumed to be the same for males and females.

Primary analysis of raw data sets
As an essential first step in producing subregional estimates, primary analysis of the 310 national raw data sets was conducted to produce
standardized estimates of prevalence of underweight as defined in section 1.1. This was necessary because many nutritional surveys used distinct definitions of malnutrition (i.e. different anthropometric indicators, reporting systems, cut-off points and reference values) making impossible the pooling of reported prevalences. There were three steps involved in this analysis: (i) identifying the data holder for each of the individual surveys; (ii) requesting re-analysis of the original data sets following the standardized definition, or otherwise, requesting a copy of the raw data set for standard analysis by the WHO Department of Nutrition; and (iii) initiating quality control procedures for each individual survey. Countryspecific prevalences of child underweight by age, sex and subregion derived for each of the national surveys listed in Appendix A can be found on the web site of the WHO Global Database on Child Growth and Malnutrition at http://www.who.int/nutgrowthdb.

## Subregional estimates: Underweight as a dichotomous variable

The methodology applied to derive the underweight estimates depended on the availability of data points for the different subregions. In detail these were as follows: for AFR-D, AFR-E, AMR-B, AMR-D, EMR-B, EMR-D, SEAR-B, SEAR-D and WPR-B the underweight estimates were calculated using a multilevel model. Multilevel modelling allows for more than one component of variation, which in this case includes between subregions, between countries within subregions and between surveys over time within countries. This multilevel model is an extended form of regression, which separates estimates for the three levels of variation, and the total variation is obtained by combining over the three levels. To adjust for skewness in the distribution of prevalence, the model used the logit transform of the underweight prevalence, with the additional advantage of stabilizing the variance. Because estimates were calculated on the logistic scale, estimated prevalence and their CIs were derived by back-transformation. The nature of the logistic function ensured that all estimated prevalence and their CIs would lie above zero. CIs for prevalences close to zero were asymmetric, and were narrower than for values close to $50 \%$-these are intrinsic properties of the logistic function (Armitage and Berry 1994).

Multilevel modelling was implemented in the Statistical Analysis System (SAS) Proc Mixed program, a procedure that accommodates both categorical and continuous covariates and incomplete series of time measurements, and allows for the added variability introduced by the multiple levels of analysis. Analyses were conducted separately for each subregion, given that the trend of underweight between subregions could differ substantially.

Separate analysis for each subregion required that two rather than three levels be modelled, thus reducing complexity of the model. An assumption of the analyses was that the extent of available data for countries was not related to the prevalence of underweight. In other
words, it was assumed that the trend of the prevalence over time for a subregion could be estimated in an unbiased manner from the data available. Under this assumption the model accommodated the variable patterns of available surveys for the countries. Countries with only one survey contributed information to the estimation of the overall intercept, whereas countries with more than one survey also contributed to the estimation of the regression coefficient(s) relating the trend to the survey year. The models specified a linear trend relationship between prevalence of underweight and survey year. Thus, these models assumed that the rate of change in the prevalence of underweight was constant.

Possible non-linear trends were examined by including quadratic and cubic polynomial terms. There was some evidence for non-linear relationship in only one of the subregions (SEAR-D), showing slightly larger differences between countries and indicating a better fit using the quadratic and cubic functions. However, due to unrealistic drops in prevalence the model outcome was discarded. Further explanation on the multilevel modelling approach to derive estimates has been described elsewhere (ACC/SCN 2000b; de Onis et al. 2000).

No modelling was possible in AMR-A, EUR-A, EUR-B, EUR-C and WPR-A due to lack of sufficient national survey data. To derive estimates for these subregions we proceeded as follows:

- In AMR-A and EUR-A, which are composed of developed countries, we assumed that children have a similar nutritional status as the reference population. Therefore, these two subregions were assigned the prevalence values derived from the international reference population, i.e. $2.3 \%$ (theoretical minimum). For these subregions no CIs were available and uncertainty was assumed as zero.
- In EUR-B, EUR-C and WPR-A, we calculated the weighted mean prevalence of underweight following the method of de Onis and Blössner (2000) for estimating prevalence and trends of overweight among preschool-age children in developing countries. Based on the available survey data the CIs fell within a $95 \%$ CI of: $0.1-15.5$ in EUR-B; 0.1-5.1 in EUR-C; and 0.7-6.9 in WPR-A.

Subregional estimates: Underweight as a multi-Categorical variable
Growth in populations of children is normally distributed. In a standard normal distribution the SD is 1 and the mean is located at 0 . As there is a relationship between the prevalence falling below the cut-off ( $<-2$ SDs) and the mean $z$-score, to convert the mean $z$-score to a prevalence based on $<-2$ SDs, the probit function, which converts $z$-score values to cumulative percentiles, was used as recommended by an Expert Committee (WHO 1995b). To derive probability that the $z$-score of a child is between two cut-off points (<-3SDs; -3 SDs to -2 SDs; -2 SDs to -1 SD; and $>-1$ SD), we calculated the difference between the two cumulative
probabilities obtained from the probit function. Prevalence data below -3 SDs were derived by subtracting the calculated values for the interval -3 to -2 SDs from the total of the prevalence below $<-2$ SDs provided by the categorical analysis (see Table 2.1 and section 4.2), which included all ranges below this cut-off.

### 2.3 Exposure estimates

The prevalence of low weight-for-age among children aged 0-4 years by subregion is listed as a dichotomous variable in Table 2.1 (a) and as a multi-categorical variable in Table 2.1 (b), below.

## 3. Prevalence of underweight among women of reproductive age

Subregional BMI estimates listed in Table 2.2 are from chapter 8. Underweight status is widespread among women of reproductive age in developing countries, especially in sub-Saharan Africa and South Asia. Of 26 sub-Saharan African countries with recent ( $<10$ years old) survey estimates, 23 have greater than $30 \%$ prevalence of $\mathrm{BMI}<20 \mathrm{~kg} / \mathrm{m}^{2}$-five of which (Chad, Eritrea, Ethiopia, Madagascar and the Niger) have prevalence $>50 \%$. Among South Asian women, $70-76 \%$ in Bangladesh and India have a BMI $<20 \mathrm{~kg} / \mathrm{m}^{2}$, along with $54-61 \%$ in Cambodia and Nepal. Low BMI is less common in the Americas, where prevalence of

$\mathrm{BMI}<20 \mathrm{~kg} / \mathrm{m}^{2}$ among women of reproductive age is generally below 20\% (ACC/SCN 2000b; DHS web site, http://www.measuredhs.com).

## 4. Risk factor-Disease Relationships

A synergistic relationship between malnutrition and infection has been recognized for decades (Scrimshaw et al. 1968), providing a foundation for the choice of health outcomes in this analysis, but the bi-directional nature of the relationship complicates attributing causality. The changes in body size used as a marker for undernutrition in this analysis are commonly the result, in part, of previous infections, raising the possibility that co-existing infection is responsible for some of the observed risk relationship. Age, sex, socioeconomic status, season, breastfeeding status and behavioural factors will also influence both anthropometric status and risk of infection (Pelletier 1994).

Undernutrition is most prevalent where poverty persists, and it is often difficult to isolate the effects of undernutrition from the complex web of environmental and socioeconomic factors that contribute to mortality and morbidity in such surroundings. In reviewing the various risk relationships, the likelihood of causality was considered according to Hill's standards (Hill 1965). In each case, there was judged to be sufficient biological plausibility and experimental evidence to support the relationship. We chose risk relationships that have been reported by multiple researchers in different populations under different circumstances. The associations generally, albeit not always, persisted after adjustment for prior morbidity and known confounders. Further, we selected for analysis only those studies in which anthropometric assessment clearly preceded the observed health outcome. In previous analyses (Pelletier 1994) and in our analysis, the consistency of the risk relationship between weight-for-age and mortality in different settings with quite different mortality rates and environmental conditions strongly suggests a causal rather than confounding relationship.

The relationship between undernutrition and disease may be mediated through many biological mechanisms. The lack of adequate protein and energy is associated with numerous immunological effects, including impairment of antibody and complement formation; atrophy of the thymus and other lymphoid tissues; reduction in T-lymphocytes; depressed lymphocyte activation; decreased secretory immunoglobin A (IgA) concentrations; and delayed cutaneous hypersensitivity reaction (Rivera and Martorell 1988; Scrimshaw and SanGiovanni 1997). Undernutrition is associated with impaired turnover and maturation of intestinal epithelial cells and compromised epithelial tissue integrity (Patwari 1999). Other anatomic barriers and secretory forms of protection such as lysozymes and mucus are also altered by undernutrition (Scrimshaw and SanGiovanni 1997).

In the course of the review, several health outcomes were dropped from further consideration toward the final burden of disease estimate. In many instances, there was insufficient published evidence within a developing country setting to support a causal relationship between low weight-for-age or BMI and the outcome, although the relationship might be more widely supported given a different choice of anthropometric indicator. Ultimately, risk estimates were derived for eight outcomes for childhood underweight:

- malaria mortality;
- malaria incidence;
- pneumonia (acute lower respiratory infection [ALRI]) mortality;
- pneumonia/ALRI incidence;
- diarrhoea mortality;
- diarrhoea incidence;
- measles mortality; and
- all-cause child mortality.

All of the estimates apply to children aged $0-4$ years. In addition, mortality due to perinatal causes among neonates was attributed to maternal underweight status. There was insufficient evidence to evaluate relationships among older age groups. Although some individual studies might suggest sex differences, the summary risk estimates here were assumed to be the same for males and females. Further, although risk relationships might vary by setting, the risk estimates were regarded in the analysis as constant across all subregions of the world.

Other outcomes such as cognitive impairment and additional pregnancy effects were reviewed below, but were not included toward the burden of disease estimate. The lack of current epidemiological evidence suitable to calculate a burden estimate does not necessarily imply the lack of an effect. For example, there is a large body of research into the influence of undernutrition on cognitive function. However, it was felt that there was too much heterogeneity in the types of studies and interventions, exposure variables, and outcome measurements to adequately quantify the undernutrition relationship through meta-analysis. There is also ample evidence describing the role of insufficient weight gain during pregnancy on the risk of IUGR, but prevalence data on pregnancy weight gain in developing countries are scarce.

### 4.1 Risk of mortality due to childhood infections

It has been demonstrated that a child's risk of dying due to undernutrition is not limited to only those children with the most severe undernutrition (Pelletier et al. 1994). Rather, there exists a spectrum of risk
associated with all degrees of undernutrition-mild, moderate and severe. Although the risk of dying is highest among those most undernourished, when one considers the small but significantly elevated risk of mortality associated with mild and moderate undernutrition and the high prevalence of mild undernutrition worldwide, much of the burden of childhood deaths due to undernutrition may be attributable to mild and moderate, rather than to severe undernutrition.

Pelletier et al. (1994) estimated the relations between weight-for-age and risk of mortality from all causes, and used this information to calculate the burden of child deaths attributable to undernutrition. These relations however are likely to vary depending on specific causes of death. For example, the relative risk of dying from malaria associated with varying degrees of undernutrition may not be similar to the risk for diarrhoea. Despite problems in defining cause of death, particularly in developing countries, in which one may often need to rely on verbal autopsy methods, it is worthwhile to consolidate the evidence to-date and consider the implications of analyses relating variation in anthropometric status and risk of dying across the principal causes of death for children in developing countries: diarrhoea, pneumonia, measles and malaria.

## METHODS FOR ESTIMATING RISK OF MORTALITY

Initially, we surveyed the published literature to gather data to estimate the relationship between anthropometric status and cause-specific mortality (Rice et al. 2000). Because insufficient data were available, we contacted investigators with relevant data (published or unpublished) and asked them to contribute specific study results for this analysis. We sought community-based prospective cohort studies in which anthropometric status was assessed to determine weight-for-age, vital status monitored and cause of death determined by documented methods. Data sets ultimately contributing to the mortality analysis are listed in Table 2.3.

Each investigator was asked to provide the following information: (i) a description of their study; (ii) the number of children in the study or child-years of study with WAZ $<-3,-2$ to $-3,-1$ to $-2,0$ to -1 and $>0$; and (iii) deaths in each category attributable to diarrhoea, pneumonia, measles, malaria, or other cause and total (all-cause). During analysis, we collapsed the last two categories of anthropometric status, so that the reference group would be composed of those children with WAZ >-1.

## Analytic methods used to combine mortality data

We followed the procedures of Pelletier et al. $(1993,1994,1995)$ and used the SAS Proc Mixed program for all procedures. Because this has been described elsewhere, we describe the steps only briefly here. First, we calculated the mortality rate (per 1000) by anthropometric status and each cause of death for each study. These rates are listed in Table 2.4
Table 2.3 Data sets with information contributing to the childhood mortality analysis

| Country | Study | Age range (months) | Follow-up (months) | Number of children |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  |  |  |  | $<-3$ SDs | $>-3$ to $<-2$ SDs | $>-2$ to $<-1$ SD | >-I SD |
| Sudan | Fawzi et al. (1997) | 6-72 | 6 | 365 | 985 | 1123 | 592 |
| Senegal | Garenne et al. (1987) | 0-59 | 6 | 1663 | 2186 | 2035 | 1249 |
| Guinea-Bissau | Andersen (1997) | 0-59 | 6-12 | 1155 | 4366 | 7341 | 2731 |
| Ghana | WHO/CHD (1998) | 0-12 | 12 | 46 | 183 | 506 | 1410 |
| Nepal | West et al. (1991, 1997) | 0-72 | 12 | 1030 | 2082 | 2002 | 892 |
| Bangladesh | Arifeen et al. (2001) | $0-11$ | 3 | 79 | 250 | 475 | 478 |
| Pakistan | Khan et al. (1993); <br> Jalil et al. (1993) | 0-24 | 6 | 309 | 778 | 1182 | 1165 |
| India | WHO/CHD (1998) | 0-12 | 12 | 172 | 639 | 1259 | 1295 |
| Indonesia | Sutrisna et al. (1993) | 0-60 | 18 | 207 | 240 | 797 | 4856 |
| Philippines | Ricci and Becker (1996) | 0-59 | 3 | 800 | 3144 | 4834 | 5115 |

Figure 2.1 Underweight and all-cause mortality: (a) deaths per I000; (b) logarithm of deaths per 1000

and presented graphically in Figures 2.1(a)-2.5(a). We then calculated the logarithm of the mortality rate by anthropometric status and each cause of death for each study, and re-graphed the data (Figures $2.1[\mathrm{~b}]-2.5[\mathrm{~b}])$. Second, we regressed the logarithm of mortality on WAZ and compared these results with regressions of the simple mortality rates by WAZ. Third, we compared the goodness-of-fit characteristics for the two models ( $\mathrm{R}^{2}$ and MSE). The models with $\log$ mortality rate as the outcome had better goodness-of-fit. For these analyses, we utilized a weighted regression with the weighting scheme of Pelletier and col-

Figure 2.2 Underweight and diarrhoea mortality: (a) deaths per 1000; (b) logarithm of deaths per 1000

leagues: (1/deaths) + (1/children). Fourth, we utilized weighted random effects models (Proc Mixed in SAS—see section 2.2 under subregional estimates), to provide combined estimates of the relation between weight-for-age and risk of mortality. The midpoint of the anthropometric category was used for estimation, and -0.5 SD was considered the value of the reference category. The results of the regression analyses are provided in Table 2.5. From these coefficients, estimated relative risk and $95 \%$ CIs were calculated. These steps were performed for all-cause mortality as well as by cause of death.

Figure 2.3 Underweight and pneumonia mortality: (a) deaths per I000; (b) logarithm of deaths per 1000

(b)

## Results

In all, we identified 12 potential studies, and have utilized data from 10 studies in the current analysis. We excluded two studies from the analysis: data from Peru were excluded because the study was too small and provided insufficient deaths for the analysis; data from Brazil were excluded because they resulted from a case-control study and were therefore not appropriate for our analysis.

The 10 studies were conducted in sub-Saharan Africa and Asia (Table 2.3). Each study contributed data on deaths due to diarrhoea and pneu-

Figure 2.4 Underweight and measles mortality: (a) deaths per 1000; (b) logarithm of deaths per 1000

monia (see Figures 2.2 and 2.3); however, exposure to infectious diseases such as malaria and measles depends on the ecology of the study setting and health care utilization (i.e. measles vaccination rates), and thus, not all studies contributed data on these causes of death. In all, six studies from Ghana, Guinea-Bissau, Indonesia, Nepal, the Philippines and Senegal contributed data on deaths due to measles (Figure 2.4). Three studies, from Ghana, Guinea-Bissau and Senegal contributed data on malaria-related deaths (Figure 2.5).

From the regression analyses we calculated the relative risk (95\% CI) of death by cause of death for each category of weight-for-age as

Figure 2.5 Underweight and malaria mortality: (a) deaths per I000; (b) logarithm of deaths per 1000

Table 2.5 Regression coefficients for models relating low weight-forage with mortality, by cause

Calculated at $-3.5,-2.5,-1.5$ vs 0.5 SD weight-for-age.
compared to the reference category of weight-for-age >-1 SD (Table 2.6). As shown, there are significant risks of death associated with low weight-for-age for overall mortality as well as for each cause of death examined.

Several results on the relationships between anthropometric status and specific causes of mortality should be interpreted with caution. First, studies on the influence of low weight-for-age on measles mortality have yielded equivocal results. For example, a community-based longitudinal study by Chen et al. (1980) in Bangladesh found that underweight children were at over twice the risk for measles mortality (risk ratio 2.37, $95 \%$ CI 0.96-5.86), while Aaby et al. (1988) observed little effect attributable to pre-existing nutritional status in Guinea-Bissau (estimated risk ratio $0.83,95 \%$ CI $0.25-2.78$ ). Other factors, such as intra-household crowding and the different levels of exposure experienced by primary and secondary cases, appeared to have greater influence on clinical outcome. Second, in the study by Andersen (1997) in Guinea-Bissau, deaths due to malaria were reported as due to fever, and thus deaths due to febrile illnesses other than malaria were necessarily included. However, as shown in Figure 2.5 (b), the results are quite consistent with those from Senegal. The results from Ghana suggest a different pattern of relationship with mortality risk, but it should be noted that the number of deaths due to malaria is quite small $(n=8)$. Further research is needed to refine these estimates. Finally, as described earlier, poor nutritional status is associated with poverty and poor environment. Some of the effects of such factors on child health are mediated through modifying anthropometry and some through other mechanisms. Therefore, it is likely that the hazard estimates presented here are affected by confounding due to a number of such factors.

### 4.2 RISK OF MORBIDITY FROM CHILDHOOD INFECTIONS

The incidence of infection and the risk of other morbidities associated with underweight status were estimated through a literature review and meta-analysis of published data.

## Search Strategy for identifying studies

Articles relating to undernutrition were identified for review based upon database searches of literature published between 1966 and 2001 in English, or having an English abstract. Searches of Medline, Popline and PsychInfo databases were conducted through PubMed (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi) and Internet Grateful Med (http://igm.nlm.nih.gov, now discontinued) using numerous keywords, author names and "related articles" links. After reviewing the abstracts, English-language articles that examined the relationship between anthropometric status and health outcomes among human populations were selected.

Once copies of articles were obtained, additional publications were identified from the reference lists of those articles. Several nutrition researchers were consulted as to their awareness of any ongoing studies or additional published or unpublished data. However, beyond this and the search strategy described above, there was no systematic attempt to identify unpublished studies or dissertations.

## INCLUSION/EXCLUSION CRITERIA

The studies considered for review were restricted to: (i) original research reports of community-based or facility-based controlled trials, cohort studies, case-control studies, cross-sectional studies and retrospective analyses of records; (ii) critical review articles that contained original research results not available elsewhere; and (iii) meta-analyses of original research results. Studies that were excluded from the review and analysis were: (i) animal studies; (ii) case reports; (iii) ecological analyses; (iv) studies of special populations (e.g. dialysis patients, acquired immunodeficiency syndrome [AIDS] patients); (v) studies without a control or comparison group; (vi) studies where nutritional status was defined only by birth weight; (vii) studies where the term "malnutrition" was used without further descriptive information or reference to a source providing such information; and (viii) studies where clear risk estimates were not presented or could not be calculated from the reported data.

The analysis was limited to studies conducted among populations in developing countries, among whom poor anthropometric status was considered more likely to reflect undernutrition. Studies of protein/energy supplementation or fortification were excluded from the analysis because the exposure variable (i.e. supplemented vs not supplemented) was not compatible with the anthropometric definition of undernutrition used here. The analysis of studies was limited to those reporting weight-for-age according to either $z$-score or percentage of median relative to the Harvard (Jelliffe 1966) or NCHS/WHO (Hamill 1977; WHO 1978) references.

## ANALYTIC METHODS USED TO COMBINE INDIVIDUAL STUDY RISK ESTIMATES

Meta-analyses were performed using unadjusted data from studies that satisfied all of the inclusion/exclusion criteria and provided sufficient statistical information (e.g. sample sizes per group, means and SDs or significance test values). Original source data were not obtained for these meta-analyses. Each meta-analysis was based on data exactly as reported in the publication, whenever possible. In some cases, the data had to be adapted from reported rates and statistical information in order to convert them into comparable units of measurement or to conform to comparable nutritional categories. For example, a multiplier would be used to convert diarrhoea episodes per month into diarrhoea episodes per year, or categorical data corresponding to two or more degrees of malnutrition would be collapsed into a single category. Estimates were made of data plotted in figure form if the figure provided sufficient clarity and precision.

All modelling and testing was conducted using Intercooled STATA 6.0. Studies reviewing malaria risk associated with underweight status were combined using Mantel-Haenszel fixed-effect models and tests of heterogeneity. Relative risk of diarrhoea associated with low weight-for-age was calculated from summary data and estimates of lower and upper confidence limits were calculated using the incidence-density binomial approximation to the normal distribution. Individual study estimates were then combined using Mantel-Haenszel combination techniques and tests of heterogeneity. Random effects models were used to combine individual study estimates for risk of pneumonia associated with low weight-for-age. For each outcome, sensitivity analyses were conducted to determine if any studies were significantly driving the estimate.

Although $z$-score is now preferable, most studies reported anthropometric status in terms of percentage of median, and cut-off points to classify malnutrition varied among different studies. As a result, the definition of underweight was not absolutely consistent among the studies combined in each summary estimate. The differences in definition in such cases were distinguished in this review through the use of multiple analysis "levels", wherein studies were separated by their nutritional categorization scheme during the analysis process in order to compare and contrast the results. Analysis levels are described further in the sections on pneumonia and diarrhoea results.

Weight-for-age was analysed according to multiple categories of severity, when possible, in order to describe any potential dose-response effect and better characterize possible health risks among the large proportion of mild-to-moderate malnutrition cases. The ability to examine multiple weight-for-age levels, however, was highly limited by the available published data; the majority of studies analysed anthropometric status as a dichotomous variable only. Therefore, for all health outcomes, underweight was analysed as a dichotomous variable, comparing individuals
falling below the designated weight-for-age cut-off point to those above the cut-off point (the reference group). A drawback to the dichotomous approach is that if a dose-response trend exists, combining intermedi-ate-risk and low-risk groups into a single category for a dichotomous analysis could have the effect of underestimating the true risk. An additional analysis was conducted when data on multiple weight-for-age categories were available, in which case data were conflated into three anthropometric categories: moderately to severely underweight (e.g. weight-for-age below -2 SDs), mildly underweight (e.g. weight-for-age between -1 and -2 SDs) and normal (e.g. weight-for-age greater than $-1 \mathrm{SD})$. Risk ratios were then estimated for both categories in relation to the reference category of weight-for-age >-1 SD. When weight-for-age was defined by percentage of median, the overall analysis was subdivided into separate analysis levels according to the cut-off points used.

## MEASLES RESULTS

There were an inadequate number of eligible studies for a summary risk analysis of weight-for-age and measles incidence. Evidence from an observational study in the Gambia (Lamb 1988) and a controlled supplementation trial in India (Gopalan et al. 1973) suggest, however, that pre-morbid underweight status has no significant effect on the incidence of measles infection. In India, Sinha et al. (1977) observed a reduced incidence of measles rash among children in the lowest weight percentiles, but this may represent a lowered immune response rather than a reduced incidence of infection. Beau et al. (1987) in Senegal noted a higher prevalence of measles among hospitalized children who were wasted at admission, but reverse causality would explain this observation.

## Malaria results

Research and clinical observation over the past several decades have generated debate as to how undernutrition may influence susceptibility to malaria. Conflicting results occur, in part, because susceptibility to malaria attack and/or infection is highly dependent on the individual's immune status, which, in turn, is influenced by factors such as age, pregnancy status and the level of endemicity within a population (Shankar 2000). The relationship between malaria and undernutrition has been examined according to several outcome variables, including presence or density of malaria parasites in the blood, episodes of malarial illness, incidence of complicated malaria (cerebral malaria or severe malarial anaemia) among malaria cases and case-fatality. This comparative risk analysis focused only on the incidence of malaria attacks, defined clinically as episodes of fever with slide-confirmation of parasites in the blood, or, in some studies, less specifically as fever with chills. Most of the data related to infection by Plasmodium falciparum, although some studies included data on Plasmodium vivax, as well.

Table 2.7 Risk of malaria attack associated with low weight-for-age from five studies

| Location | Study | Study type | Cut-off point | Sample <br> size | Risk estimate (95\% CI) |
| :---: | :---: | :---: | :---: | :---: | :---: |
| Congo | Tonglet et al. (1999) | Community-based cohort | WA <25th percentile | 842 | $R \mathrm{R}=0.92$ (0.72-1.17) |
| Gambia | Snow et al. (1991) | Community-based cohort | WA < $70 \%$ | 138 | $R \mathrm{R}=1.52$ (0.59-3.93) |
| Nigeria | Adelekan et al. (1997) | Facility-based case-control | WAZ <-2 | 65 | $\mathrm{OR}=1.50$ (0.5I-4.4I) |
| Sudan | el Samani et al. (1987) | Community-based cross-sectional | WA < $75 \%$ | 445 | $R \mathrm{R}=1.63$ (1.18-2.27) |
| Vanuatu | Williams et al. (1997) | Community-based cohort | WAZ <-2 | 911 | $R \mathrm{R}=\mathrm{I} .28$ (0.87-I.89) |

WA Weight-for-age.

It is difficult to adequately estimate any effect of low weight-for-age on risk of malaria morbidity given the scarcity of studies reporting both weight-for-age and malaria data. Five studies were identified that fulfilled that initial requirement (Table 2.7). These studies examined nutritional status as a dichotomous variable, comparing underweight children (defined as WAZ $<-2$, weight-for-age $<70 \%$, or weight-for-age $<75 \%$ of the NCHS reference median) to adequate-weight children; there were insufficient data from eligible prospective studies to examine any potential risk associated with milder degrees of malnutrition (i.e. WAZ between -1 and -2 ). Of the five studies, cohort studies from the Gambia (Snow et al. 1991), the Congo (Tonglet et al. 1999) and Vanuatu (Williams et al. 1997) among children aged $1-4$ years, $<2$ years and $<10$ years, respectively, reported statistically non-significant differences in malaria morbidity between underweight and normal children. In a facility-based case-control study in Nigeria (Adelekan et al. 1997) malaria cases in children aged $<8$ years had slightly, albeit not significantly, lower weight-for-age than non-infected controls, but this study was dropped from the final analysis because nutritional status was assessed after the onset of illness, leaving causality ambiguous. A cross-sectional study in the Sudan (el Samani et al. 1987) observed significantly greater history of malaria attacks (defined as fever with rigors and joint pain) among underweight children aged $<5$ years, but the causality was unclear in this case, as well.

Of the remaining three prospective studies, the Congo study (Tonglet et al. 1999), which reported a relative risk of 0.92 ( $95 \%$ CI $0.72-1.17$ ) for a malaria episode, was dropped from the summary analysis because nutritional categories were defined according to local reference data. Following meta-analysis of the two remaining cohort studies, the most

Table 2.8 Combined estimate of risk for malaria attack associated with low weight-for-age from two cohort studies

| Location | Study | Risk estimate (95\% Cl) |
| :--- | :--- | :---: |
| Gambia | Snow et al. (1991) | $1.52(0.59-3.93)$ |
| Vanuatu | Williams et al. (1997) | $1.28(0.87-\mathrm{I} .89)$ |
| Combined estimate |  | $1.31(0.92-1.88)$ |

appropriate for this assessment, the combined relative risk for malaria among children having weight-for-age $<-2$ SDs was statistically nonsignificant (RR1.31, 95\% CI 0.92-1.88) (Table 2.8). This overall estimate was more heavily influenced by the Vanuatu cohort study, which reported a slightly but not significantly higher incidence of $P$. falciparum malaria (defined as fever with parasitaemia $>1000 / \mu \mathrm{l}$ ) among children who were classified as underweight prior to the period of morbidity follow-up.

## PNEUMONIA/ALRI RESULTS

Undernutrition may increase the risk of pneumonia through a number of potential mechanisms. In general, cell-mediated immunity is depressed in undernourished children (Rivera and Martorell 1988; Scrimshaw and SanGiovanni 1997). Respiratory muscles weaken, impairing the cough reflex and reducing a child's ability to adequately clear secretions from the respiratory tract or respond to hypoxia through tachypnea (Wilson 1985). Salivary IgA is decreased, compromising the integrity of the respiratory tract mucosa and leaving the mucosa susceptible to invasion by microorganisms (Lehmann et al. 1988).

Over 60 studies evaluating the relationship between acute respiratory infections and malnutrition were initially identified. These included a collaborative data group from the United States National Academy of Sciences Research Program of the Board on Science and Technology for International Development (BOSTID). We immediately excluded studies that examined upper respiratory tract infections only; did not distinguish between upper and lower respiratory tract infections in their data collection and/or analysis; limited the report to single etiological agents (e.g. only pneumococcus); or did not report anthropometric status in terms of weight-for-age. The remaining studies are briefly described below, although not all fulfilled the criteria for inclusion in a summary analysis, usually for reasons of insufficient data or statistical information. Studies that provided estimates of risk are listed in Tables 2.9 and 2.10.

Studies varied in their case definitions of ALRI and pneumonia, classifying them on the basis of mothers' recall of the physician's diagnosis (Victora et al. 1990); radiologically confirmed pneumonia (Alam et al. 1984; Fonseca et al. 1996; Victora et al. 1994); or cough and fever with

Table 2.9 Risk of pneumonia/ALRI incidence associated with low weight-for-age from studies included in summary estimate

| Analysis level | Study | Location | Cut-off point | Sample <br> size | Crude RR (95\% CI) | Adjusted RR ${ }^{\text {a }}$ (95\% CI) |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |

- No data.
a All crude relative risks reported in Table 2.9 represent risk associated with weight-for-age below the cut-off point compared to risk associated with weight-for-age above the cut-off point. Adjusted relative risks, however, varied in their referent group and in the variables adjusted as indicated in the table footnotes.
b Adjusted for income. Adjusted risk ratio was based on WAZ $<-2$ relative to $W A Z \geq 0$. Crude risk estimate of 1.32 was based on WAZ $<-2$ relative to WAZ $>-2$. (Crude risk estimate based on WAZ $<-2$ relative to WAZ $\geq 0$ is 2.38 [ $95 \% \mathrm{Cl}$ I.18-4.78].)
c Adjusted for season, socioeconomic status and geographic region. Adjusted RR was based on weight-for-age $<80 \%$ relative to weight-for-age $>90 \%$; crude RR was based on weight-for-age $<80 \%$ relative to weight-for-age $>80 \%$. (Crude RR based on weight-for-age $<80 \%$ relative to weight-for-age $>90 \%$ is 2.03 [ $95 \% \mathrm{Cl} 0.44-9.25$ ].)
rapid respiratory rate (Cunha 2000; Deb 1998; Smith et al. 1991) and/or chest indrawing (Ballard and Neumann 1995; Spooner et al. 1989; Zaman et al. 1996). The case definition for pneumonia recommended by WHO is cough or difficult breathing with rapid respiration $(>50$ breaths/min for infants aged 2 months to under 1 year; $>40$ breaths $/ \mathrm{min}$ for children aged 1 to 5 years) or chest indrawing, stridor or general danger signs such as vomiting, convulsions, lethargy, unconsciousness or inability to drink/breastfeed (WHO 1999b). The coordinated BOSTID data group defined ALRI as the presence of at least one of the following: rales or crepitations, wheezing, stridor, cyanosis, rapid respiratory rate ( $>50$ breaths $/ \mathrm{min}$ ), or chest indrawing (Selwyn 1990). Studies were considered for our summary analysis if the case definition for ALRI was consistent with the recommended WHO definition. With the exception of a Bangladesh study among diarrhoea patients aged $<12$ years (Alam et al. 1984), all of the studies examined children aged $\leq 5$ years. Incidence was reported predominantly as the number of ALRI episodes over a given follow-up period (i.e. multiple episodes per individual child counted as separate events), although a few studies reported the proportion of children with one or more ALRI episodes (i.e. multiple episodes per individual child counted as a single event).
Table 2.10 Risk of pneumonia/ALRI incidence associated with low weight-for-age from excluded studies

| Location | Study | Study type | Cut-off point | Crude risk estimate (95\% Cl) | Adjusted risk estimate ${ }^{\text {a }}$ (95\% CI) | Reason for exclusion |

[^4]
## Excluded studies

The collaborative BOSTID study reported community-based longitudinal data from Guatemala, Papua New Guinea, the Philippines and Uruguay (Selwyn 1990). In each population, researchers observed higher incidence of ALRI among underweight children aged 18-59 months, with relative risks ranging between 1.2 (Guatemala) and 2.7 (Uruguay). An increased risk was observed among the younger group of 0-17-month-old children only in the Philippines ( $\mathrm{RR}=1.3$ ). While the methodology used in these four countries was standardized for better internal comparability among study sites, the results were not included in our summary analysis because nutritional status was evaluated using an anthropometric cut-off point (10th percentile) higher than WAZ of -2 (equivalent to approximately the third percentile-Pelletier 1994) and the case definitions used in Guatemala and Uruguay could have classified asthma as ALRI.

Ten ALRI investigations were case-control studies or record reviews and were excluded because of the possibility of reverse-causality. In Colombia (Berman et al. 1983) and India (Shah et al. 1994), children with pneumonia were significantly more likely to be moderately or severely malnourished than were non-ALRI paediatric patients or outpatients. In South Africa, in contrast, odds of being malnourished were not significantly different between pneumonia patients and a control group of upper respiratory infection patients (Wesley and Loening 1996). In a case history review in Bangladesh, malnourished diarrhoea patients aged 1-5 years had a higher incidence of pneumonia during hospitalization than diarrhoea patients considered well-nourished, although the relationship was not observed in infants (Alam et al. 1984).

Case-control studies in Brazil, China and Papua New Guinea (Fonseca et al. 1996; Victora et al. 1994) compared cases to healthy controls from the surrounding community. Children having lower respiratory infections in China (Liu et al. 1991) and Papua New Guinea (Spooner et al. 1989) were at significantly greater odds of being underweight compared to healthy controls, and underweight children in Papua New Guinea were four times as likely to be admitted to the hospital with pneumonia as non-malnourished children (Barker et al. as cited in Lehmann et al. 1988). Similarly, in an urban area of southern Brazil, children aged $<2$ years hospitalized with pneumonia had a reported OR of 5.87 ( $95 \%$ CI 3.30-10.44) for weight-for-age $<-2$ SDs compared to healthy, age-matched neighbourhood controls; adjusted for age, sex, crowding and socioeconomic factors, the odds ratio decreased slightly to 4.77 (95\% CI 2.46-9.06) (Victora et al. 1994). Fonseca et al. (1996) conducted a similarly designed study in northern Brazil and found undernutrition to be the most important risk factor for pneumonia among children aged $<2$ years attending an outpatient clinic; the odds ratio for weight-for-age $<-2$ SDs among cases was 4.57 ( $95 \%$ CI 2.93-7.13) adjusted for income, parents' education and previous pneumonia.

In a community-based survey in Brazil, Cunha et al. (2000) compared anthropometric status of children aged $<5$ years according to mothers' report of respiratory illness in the previous week (Cunha et al. 2000). Adjusted for age, sex and household crowding, children with weight-forage below -2 SDs had significantly greater odds for an ALRI episode compared to children with weight-for-age >-1 SD.

Prospective cohort studies that assessed anthropometric status prior to illness were more appropriate for evaluating malnutrition as a causal factor in ALRI incidence. In rural Papua New Guinea, Smith et al. (1991) assessed nutritional status and subsequent incidence of ALRI through twice-weekly home visits, reporting an age-adjusted incidence rate ratio of approximately 2.1 ( $95 \%$ CI $1.25-3.4$ ) associated with WAZ $<-2$ relative to weight-for-age $>0 \mathrm{SD}$. There was no evidence of confounding by socioeconomic status (defined by education, income and household crowding) or previous episodes of illness. The data, however, were reported only in figure form and lacked sufficient statistical information for inclusion in the meta-analysis. An earlier cohort study in Papua New Guinea by Binns (1976) observed a relative risk of 1.59 for pneumonia among children having weight-for-age $<80 \%$, but, likewise, did not report sufficient statistical data for inclusion (such as sample sizes per weight-for-age category).

## Studies included in the risk estimate

James (1972) in urban Costa Rica reported the highest risk estimate among cohort studies. Based on weekly physician visits and mothers' recall, underweight children aged $<5$ years had a similar number of overall respiratory tract infections as normal-weight children, but experienced a relative risk of 12.4 ( $95 \%$ CI $3.11-49.25$ ) for bronchopneumonia, with no apparent differences between groups in breastfeeding duration, age distribution, levels of household crowding, incomes or sanitation. In urban Brazil, Victora et al. (1990) followed a cohort of infants for subsequent hospital admissions, reporting a significant relative risk (adjusted for family income) of 1.75 for pneumonia among children with pre-morbid WAZ $<-2$ compared to $\geq 0$. The risk estimate remained statistically significant after adjusting for previous pneumonia hospitalizations (data not reported). Incidence referred to hospital admissions, which represented only the more severe cases of ALRI, and there is potential bias if underweight ALRI cases are more likely to be admitted than the normal weight cases. In a community-based cohort study in Bangladesh, Zaman et al. (1996) followed up morbidity every four days and observed an increased, but not statistically significant, risk of 1.25 between low weight-for-age and subsequent incidence of ALRI among children aged $\leq 5$ years; adjusted for age, sex and socio-demographic variables, the relative risk became statistically significant, with a one-unit decrease in WAZ being associated with a $55 \%$ increase in the incidence of ALRI. A smaller cohort study in Kenya reported a slightly higher,
but statistically non-significant, relative risk for ALRI of 1.8 (95\% CI $0.52-6.4$ ) among children aged 18-25 months with weight-for-age $<80 \%$ relative to weight-for-age $>90 \%$, adjusted for season, socioeconomic status and geographic region (Ballard and Neumann 1995). In an urban and rural community-based cohort study in India (Deb 1998), underweight children aged $<5$ years experienced a significantly higher rate of pneumonia over the course of 18 months relative to normal-weight children $(\mathrm{RR}=2.53)$, although it was not reported how comparable malnourished and normal groups were in relation to potentially confounding variables.

## Relative risk estimate

There were an insufficient number of studies reporting multiple categories of weight to compare the risk of ALRI associated with mild-to-moderate degrees of underweight, and, therefore, only a dichotomous analysis was performed. Two cohort studies reported anthropometric status in terms of $z$-score and were treated as "analysis level one" (Table 2.11). Analysis levels three and four used cut-off points in terms of percentage of median. (Analysis level two was reserved for studies using a cut-off point of $70 \%$, but no eligible studies using that cut-off point were included here.)

Relative risks according to cut-off point are represented graphically in Figure 2.6 and summary risk estimates are listed in Table 2.12 according to analysis level. Overall, community-based cohort studies that

Table 2.1I Analysis levels according to anthropometric classification used

| Analysis level | Comparison |
| :--- | :---: |
| 1 | WAZ $<-2$ vs WAZ $>-2$ |
| 2 | WA $<70 \%$ vs WA $>70 \%$ |
| 3 | WA $<75 \%$ vs WA $>75 \%$ |
| 4 | WA $<80 \%$ vs WA $>80 \%$ |

Table 2.12 Combined estimate of risk for pneumonia/ALRI incidence associated with low weight-for-age

| Study type | Analysis level | Number of studies | Combined risk <br> estimate (95\% Cl) |
| :--- | :---: | :---: | :---: |
| Cohort | I | 2 | $1.28(0.86-\mathrm{I} .89)$ |

Figure 2.6 Relative risk of pneumonia/ALRI according to weight-for-age cut-off point used in study

provided sufficient results and statistical data yielded a combined risk estimate for ALRI of 1.86 associated with low weight-for-age (Table 2.12). Even excluding the high estimate observed in the study by James (1972), the risk ( $R R=1.72$ ) remained statistically significant.

## DIARRHOEA RESULTS

There is a large body of literature examining the relationship between malnutrition and diarrhoea, and cross-sectional studies among children have consistently shown a trend of increasing diarrhoea prevalence associated with decreases in anthropometric status. Malnutrition and concomitant growth faltering and weight decline are not uncommon following severe bouts of diarrhoea among children in developing coun-
tries, but the reverse relationship-that pre-morbid undernutrition increases susceptibility to subsequent diarrhoea attack-is more uncertain. We selected prospective studies that specifically examined premorbid anthropometric status as a risk factor for subsequent diarrhoea, rather than the reverse relationship. Studies that simultaneously assessed weight-for-age and diarrhoea were not considered because the direction of the relationship could not be determined-i.e. there was potential reverse causality with regard to the risk relationship. All of the studies related to children aged $\leq 5$ years; little if any data were available for older age groups. In some studies, morbidity was compared to the initial assessment of nutritional status only, whereas other studies reclassified children, as necessary, according to periodic follow-up measurements. An episode of diarrhoea was typically defined as three or more loose, liquid or watery stools, or at least one bloody stool in a 24 -hour period. An episode was generally considered terminated when normal stool patterns returned for at least three days. Some of the outcome variables relating to diarrhoea included incidence of general diarrhoea, incidence of dysentery and incidence of persistent diarrhoea, defined as diarrhoea lasting 14 days or longer. We restricted our analysis to the incidence of general diarrhoea, and excluded studies that focused solely on a single pathogenic agent (e.g. Cryptosporidium, Vibrio cholerae), watery diarrhoea alone or bloody diarrhoea alone.

Literature supports an increased risk of diarrhoea mortality associated with low weight-for-age (Bhan et al. 1986; Chen et al. 1980; Fawzi et al. 1997; Rice et al. 2000; Yoon et al. 1997), but the effect on diarrhoea incidence has been less clear. Cohort studies in Bangladesh (Baqui et al. 1993; Chowdhury et al. 1990), Brazil (Schorling et al. 1990), Costa Rica (James 1972), the Congo (Tonglet et al. 1999), Ethiopia (Lindtjorn et al. 1993), the Gambia (Tomkins et al. 1989), Ghana (Biritwum et al. 1986), Guatemala (Gordon et al. 1964), India (Ghai and Jaiswal 1970; Walia et al. 1989), Mexico (Sepulveda et al. 1988), Papua New Guinea (Binns 1976) and the Sudan (el Samani et al. 1988; Kossman et al. 2000), reported higher diarrhoea incidence rates among underweight children (rate ratios of 1.1 to 2.4 ), while other studies observed no statistically significant effect (Anand et al. 1994; Bairagi et al. 1987; Bhan et al. 1986; Black et al. 1984; Chen et al. 1981; Henry et al. 1987; Khan and Yunus 1990; Mathur et al. 1985; Molbak et al. 1997b; Thongkrajai et al. 1990; Tomkins 1981; Victora et al. 1990). Factors such as age, socioeconomic status, season, breastfeeding and recent history of diarrhoea, among others, can be important confounders in the relationship between anthropometric status and diarrhoeal illness. When statistical adjustment had been made for such variables, several studies (e.g. el Samani et al. 1988; Kossman et al. 2000; Schorling et al. 1990; Sepulveda et al. 1988; Tonglet et al. 1999; Wierzba et al. 2001) continued to show a significant relationship, while others (Chowdhury et al. 1990; Lindtjorn et al. 1993) did not.

Table 2.13 Diarrhoea cohort studies included in dichotomous analysis

a All crude risk estimates in Table 2.13 represent incidence below cut-off relative to incidence above cut-off. Adjusted risk estimates, however, vary in their referent category and adjusted variables as shown in the following table footnotes.
b Estimate adjusted for age, sex, socioeconomic status, breastfeeding and previous morbidity. WAZ <-2 vs WAZ >-2.
c Estimate adjusted for age. WAZ $<-2$ vs WAZ $>-2$. When stratified by previous diarrhoea experience, age-adjusted rate ratios were $I .00(0.75-I .33)$ and 1.26 (I.07-I.49) for underweight children without recent morbidity and with recent morbidity, respectively.
d Estimate adjusted for previous diarrhoea morbidity, age, sex and household crowding. Estimate is an OR comparing WAZ $<-3$ to WAZ >-3.
e Estimate adjusted for income. WAZ $<-2$ vs WAZ $\geq 0$.
f Estimate adjusted for age. Weight-for-age $<75 \%$ vs weight-for-age $\geq 90 \%$.
g Estimate adjusted for age, sex, season, socioeconomic status and previous morbidity. Weight-for-age $<90 \%$ vs weight-forage $\geq 90 \%$.

Table 2.14 Analysis levels for dichotomous analysis according to anthropometric definition used in study

| Analysis level | Comparison |
| :--- | :--- |
| 1 | WAZ $<-2$ vs WAZ $>-2$ |
| 2 | WA $<70 \%$ vs WA $>70 \%$ |
| 3 | WA $<75 \%$ vs $W A>75 \%$ |
| 4 | WA $<80 \%$ vs WA $>80 \%$ |
| 5 | WA $<85 \%$ vs WA $>85 \%$ |

Table 2.13 summarizes prospective studies used to estimate diarrhoea incidence according to weight-for-age. The majority of diarrhoea studies reported anthropometric status in terms of percentage of median rather than $z$-score and the cut-off points varied by study. In India, for example, most studies conformed to the Indian Academy of Pediatrics classification in which weight-for-age $>80 \%$ represents normal status and weight-for-age $<70 \%$ represents second-degree, third-degree or fourth-degree malnutrition (Indian Academy of Pediatrics 1972). Many others used the Gomez classification, defining second-degree malnutrition and worse as weight-for-age $<75 \%$ (Gomez et al. 1956). For comparison, studies were grouped into different analysis levels according to the cut-off points used to classify malnutrition (Table 2.14).

## Dichotomous estimate

In developing a summary risk estimate, nutritional status was first examined as a dichotomous variable comparing all children below the cut-off point ("malnourished") to children above that point (reference group). The dichotomous approach allowed for the inclusion of the greatest number of studies, since many studies did not further subdivide the malnourished group into discrete anthropometric categories.

## Excluded studies

Ten studies that were identified were excluded from the risk analysis (Table 2.15). Seven prospective studies were excluded due to insufficient statistical data (e.g. sample sizes per anthropometric category), data presented as a figure only, or the use of a different growth reference. Six of the seven reported an increased incidence of diarrhoea episodes associated with low weight-for-age, including studies in the Sudan (Kossman et al. 2000) and the Congo (Tonglet et al. 1999) that adjusted for previous diarrhoea morbidity. An additional three cross-sectional studies in Ecuador (Brussow et al. 1993), India (Luwang and Datta 1982) and El Salvador (Stetler et al. 1981) reported risk estimates on the order of 1.45 to 1.57 , but reverse causality disqualified the studies.

## Studies included in the risk estimate

Figure 2.7 illustrates the distribution of individual study risk estimates according to the cut-off point used. Twenty cohort studies provided sufficient results and statistical data for inclusion in a summary estimate (Table 2.13). The evidence regarding risk of diarrhoea was equivocal

Table 2.16 Combined estimate for diarrhoea incidence from dichotomous analysis

| Study type | Analysis level | Number of studies | Combined risk estimate (95\% Cl) |
| :--- | :--- | :---: | :---: |
| Cohort | 1 | 4 | $1.25(1.04-1.50)$ |
| Cohort | 2 | 4 | $1.24(0.90-1.70)$ |
| Cohort | 3 | 9 | $1.18(1.05-1.33)$ |
| Cohort | $4+5$ | 3 | $1.51(1.20-1.90)$ |
| Combined estimate | $1+2+3+4+5$ | 20 | $1.23(1.12-1.35)$ |

among these studies, with half reporting no significant effect. Individual studies reported crude risk estimates ranging between 0.78 in Brazil (Victora et al. 1990) and 1.86 in Mexico (Sepulveda et al. 1988). Three of four studies that adjusted for previous diarrhoea morbidity found a significantly increased risk of diarrhoea incidence associated with low weight-for-age (el Samani et al. 1988; Schorling et al. 1990; Wierzba et al. 2001). The fourth, in Bangladesh, observed an increased risk of diarrhoea among underweight children $(R R=1.26)$ who had already suffered diarrhoea within the preceding three months, but the risk was not significant for those children without recent diarrhoea experience ( $\mathrm{RR}=1.00$ ) (Baqui et al. 1993). In the most recently published investigation, Wierzba et al. (2001) in Egypt observed that WAZ $<-2$ predisposed toward increased incidence of diarrhoea among children aged $<3$ years, yielding a relative risk of 1.7 ( $95 \%$ CI1.2-2.3) compared to $z$-score $>-2$, after adjusting for age, sex, socioeconomic status, breastfeeding and previous episodes of diarrhoea.

## Dichotomous relative risk estimate

Based on all cohort studies, a combined estimate suggested underweight children were at a significantly increased relative risk of 1.23 (95\% CI 1.12-1.35) for developing an episode of diarrhoea (Table 2.16). The estimate based on a cut-off point of $z$-score $<-2(R R=1.25)$ was similar to the estimate using percentage of median $<70 \%(R R=1.24)$ and percentage of median $<75 \% ~(R R=1.18)$. Higher cut-off points of $80 \%$ or $85 \%$ yielded a higher relative risk of 1.51 , possibly due to the small number of studies or the comparatively better nutritional status of the referent group.

## Multi-categorical estimate

We also attempted to examine the risk of diarrhoea incidence according to multiple anthropometric categories, comparing incidence among moderately to severely underweight (e.g. WAZ $<-2$ ), mildly underweight (e.g. WAZ between -2 and -1 ) and "normal"(e.g. WAZ >-1) children. The

Table 2.17 Analysis levels for multiple categorical analysis according to anthropometric classification used in study

| Analysis level | Underweight categories | Cut-off point |
| :--- | :--- | :--- |
| I | Moderate-severe | WAZ $<-2$ |
|  | Mild | WAZ -2 to -I |
|  | Normal (referent) | WAZ >-I |
| 2 | Moderate-severe | WA $<70 \%$ |
|  | Mild | WA $70-80 \%$ |
|  | Normal (referent) | WA $>80 \%$ |
| 3 | Moderate-severe | WA $<75 \%$ |
|  | Mild | WA 75-90\% |
|  | Normal (referent) | WA $>90 \%$ |
|  | Moderate-severe | WA $<60$ |
|  | Mild | WA $60-85 \%$ |
|  | Normal (referent) | WA $>85 \%$ |

studies used different cut-off points based on percentage of median and $z$-score and were subdivided into analysis levels according to the anthropometric classification scheme used (Table 2.17). A subset of 10 cohort studies reporting multiple anthropometric categories provided sufficient statistical data for inclusion in a summary analysis (Table 2.18).

The different classification schemes complicated combining studies to a greater extent than in the dichotomous analysis. Eight of 10 studies, however, fell into the second or third analysis levels, which produced relative risks of 1.23 and 1.28 , respectively, associated with moderate to severely low weight-for-age (Table 2.19). The corresponding risk estimates associated with mildly low weight-for-age were 1.17 and 0.95 for these analysis levels (Table 2.20). The overall risk estimates for diarrhoea based on all analysis levels were 1.25 (statistically significant) for moderate and severe underweight and 1.12 (not statistically significant) for mild underweight. Since the risk relationship was not significant for mild underweight, only the risk for moderate-severe underweight was considered toward the burden of disease estimate. This value (1.25) was similar to the value calculated in the dichotomous analysis (1.23). As there was no significant difference between the two estimates and the dichotomous value was based on a larger number of studies, the dichotomous value of 1.23 was selected for calculating burden of disease.

## Summary of morbidity risk estimates

Three morbidity outcomes contributed to the overall calculation of disease burden: diarrhoea incidence, pneumonia/ALRI incidence and malaria incidence. Table 2.21 summarizes the risk of disease incidence associated with low weight-for-age for each outcome. There was no evidence that undernutrition contributed to incidence of measles and other disease relationships cannot be adequately quantified at this time.

Table 2.18 Cohort studies of diarrhoea incidence included in categorical analysis

| $I+2+3+4$ |  | 10 | $1.25(1.03-1.52)$ |

### 4.3 RISK OF MORTALITY DUE TO PERINATAL CONDITIONS

"Perinatal conditions" are responsible for approximately $18 \%$ of all deaths among children aged $<5$ years in developing countries (de Onis et al. 1998). These deaths, concentrated in the neonatal period ( $\leq 28$ days postpartum), result mostly from low birth weight, birth asphyxia and trauma, neonatal infections (e.g. tetanus and syphilis) and congenital

Table 2.20 Combined estimates of diarrhoea incidence associated with mild underweight status relative to WAZ >-I

| Analysis level | Category | Number of studies | Combined risk estimate (95\% Cl) |
| :--- | :--- | :---: | :---: |
| I | WAZ -2 to -I | 1 | $1.93(1.05-3.56)$ |
| 2 | WA 70-80\% | 4 | $1.17(1.05-1.31)$ |
| 3 | WA 75-90\% | 4 | $0.95(0.68-1.34)$ |
| 4 | WA 60-85\% | 1 | $2.15(0.99-4.64)$ |
| $1+2+3$ |  | 9 | $1.09(0.92-1.29)$ |
| $1+2+3+4$ |  | 10 | $1.12(0.95-1.32)$ |

Table 2.21 Relative risk of morbidity associated with weight-for-age <-2SDs

| Morbidity outcome | Relative risk (95\% CI) |
| :--- | :---: |
| Diarrhoea incidence | $1.23(1.12-\mathrm{I} .35)$ |
| Pneumonia incidence | $1.86(1.06-3.28)$ |
| Malaria incidence | $1.31(0.92-1.88)$ |

anomalies (Anonymous 1999). In developed regions such as North America and western Europe, $23 \%$ of neonatal deaths are due to congenital anomalies and an additional $65 \%$ are the result of other perinatal conditions (C. Stein, personal communication, 2001). Of the deaths from perinatal conditions, the largest share ( $32-65 \%$ ) is attributed to low birth weight.

The Global Burden of Disease (GBD) study categorizes low birth weight, birth asphyxia, birth trauma and other conditions (such as neonatal sepsis, maternal and placental complications, respiratory distress, fetal blood loss, fetal haematological disorders, anaemia, perinatal infections and maternal diabetes) as "perinatal conditions", while deaths due to congenital anomalies, neonatal tetanus and syphilis are addressed separately (WHO 1992a). Among these conditions, low birth weightspecifically that due to IUGR-is the most strongly linked to undernutrition and is the only perinatal condition considered in our analysis.

Low birth weight is defined as birth weight below 2500 grams. It is a product of IUGR, preterm birth, or both in combination (Kramer 1987). In developing countries, the majority of low-birth-weight births are due to IUGR (usually defined as birth weight less than the tenth percentile of weight-for-gestational-age) whereas preterm birth ( $<37$ weeks gestation) is the predominant cause in most developed countries (Ashworth 1998). Preterm low-birth-weight infants tend to have higher neonatal mortality rates than full-term, growth-retarded infants; at
highest risk are low-birth-weight infants who are both growth-retarded and preterm (Barros et al. 1992; Behrman et al. 1971; Cogswell and Yip 1995; Gray et al. 1991; Sappenfield et al. 1987).

The etiology of IUGR is complex and multifactorial. In developing countries maternal undernutrition is the major determinant of IUGR, and evidence across populations has demonstrated a greater incidence of IUGR births among women who are underweight or stunted prior to conceiving, or who fail to gain sufficient weight during pregnancy (Bakketeig et al. 1998; King and Weininger 1989; Kramer 1987; WHO 1997). Poor maternal nutrition during pregnancy is thought to account for $14 \%$ of IUGR in developing countries; maternal stunting may account for $18.5 \%$ (ACC/SCN 2000b). Malaria, other acute and chronic infections and cigarette smoking are also important etiologic factors for IUGR in developing countries. In developed countries, smoking is the most important determinant of IUGR, followed by factors such as maternal nutrition, pre-eclampsia, genetic factors and alcohol or drug use (Bakketeig et al. 1998). IUGR is also associated with multiple births and primiparity (Cogswell and Yip 1995).

Fetal growth retardation takes different forms, which may have different implications for neonatal and infant health. IUGR can be subdivided into asymmetric (wasted) IUGR, characterized by adequate length and head circumference, but reduced weight and low ponderal index; and symmetric (stunted) IUGR, in which the ponderal index is normal but weight, length and head circumference are all reduced (Bakketeig 1998). Symmetric IUGR generally reflects early onset or chronic undernutrition in utero, while asymmetric IUGR is thought to result from undernutrition of later onset (Ashworth 1998). The difference may be clinically important, as asymmetrically growth-retarded infants have demonstrated higher risks of asphyxia, hypoglycaemia and other morbidities, and higher mortality rates in the early neonatal period (Ashworth 1998; Caulfield et al. 1991; Villar et al. 1990). Stunted infants, on the other hand, have greater risks of mortality in later infancy (Ashworth 1998; Balcazar and Haas 1990; Cheung et al. 2001).

The evidence relating low maternal BMI to preterm birth is more ambiguous. A 1995 WHO meta-analysis based on data sets from 20 developed and developing countries calculated a combined OR of 1.3 ( $95 \%$ CI 1.1-1.4) for preterm birth associated with pre-pregnancy BMI $<20 \mathrm{~kg} / \mathrm{m}^{2}$ (WHO 1995b). Individual studies, however, have been inconsistent. In Papua New Guinea, BMI was found to be a significant predictor of preterm delivery; a one-unit increase in BMI was associated with a reduced risk of preterm delivery ( $\mathrm{OR}=0.79$, $95 \%$ CI $0.66-0.94$ ), and remained significant after being adjusted for haemoglobin concentration, smoking, gravidity and anti-malarial use (Allen et al. 1998). A case-control study in India observed an increased risk of preterm birth with underweight status as well (Mavalankar et al. 1994). Other studies in Malawi (Pelletier et al. 1995) and Indonesia (Husaini et al. 1995)
reported little or no association between pre-pregnancy BMI and preterm delivery. In developed settings, studies from Canada (Kramer et al. 1995), Italy (Spinillo et al. 1998), the United Kingdom (Sebire et al. 2001) and the United States (Edwards et al. 1979; Naeye 1990; Siega-Riz et al. 1996) observed higher rates of preterm labour or delivery among underweight women, while other studies in Canada (Kramer et al. 1992), Finland (Rantakallio et al. 1995) and Sweden (Cnattingius et al. 1998) did not. Recently, in a study in the United States of America based on the National Maternal and Infant Health Survey found that underweight women had an increased risk for preterm delivery only when their pregnancy weight gain was inadequate (Schieve et al. 2000). Because of the uncertain risk relationship, low birth weight due to preterm birth was excluded from our analysis.

Although many studies conducted in developing countries examined the influence of maternal body size on infant birth weight and others compared neonatal mortality rates according to birth weight, few studies directly compared maternal weight to neonatal or perinatal mortality. These studies used postpartum weight as a proxy for pre-pregnant weight, and therefore, possible effects of pregnancy weight gain cannot be excluded. Among these, a slightly elevated risk of early neonatal death (adjusted $\mathrm{OR}=1.4,95 \%$ CI 1.0-1.9) was associated with maternal weight below 50 kg in a nested case-control study in Brazil (Gray et al. 1991). The authors adjusted for low birth weight in one regression model to distinguish between risk factors that might operate in part through low birth weight and factors that might influence neonatal death independently. Low maternal weight remained significantly associated with neonatal death only when low birth weight was excluded from the model, suggesting maternal weight influences neonatal death through low birth weight.

In other studies, maternal weight $<40 \mathrm{~kg}$ and low weight-to-height ratio were significantly associated with perinatal death in Ahmedabad, India ( $\mathrm{OR}=2.9,95 \%$ CI $1.8-4.7$ and $\mathrm{OR}=3.0,95 \% 1.9-4.4$, respectively), adjusted for maternal age, parity, obstetric history and antenatal care (Mavalankar et al. 1994). In the Sudan, maternal weight below 50 kg was significantly associated with perinatal death, after adjustment for birth interval, prior fetal loss and antenatal care, among other factors (adjusted OR=2.3, 95\% CI 1.1-4.8) (Taha et al. 1994). In a commu-nity-based case-control study in Punjab, perinatal death was significantly associated with weight $<40 \mathrm{~kg}$ and height $<152 \mathrm{~cm}$, but not BMI $<20 \mathrm{~kg} / \mathrm{m}^{2}$, after controlling for factors such as birth interval and length of gestation (Sachar and Soni 2000).

In developed countries, there is a consistent association between maternal underweight status and low birth weight, but the evidence relating maternal underweight status to perinatal death has been mixed. In New York City, low BMI prior to pregnancy was associated with slightly, but not significantly, higher perinatal mortality rates in one hospital-
based study (Bracero and Byrne 1998). Another analysis using data from the USA Collaborative Perinatal Study reported reduced perinatal mortality for infants of underweight mothers; among mothers with low pregnancy weight gain ( $<0.8 \mathrm{~kg} /$ month $)$, however, underweight status was associated with higher perinatal mortality (Naeye 1990). In Australia, the odds ratios for stillbirth/neonatal death (adjusted for gestational age, parity, smoking and maternal age) were 1.65 and 2.64 among women with low postpartum BMI (defined for postpartum women as $20-$ $\left.24.4 \mathrm{~kg} / \mathrm{m}^{2}\right)$ and very low postpartum BMI ( $<20 \mathrm{~kg} / \mathrm{m}^{2}$ ), respectively (Cattanach et al. 1993). In Finland, perinatal and childhood mortality rates were similar between women having low and normal BMI (Rantakallio et al. 1995), and in Sweden low maternal BMI was associated with reduced risk of late fetal death and a slightly, but not significantly, reduced risk of early neonatal death relative to maternal BMI of $20-25 \mathrm{~kg} / \mathrm{m}^{2}$ (Cnattingius et al. 1998).

Such studies have generated uncertainty about the significance of low birth weight, per se, as an intermediate variable in the causal pathway between prenatal factors and perinatal mortality (Rush 2001; Wilcox 2001). As with other anthropometric indicators, birth weight is regarded as a proxy for underlying biological processes that must be inferred. All prenatal factors that influence birth weight may not affect infant health equally. For example, high altitude is associated with lower birth weight, but not necessarily higher mortality (Cogswell and Yip 1995; Wilcox 2001). Therefore, caution must be taken when generalizing across populations.

## Estimate of mortality due to perinatal conditions

The relationship between maternal underweight status and neonatal mortality was estimated by considering two stages of the conceptual pathway mediated through IUGR. First, what is the proportion of IUGR attributable to poor maternal pre-pregnancy anthropometric status? And second, what proportion of neonatal mortality can be attributed to IUGR? There are four components to this equation: the proportion of IUGR births among live births in each subregion, an estimate of infant mortality risk associated with IUGR, subregional prevalence of underweight status among women of reproductive age and an estimate of the risk of IUGR associated with pre-pregnant underweight status.

By estimating the risk of IUGR in relation to pre-pregnancy BMI only, we are not considering the fraction of IUGR attributable to inadequate weight gain during pregnancy, and are potentially underestimating the overall influence of maternal weight on infant birth weight. Gains in pre-pregnancy and pregnancy weight have independent, additive effects on birth weight (Krasovec and Anderson 1991). Across diverse populations, low pregnancy weight gain, particularly in the second and third trimesters, has been associated with risk ratios of 1.7 to 2.0 for IUGR; among mothers who are below average height or weight before preg-
nancy, the risk ratios are 3.1 and 5.5, respectively (Strauss and Dietz 1999; WHO 1997). The prevalence data on pregnancy weight gain in developing countries is scarce, but there is evidence that poor weight gain is common, especially among women who have low pre-pregnancy BMI and must gain more to compensate. In rural Indonesia, for example, $79 \%$ of women in a cohort study failed to reach their recommended total weight gain, including $82.4 \%$ of the women with a pre-pregnancy BMI below $20 \mathrm{~kg} / \mathrm{m}^{2}$ (Winkvist et al. 2002).

## Methods

The overall attributable fraction of neonatal mortality due to maternal underweight status was calculated as the product of the attributable fraction of neonatal mortality due to IUGR and the attributable fraction of IUGR due to maternal underweight status. Attributable fractions were calculated according to the formula $[(\mathrm{P})(\mathrm{RR}-1)] /[1+(\mathrm{P})(\mathrm{RR}-1)]$, where P is the prevalence of the risk factor and RR is the associated risk ratio. Prevalence and risk ratio estimates were derived from available published and unpublished sources.

## Incidence of IUGR

Classification of IUGR in developing countries can be problematic because gestational age cannot be accurately determined in most cases, and reference curves that are adjusted for gestational age are not widely used (ACC/SCN 2000b). Therefore, the incidence of low birth weight at term (referred to as "term-LBW" or "IUGR-LBW") is used as the best proxy for IUGR incidence, although this will underestimate the actual incidence of IUGR because it excludes growth-retarded infants born preterm and those born over 2500 grams but below the tenth percentile for their gestational age (de Onis et al. 1998).

Incidence rates of IUGR-LBW for most developing countries were previously estimated by de Onis et al. (1998) using low birth weight estimates from the WHO database on Low Birth Weight, compiled by the Maternal Health and Safe Motherhood Programme (WHO 1992b). The authors applied a linear regression model $[\mathrm{Y}=-3.2452+0.8528 \mathrm{X}]$ derived from numerous studies in developing countries where birth weight and valid gestational age assessments were recorded. The dependent variable in the model was IUGR-LBW and the independent variable was the total incidence rate of low birth weight ( $\beta=0.8528$; SE $=0.0282 ; P=0.0001 ; r=0.96$ ) (de Onis et al. 1998; Villar et al. 1994). The linear regression model was found to be unsuitable as a predictor of IUGR-LBW in developed countries, however.

Incidence rates of IUGR-LBW in developed countries were based on Medline (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi), Popline (http://db.jhuccp.org/popinform/index.stm) and Google (http://www.google.com/) searches for country-level data sets and nationally-representative study samples that reported rates of IUGR-

LBW or sufficient statistical information (including numbers of births, mean birth weights and SDs or percentiles according to week of gestation) for calculating the rate of IUGR-LBW among total live births. The studies used in estimating rates were published between 1993 and 2001. The data reported in most studies were collected between 1992 and 2001, although in a few instances the data reflect populations from as early as 1984. In general, the reported data were limited to singleton births and excluded births having major congenital anomalies. Where data were unavailable-as was the case for the majority of European countries-the rate of IUGR-LBW was assumed for these purposes to be equivalent to the rate in AMR-A, or $2.5 \%$ of total live births (Kramer et al. 2001; Ventura et al. 1999). Estimates of small-for-gestational-age incidence were not appropriate for this analysis because they can include births weighing over 2500 grams. The estimated incidence rate of IUGRLBW for each country was multiplied by the estimated total number of live births in that country for the year 2000; the country estimates were then collapsed into the 14 subregions in order to calculate subregional rates (Table 2.22). Estimates of live births per year for each country were taken from the United Nations Population Division (UN 2001).

## IUGR and risk of neonatal mortality

Rice et al. (unpublished) calculated the risk of neonatal mortality associated with IUGR-LBW in an initial review and meta-analysis of the rela-

| World |  |  |  |

tionship between malnutrition and cause-specific mortality. The authors conducted a Medline search for English-language research reports published between 1966 and 1999 on child mortality, nutritional status, low birth weight, perinatal causes of death and neonatal mortality, excluding studies conducted in developed countries. They selected community and hospital-based studies that reported sufficient statistical and followup data on infants who were low birth weight at term, excluding data on very low birth weight $(<1000 \mathrm{~g})$ infants. Follow-up times and cut-off points varied among the studies as summarized in Table 2.23. Unadjusted data from studies were combined according to the random-effects method described by Morris (Everson and Morris 1983; Morris 1983). The combined risk estimate from all studies was 5.53 (3.74-8.17) and the risk estimate from the subset of studies using a 2500 g cut-off was 6.00 (3.63-9.90). Because the overall combined estimate of 5.53 was heavily weighted toward studies with short post-natal follow-up periods and higher birth weight cut-off points, we selected the 6.00 risk estimate for our calculations.

An elevated mortality risk has been observed among IUGR-LBW infants in developed countries, as well. Ashworth (1998) estimated the risk of neonatal mortality according to birth weight, combining 10 data sets from developing and developed countries (predominantly weighted toward births in the United States) and excluding most preterm births. Individual studies showed a consistent dose-response effect of increasing mortality risk with decreasing birth weight. Compared to birth weight of $2500-2999 \mathrm{~g}$, the overall relative risk associated with birth weight between 2000 g and 2499 g was 4.0 and the risk associated with birth weight $1500-1999 \mathrm{~g}$ was 18.0 . An overall dichotomous risk estimate comparing birth weight $<2500 \mathrm{~g}$ to $>2500 \mathrm{~g}$ was not reported, but after pooling published data from four (Behrman et al. 1971; Binkin et al. 1985; Lubchenco et al. 1972; Sappenfield et al. 1987) of six United States studies included in the estimate, the combined risk for neonatal mortality associated with birth weight $<2500 \mathrm{~g}$ at term was $10.64(95 \%$ CI 9.94-11.38). This crude estimate is based on mostly white, singleton births between 38 and 42 weeks gestation and excludes births below 1000 g .

## Prevalence of low maternal BMI

Refer to section 3: prevalence of underweight among women of reproductive age.

## Maternal pre-pregnancy BMI and risk of IUGR

In $1995, \mathrm{WHO}$ published a meta-analysis based on data sets from 25 studies that related maternal anthropometry to pregnancy outcomes (WHO 1995b). These sets represented over 111000 births in 20 developing and developed countries throughout the world. Countries were grouped together for analysis according to similarities in the population

distributions for various anthropometric indicators, including prepregnancy weight, height, BMI and arm circumference. Table 2.24 describes the composition of analysis groups and the corresponding BMI cut-offs. Unadjusted odds ratios for pregnancy outcomes were then calculated by comparing the lowest quartile to the highest quartile within each analysis group.

Results are presented in Table 2.25. The meta-analysis reported significantly greater risk for IUGR associated with pre-pregnancy BMI below $19.7 \mathrm{~kg} / \mathrm{m}^{2}$ relative to BMI above $24.2 \mathrm{~kg} / \mathrm{m}^{2}$, with an overall OR of 1.8 ( $95 \%$ CI 1.7-2.0). This estimate was consistent across the analysis groups (with the exception of group one studies) despite the differences in their cut-off and reference points.

## Results

Subregional estimates of the attributable fraction of IUGR due to low pre-pregnancy BMI are listed in Table 2.26 for women aged 15-29 and

30-44 years based on the prevalence of low BMI and the risk ratio of 1.8 reported by the WHO meta-analysis. Table 2.27 lists the attributable fraction of neonatal deaths due to IUGR-LBW for each subregion based on the prevalence of IUGR-LBW and the risk ratio of 6.0 calculated by Rice et al. (unpublished). The results of both tables are summarized in Table 2.28 with the overall attributable fraction of neonatal deaths due to low pre-pregnancy BMI. The fraction of neonatal deaths attributed to maternal BMI ranged between $0.8 \%$ (women aged 30-44 years in EUR-C) and 16.6 \% (women aged 15-29 years in SEAR-D).

### 4.4 Other health outcomes

Other important health outcomes related to underweight status were reviewed, but ultimately not used for burden of disease estimates. The adverse effects of undernutrition on risk of dysentery and persistent diarrhoea, pregnancy outcome, cognitive function and chronic diseases in later life are described below.

## Dysentery and persistent diarrhoea

Dysentery, defined by diarrhoea with blood, was specifically examined in two community-based prospective studies, both among children aged $<24$ months in Bangladesh. Henry et al. (1987) observed no significant difference in incidence of dysentery between children having weight-for-

age $<75 \%$ and those above $75 \%$. Black et al. (1984) found that incidence of Shigella diarrhoea, specifically, did not vary significantly according to weight-for-age.

The incidence of persistent diarrhoea, defined as an episode lasting 14 or more days, was greater among underweight children in communitybased studies in Brazil (Guerrant et al. 1992; Schorling et al. 1990), India (Bhandari et al. 1989) and Bangladesh (Baqui 1990). Children aged <5 years having weight-for-age at or below $75 \%$ in the Brazil cohort study were at a relative risk of 1.59 for persistent diarrhoea. In Bangladesh, the relative risk for persistent diarrhoea among children having $z$-score $<-2$ was 1.29 . Combining unadjusted figures from the two cohort studies yielded an overall relative risk of 1.35 ( $95 \%$ CI $0.97-1.90$ ). In a case-control study in India, pre-morbid weight-for-age below $70 \%$ was significantly more common among persistent diarrhoea cases compared to healthy age-matched controls, producing an OR of 3.25 (95\% CI 1.46-7.29). A community-based cohort study in Guinea-Bissau (Molbak et al. 1997) assessed risk according to stature and observed a statistically non-significant relative risk of 1.17 ( $95 \%$ CI $0.68-2.01$ ) associated with height-for-age $z$-score $<-2$.

## Other pregnancy outcomes

There is extensive literature supporting the influence of maternal undernutrition on fetal growth and risk of low birth weight as described in previous sections, but the relationship between low pre-pregnancy BMI and other adverse reproductive outcomes such as fetal death and maternal mortality is less clear. Research on maternal undernutrition as a risk factor for congenital anomalies, other than those attributable to micronutrient deficiencies (e.g. folic acid) is lacking.

## Obstructed labour and maternal mortality

Few studies from developing countries have been published relating low BMI to maternal mortality, although studies have described an increased risk of obstructed or prolonged labour associated with maternal height of 160 cm and below (Adadevoh et al. 1989; Anonymous 1984; Bhatt et al. 1967; Essex and Everett 1977; Konje and Ladipo 2000; Kwawukume et al. 1993; Mati 1983; Sokal et al. 1991; Tsu 1992), and one study in India reported an increased risk of caesarean section associated with low weight-height product index (weight times height over weight times height of reference population median) (Thilothammal et al. 1992). This risk may result from cephalopelvic disproportion (CPD) between mother and fetus (Rush 2000), increasing the likelihood of intrapartum caesarean delivery (Adadevoh et al. 1989; Merchant et al. 2001; Sokal et al. 1991; Tsu 1992) and perinatal distress (Merchant et al. 2001). In Nigeria, primigravida women below 150 cm were at a relative risk of 10.34 for CPD relative to women 160 cm or taller (Harrison et al. 1985). In Malawi, the odds ratio for CPD associated

- No data.
with height at or below 154 cm was 3.8 , adjusted for birth weight and parity (Brabin et al. 2002).

The 1995 WHO meta-analysis examined assisted delivery, defined as non-spontaneous delivery covering a range of complications (but not prolonged labour), and estimated an odds ratio between 1.0 and 2.1 (1.6, overall) associated with maternal height below the 25 th percentile (WHO 1995b). The odds ratio for assisted delivery according to prepregnancy BMI was 0.7 , explained as the result of constrained fetal growth reducing the risk of CPD; however, numerous studies have found that an association between maternal anthropometric status and assisted delivery remains after adjusting for multiple parameters of fetal size (Witter et al. 1995).

## Fetal death

Fetal death may be more common among underweight mothers (Tables 2.29 and 2.30). A community-based cohort study in India reported significant risks of spontaneous abortion (defined in the study as death <28 weeks' gestation) and late fetal death (>28 weeks) associated with both short stature and low absolute weight (Agarwal et al. 1998). A case-control study in the Sudan reported an adjusted odds ratio for stillbirth of 2.3 associated with absolute weight below 50 kg (Taha et al. 1994). On the other hand, Conde-Agudelo et al. (2000) analysed over 800000 births recorded in the Perinatal Information System database, a system used by over 700 hospitals throughout Latin American and the Caribbean, and found no significant risk of fetal death associated with BMI $<19.8 \mathrm{~kg} / \mathrm{m}^{2}$ relative to BMI between 19.8 and $26.0 \mathrm{~kg} / \mathrm{m}^{2}$.

## Post-neonatal consequences of IUGR

Growth-retarded neonates may experience partial catch-up growth in the first two years of life relative to non-IUGR controls, but they remain shorter and lighter than controls and are more likely to be classified as underweight (Martorell et al. 1998). They are at increased risk of infection in infancy as a result of multiple immunological abnormalities, including reduced T - and B -lymphocyte numbers and activity, lower

- No data.
a OR adjusted for prior fetal loss, number of antenatal care visits and malaria in early pregnancy. Several socioeconomic status indicators were assessed, but none was significantly associated with stillbirth and therefore were not included in the final regression model.
b Relative risk adjusted for antenatal care, age, literacy, cigarette smoking and prior fetal loss. Study addressed fetal death, defined as death $>20$ weeks' gestation.
levels of IgG and impaired bactericidal polymorphonuclear neutrophil function (Ferro-Luzzi et al. 1998; Xanthou 1985). Depending on the severity of the growth retardation, this immune deficiency may persist into later childhood (Chandra 1977). In addition to higher neonatal mortality rates, IUGR infants are at increased risk of mortality in the postneonatal period, including an increased risk of sudden infant death syndrome (Ferro-Luzzi et al. 1998).

IUGR may increase the risk of neurological dysfunction and mild cognitive impairment. IUGR infants show higher rates of hyperactivity, attention deficit and impaired motor coordination, depending on the degree of growth retardation, but the association of IUGR with low socioeconomic status and hypoxia makes it difficult to interpret the impact of IUGR (Goldenberg et al. 1998). Similarly, IUGR children have manifested small, but statistically significant IQ and developmental deficits, aggravated by impoverished environmental surroundings and poor psychosocial stimulation, but few studies have been conducted in developing countries, and socioeconomic factors may be confounding the relationship (Grantham-McGregor et al. 1998).

IUGR has been associated with increased susceptibility to chronic diseases in later life. The "fetal origins of disease" hypothesis posits that fetal undernutrition causes permanent structural and metabolic changes that potentiate subsequent risk of cardiovascular and endocrine disease (Barker 1995). IUGR infants have demonstrated insulin resistance and
higher blood pressure in childhood, and increased rates of ischaemic heart disease and non-insulin-dependent diabetes mellitus have been observed among adults who were born growth-retarded (Barker 1995; Chatelain et al. 1998; Law et al. 2001; Stein et al. 1996). Studies are inconsistent and causality is uncertain, but the possible risk relationship has important health implications for developing countries as they undergo epidemiological transition.

## Cognitive function

Cognitive function has been studied in terms of global measures of development and intelligence such as IQ, along with school performance and more narrowly defined intellectual, psychomotor, and behavioural skills such as attention, memory, verbal reasoning, motivation, visual-spatial abilities and social interaction. An array of psychometric tests and scales have been used to evaluate these functions, including modified versions of Stanford-Binet, Weschler Intelligence Scale for Children (WISC), Bayley Scales of Infant Development, Griffiths Mental Development Scale, Goodenough Drawing Test, Raven's Progressive Matrices, Piagetian tests of conservation and the Bender Visual Motor Gestalt Test. A major portion of research into malnutrition and cognition has addressed whether early childhood presents a critical period of vulnerability during which severe undernutrition causes lasting cognitive deficits in later life, and if potential deficits are amenable to subsequent nutritional and psychosocial interventions.

The immediate response to acute malnutrition is irritability, lethargy and apathy (Grantham-McGregor 1984). During this stage, children demonstrate lower activity levels and reduced exploratory behaviour and developmental quotients tend to be extremely low (Grantham-McGregor 1984). Electroencephalograms performed on children with acute malnutrition show nonspecific abnormalities (e.g. diffuse slowing of background rhythm) that improve with recovery (Chopra and Sharma 1992). During recovery and rehabilitation, behaviour improves to normal or near-normal levels and developmental quotients generally improve, but the long-term developmental implications remain uncertain (GranthamMcGregor 1995).

Numerous short-term and long-term follow-up studies have reported lasting developmental deficits associated with an early history of marasmus and/or kwashiorkor. Persistent deficits have been described in shortterm memory (Nwuga 1977), visual-spatial perception (Champakam et al. 1968; Cravioto et al. 1971; Ghai 1975; Hoorweg and Stanfield 1976; Reyes et al. 1990; Stoch and Smythe 1976), motivation (Stoch and Smythe 1967), Piagetian conservation tasks (Galler and Ramsey 1987) and perceptual-motor function (Grantham-McGregor et al. 1997). Poor academic performance and behavioural learning disabilities have also been recognized (Galler et al. 1984, 1990; Richardson et al. 1973).

Studies that assessed general measures of cognitive function among school-age children have observed significantly lower overall developmental and intelligence scores associated with early malnutrition (Berkman et al. 2002; Bhat et al. 1973; Birch et al. 1971; Botha-Antoun et al. 1968; Cabak and Najdanvic 1965; Cravioto et al. 1971; Fisher 1972; Galler et al. 1983, 1987a, 1987b; Hertzig et al. 1972; Ivanovic et al. 2000; McLaren et al. 1973; Mehta et al. 1975; Mendez and Adair 1999; Parekh et al. 1974; Pek et al. 1967; Sigman et al. 1991; Srikantia and Sastri 1971; Stoch and Smythe 1967, 1976; Udani et al. 1976). IQ differentials among these studies were predominantly in the order of 8 to 18 points. Studies in South Africa (Evans et al. 1971, 1980), however, observed no significant IQ difference between early kwashiorkor cases and non-hospitalized siblings. In Jamaica, Richardson et al. (1978) observed that height-for-age or weight-for-height among severely malnourished infants had no significant effect on IQ scores at school age after adjusting for social and environmental factors.

Among most of the studies showing long-term deficits, it could not be distinguished whether the observed impairment was related to the severe episode of acute malnutrition or to underlying or subsequent chronic undernutrition. In Jamaica, Grantham-McGregor (1982) reported that initial height-for-age, but not weight-for-height or presence of oedema, significantly predicted developmental quotients one month after hospitalization, suggesting the presence of chronic malnutrition was more closely associated with cognitive function than acute malnutrition (Grantham-McGregor 1982; Grantham-McGregor et al. 1989a, 1989b). In a long-term longitudinal study by Walker et al. (2000) height and head circumference in the first 24 months of life were found to be more significantly predictive of IQ at age 11 years than were anthropometric measurements taken at or near the time of cognitive testing, even after controlling for age, sex and socioeconomic factors, suggesting chronic malnutrition at an early age could have enduring effects on intelligence despite subsequent improvements in growth (Grantham-McGregor et al. 2000). In Peru, school-age children who were severely stunted in the second year of life scored 10.0 points lower than those moderately stunted or not stunted in the second year of life, after adjusting for socioeconomic status and schooling (Berkman et al. 2002). In the Philippines, severe stunting at 2 years of age was significantly associated with cognitive deficits at age 8 years, adjusting for schooling, socioeconomic status, sex and other covariates, but the differences were not significant by age 11 years (Mendez and Adair 1999). In Jamaica, Richardson (1976), observed that the long-term cognitive effect of early acute malnutrition was more heavily determined by chronic undernutrition and social background factors such as caretaker capability, presence of electricity and appliances, and child's access to toys, radio or stories. For the children having adequate growth and an advantageous social back-
ground, malnutrition during infancy was associated with an average IQ only 2 points lower than those not malnourished during infancy; for those experiencing both an unfavourable background and inadequate growth, the difference in IQ between children with and without malnutrition during infancy was 9 points by age $6-10$ years (Richardson 1976).

A large number of correlational studies have examined the association between current anthropometric status and cognitive function. Low height-for-age was significantly associated with low IQ or poor school achievement in Brazil (Paine et al. 1992), China (Jamison 1977), Guatemala (Johnston et al. 1987), India (Agarwal et al. 1987), Nepal (Moock and Leslie 1986) and the Philippines (Florencio 1988), but not Chile (Colombo et al. 1988). Deficits in other developmental scores were observed among stunted children in Chile (Monckeberg 1972), Guatemala (Lasky et al. 1981), India (Agarwal et al. 1989), Jamaica (Powell and Grantham-McGregor 1985) and Nigeria (Ashem and Janes 1978). Low weight-for-age has been associated with delayed motor development (Agarwal et al. 1992; Groos 1991; Heywood et al. 1991; Sathy et al. 1991; Vazir et al. 1998), delayed language development (Agarwal et al. 1992; Vazir et al. 1998) and poor performance on conservation tasks (Agarwal et al. 1989). Lower scores on aggregate measures such as IQ have been observed among underweight children in Ethiopia (Aboud and Alemu 1995), India (Agarwal et al. 1992; Gupta et al. 1975; Kalra et al. 1980; Lahiri et al. 1994; Sathy et al. 1991; Singh and Sidhu 1987; Upadhyay et al. 1989), Indonesia (Pek 1967), Kenya (Sigman et al. 1989) and Thailand (Rajatasilpin et al. 1970), with evidence of progressively increasing cognitive impairment associated with decreasing weight-for-age (Agarwal et al. 1992; Kalra et al. 1980; Lahiri et al. 1994; Sathy et al. 1991; Singh et al. 1976; Upadhyay et al. 1989). The differences in mean IQ between normal and underweight children in these correlational studies ranged between 7 and 31 points.

Among the more recent of these studies to report IQ, Agarwal et al. (1992) found Indian children aged 36 months with weight-for-age below $70 \%$ had a mean IQ approximately 8.7 points lower than adequately nourished children with weight-for-age of $80 \%$ or above; the relative risk for IQ below 80 points associated with underweight status (weight-forage $<80 \%$ ) was 2.33 ( $95 \%$ CI 1.46-3.74). Upadhyay et al. (1989) reported a difference of 7.2 points between children below $75 \%$ and those above $90 \%$. Lahiri et al. (1994) observed a significant trend toward lower IQ scores with decreasing weight-for-age (chi-square $=6.78$, $P<0.05$ ) among children aged 3-6 years from low socioeconomic levels in rural India, but the effect was not statistically significant when adjusted for age and educational exposure.

Neuroanatomical changes observed in animal models of PEM offer a theoretical foundation for the possibility that severe early malnutrition, particularly during the period of rapid brain growth and myelination in the first two years of life, presents a permanent structural insult to
brain function, leading to irreversible intellectual impairment (Strupp and Levitsky 1995). PEM has also generated abnormalities in neurotransmitter activity and receptor number (Levitsky and Strupp 1995). However, it is widely held now that neurobiological changes, on their own, are not sufficient to explain the complicated, multifactorial relationship between undernutrition and cognition, particularly among mild-to-moderately undernourished cases (Pollitt 1987). Increasing attention has been paid to environment, social context and experiential factors as potential modifiers or confounders of the nutrition-cognition relationship. Lack of energy, impaired psychomotor function and poor social interaction may prevent a child from exploring her surroundings as fully as other children, leading to less stimulation and slower acquisition of skills (Grantham-McGregor et al. 1989a, 1989b). The poverty associated with malnutrition is an environment of scarce resources, overcrowding, poor sanitation, illiteracy, few adequate educational opportunities and high morbidity, lacking in constructive forms of cognitive stimulation. Households tend to have few toys or books, social contacts are limited, and parents may offer less care and attention because of poor health, low income, low intelligence and education levels or large family sizes (Grantham-McGregor 1995). Returning to such an environment following severe malnutrition in infancy, for example, may explain persisting cognitive deficits observed in follow-up studies of infant malnutrition. Saco-Pollitt et al. (1985) offered a cumulative deficit hypothesis that suggests cognitive deficits increase as children are continuously exposed to environments that fail to meet their physiological, emotional and educational requirements (Pollitt 1987). Experimental studies have utilized interventions based on some of these neurobiological and psychosocial concepts.

Intervention studies to prevent or remedy impairments have focused on two general types of treatment: nutritional supplements provided to very young children and, in some cases, pregnant women; and psychosocial stimulation with or without nutritional supplementation provided to very young children. Evidence from nutritional interventions among high-risk or undernourished children has suggested early ( $<2$ years of age) supplementary feeding improves their developmental scores, with some indication of long-term benefits. Short-term ( 90 days) and long-term (2-3 years) supplementation programmes in Colombia (Waber et al. 1981), Guatemala (Pollitt et al. 1993), Indonesia (Hussaini et al. 1991) and Jamaica (Grantham-McGregor et al. 1991) have improved motor development among infants. Concurrent improvements in other developmental outcomes have been less consistent, but Waber et al. (1981) in Colombia observed significantly higher scores in per-sonal-social, speech and language, and performance subscales in addition to locomotor and eye-hand coordination subscales among infants supplemented until 3 years of age. Long-term follow-up identified improvements in certain achievement-related abilities, but not basic cog-
nitive skills by 6 years of age (Gorman et al. 1995). In India, Elizabeth and Sathy (1997) reported larger gains in developmental quotient and higher overall IQ (+2.6 points) among malnourished infants by the end of a two-year nutritional management and supplementation intervention. In Guatemala, children exposed to prenatal and early postnatal supplementation demonstrated long-term cognitive benefits, performing significantly better at ages 13-19 years on general intelligence tests and achievement-related subtests of numeracy, general knowledge, reading and vocabulary, even after adjusting for socioeconomic factors and educational experience; some information-processing tasks showed improvement as well (Pollitt et al. 1995). In Indonesia, infants who began 90 days of supplementation before 18 weeks of age demonstrated a positive effect on memory skills at 8 years of age, but differences in other cognitive processes were not significant (Pollitt et al. 1997).

Intervention programmes based on early psychosocial stimulation have improved developmental scores among moderately to severely malnourished infants and preschool-age children. Various studies have employed educational day care programmes (McKay et al. 1978), clinicbased therapy and education (Elizabeth and Sathy 1997) and weekly home visits with mothers and infants (Grantham-McGregor et al. 1994; Waber et al. 1981). In Jamaica, demonstrating play techniques to mothers and severely malnourished infants at home over three years was associated with both immediate and long-term improvements in global intelligence and development scores relative to a non-intervened control group (Grantham-McGregor et al. 1994). At 14 years follow up, mean scores on WISC for the intervened group were 8.6 points higher than the non-intervened group, but both intervened and non-intervened groups still performed significantly worse than an adequately nourished, generally higher socioeconomic status control group (9.7 and 18.3 IQ points below, respectively). Similar results were observed in a facilitybased study in India among malnourished infants provided nutritional management with or without cognitive stimulation (Elizabeth and Sathy 1997). At the end of two years, both interventions were associated with significant improvements in developmental quotients, with the final IQ of stimulated infants 8.3 points higher than those receiving nutritional management alone, but both treatment groups ultimately performed below an adequately nourished/higher mean socioeconomic status control group by 5.4 to 13.7 IQ points. In a community-based component of the study, stimulated infants achieved IQ scores 6.5 points higher than an untreated, comparable control group and 3.8 points higher than infants receiving nutritional management alone; it is too early to know long-term effects in this case.

In Colombia, McKay et al. (1978) assigned underweight children aged 3 years to varying durations of an integrated health, nutrition and education programme and found that earlier initiation and longer duration of intervention were associated with higher general cognitive scores.

However, by school age, the intervened groups continued to score below an adequately nourished, higher socioeconomic status control group, and the absence of a comparable malnourished/low socioeconomic status control group made the absolute effect of the intervention unclear. Waber et al. (1981) evaluated cognitive development of nutritionally at-risk Colombian infants according to their exposure to prenatal and postnatal nutritional supplementation and a maternal-and-child educational programme. Nutritional supplementation was associated with higher scores on tests of primarily motor skills, and maternal-child education was associated with better language performance.

In a randomized controlled trial among stunted infants in Jamaica, Grantham-McGregor et al. $(1991,1997)$ assessed the immediate and long-term developmental effects of nutritional supplementation with or without psychosocial stimulation. By the end of the two-year intervention, supplementation and stimulation each had a significant benefit on developmental quotients (by 7 and 8 points, respectively), with the combination of treatments having an additive effect. Follow-up at ages 7-8 years (Grantham-McGregor et al. 1997) and 11-12 years (Walker et al. 2000), indicated persistent benefits in overall IQ, vocabulary and reasoning ability associated with the early psychosocial stimulation, but less of an effect from nutritional supplementation. Supplementation alone was associated with a benefit of 4.2 IQ points (not statistically significant), stimulation alone was associated with 6.3 points, and both treatments combined were associated with 6.1 points relative to a control group of untreated, stunted children; all three groups performed below a non-stunted, untreated control group.

Unfortunately, few studies (and no individually randomized controlled trials) assessed the cognitive benefit of sustained nutritional supplementation among school-age children in developing countries. In Guatemala, a year of supplementation had no consistent effect on children aged 5-7 years (Pollitt et al. 1993). A two-year school-based supplementation programme in India observed marginal but significant effects on IQ scores and Piagetian tasks, but treatment-related differences in school attendance may have influenced the results (Agarwal et al. 1989). Several studies have examined the short-term effects of breakfast programmes (Chandler et al. 1995) or breakfast omission (Lopez et al. 1993; Simeon and Grantham-McGregor 1989) on cognitive performance among schoolchildren. In Jamaica, controlled breakfast omission was associated with impaired performances in short-term memory, idea generation and problem-solving ability among stunted or previously malnourished children, but not among adequately nourished children (Simeon and Grantham-McGregor 1989). A subsequent randomized controlled trial found that only the undernourished children responded to breakfast supplementation, showing improvement in idea generation capacity but not memory or problem-solving skills (Chandler et al. 1995). In Chile, controlled breakfast omission had no significant effect on short-term visual
memory, problem-solving capacity, or attention, regardless of preexisting nutritional status (Lopez et al. 1993).

As with other health outcomes, the close relationship between poverty and malnutrition raises the possibility of confounding. While many of the correlational and matched case-control studies attempted to control or adjust for potential socioeconomic and environmental differences, those variables were frequently defined in broad terms and may have overlooked subtler, as-yet-unidentified, non-nutritional determinants of cognitive function. Educational status could have played a role in some findings, as well; for example, initial school enrolment may be delayed among stunted children because they appear or act younger than their chronological age (Brown and Pollitt 1996). Undernutrition could influence cognition indirectly through higher morbidity; illness could reduce activity and social interaction, or contribute to higher school absentee and drop-out rates (Mendez and Adair 1999; Neumann et al. 1991; Pollitt 1983).

Another important consideration in estimating the effect of low weight-for-age on cognitive function is possible confounding by deficiencies of iron and other micronutrients (Pollitt 1995). Iron deficiency has been associated with developmental delays (Lozoff et al. 1991; Soewondo et al. 1989; Walter 1993) and iron supplementation studies have demonstrated improvements in cognitive function among irondeficient subjects (Pollitt 1995; Pollitt and Metallinos-Katsaras 1990; Seshadri and Gopaldas 1989). Further, studies of iron deficiency and growth have observed significant covariance between the two (PeragalloGuarda 1984; Pollitt 1995), with evidence that iron supplementation improves both growth velocity (Chwang et al. 1988) and weight (Lawless et al. 1994) among anaemic children. Zinc deficiency may also play a role in cognitive ability (Golub et al. 1995). Several intervention studies described above (Elizabeth and Sathy 1997; Husaini et al. 1991; McKay et al. 1978; Waber et al. 1981) provided micronutrient-rich indigenous foods or supplements between experimental groups differentially and most observational studies did not control for other nutritional factors.

### 4.5 RISK REVERSIBILITY

Risk reversibility refers to the extent to which an increased relative risk persists among a previously exposed group after that exposure is removed. There has been some investigation of the lasting effect of fetal malnutrition on immune function of children and adults in Africa (Moore et al. 1999, 2001). However, there is insufficient evidence at this time to state that past underweight status during childhood increases the mortality or morbidity risk of malaria, measles, pneumonia or diarrhoea among those no longer underweight. Therefore, the increased risk of mortality and morbidity associated with low weight-for-age is considered completely reversible. Likewise, the risk of neonatal death attribut-
able to low maternal BMI is considered completely reversible once underweight status is corrected.

## 5. Estimates of ATtRibutable burden

Estimates of the attributable fraction, attributable mortality and attributable burden of underweight status in the age group 0-4 years were calculated for mortality due to measles, malaria, diarrhoea, pneumonia and perinatal causes based upon the above estimates of underweight prevalence, relative risk and reversibility. Attributable fractions and attributable burdens were also calculated for morbidity due to malaria, pneumonia and diarrhoea. Because we were unable to calculate relative risks of morbidity for the proportion of children falling in the weight-for-age category of -1 SD to -2 SDs , the mortality and morbidity estimates are based on different anthropometric thresholds. The mortality estimates represent the cause-specific deaths that are attributable to weight-for-age less than -1 SD, and the morbidity estimates refer to the cause-specific episodes of illness attributable to weight-for-age less than -2 SDs. The burden estimates for mortality from perinatal causes are based on maternal pre-pregnancy $\mathrm{BMI} \leq 20 \mathrm{~kg} / \mathrm{m}^{2}$ and infant deaths attributed to low birth weight. Results are listed in Tables 2.31 through 2.35

| "Perinatal conditions" include low birth weight, birth asphyxia and trauma, neonatal sepsis, maternal and placental complications, respiratory distress, fetal blood loss, fetal haematological disorders, anaemia, perinatal infections, maternal diabetes and various other conditions. The category does not include congenital anomalies, neonatal tetanus or syphilis. The burden estimates represent infant deaths due to low birth weight only. |  |  |  |  |  |

for both sexes combined according to outcome and subregion. Table 2.36 summarizes the total burden estimates associated with underweight status, including estimates of mortality directly attributable to PEM and "other" indeterminate deaths in the residual category. The total attributable fraction of mortality among children aged $<5$ years due to maternal and child undernutrition was $34.7 \%$ (Table 2.36). This was calculated from the sum of the cause-specific attributable mortality estimates divided by the estimate of total deaths among children aged 0-59 months. This fraction includes deaths directly and indirectly attributable to undernutrition. In determining the fraction of deaths indirectly caused by undernutrition, the analysis differentiated postneonatal from neonatal deaths, with maternal undernutrition considered as the risk factor for neonatal deaths.

## 6. Discussion

The results of these analyses indicate that undernutrition in young children contributes significantly toward the global burden of disease. We
estimate that undernutrition in children aged <5 years, as reflected in underweight or low weight-for-age, causes 3599800 deaths, including 815900 diarrhoea deaths, 1042900 pneumonia deaths, 261300 measles deaths and 549200 malaria deaths. The estimates also illustrate that the burden of undernutrition in children begins in utero, with approximately 148400 neonatal deaths from low birth weight attributable to maternal underweight status. The 3748200 total deaths attributable to maternal and child undernutrition constitute $34.7 \%$ of all deaths among children aged $<5$ years. The loss in DALYs associated with these deaths is stag-gering-over 126 million. Among the principal causes of death in young children, $60.7 \%$ of deaths due to diarrhoea, $52.3 \%$ of deaths due to pneumonia, $44.8 \%$ of deaths due to measles and $57.3 \%$ of deaths due to malaria are attributable to undernutrition. These attributable fractions are large because undernutrition substantially increases a child's risk of dying from common childhood illnesses, and because undernutrition is still highly prevalent in many regions of the world. In particular, the subregions SEAR-D, AFR-D and AFR-E respectively account for $32 \%, 22 \%$ and $24 \%$ of the total DALYs lost from undernutrition, followed by EMR-D (12\%) and WPR-B (6\%).

Undernutrition contributes to the morbidity burden among children as well. Our analyses indicate that having a weight-for-age less than -2 SDs places a child at increased risk of developing pneumonia, diarrhoea or malaria. We estimate that $16.5 \%$ of pneumonia, $5.3 \%$ of diarrhoea illness and $8.2 \%$ of malarial attacks are attributable to low weight-for-age, with an associated loss of DALYs amounting to 528300 for pneumonia, 98600 for diarrhoea and 253000 for malaria. Available evidence suggests that undernutrition does not influence a child's risk of contracting measles and thus none of the measles morbidity burden is attributed to this risk factor.

The relatively greater burden of death as compared to illness attributable to undernutrition is understandable, given the known synergy between illness and malnutrition. This synergy was first described by Scrimshaw et al. (1968): "The simultaneous presence of malnutrition and infection results in an interaction that is more serious for the host than would be expected from the combined effect of the two working independently". Undernutrition potentiates the risk of mortality by increasing the likelihood that the illness will be prolonged or become severe; and more prolonged or severe illness is more likely to negatively affect the nutritional status of the child, placing her at ever-increasing risk of future and more prolonged or severe illness episodes. This has been most clearly demonstrated in the literature for diarrhoeal illnesses (Black et al. 1984), and our analysis makes the extension to three other principal causes of death among young children: pneumonia, malaria and measles. Such findings underscore the need to prioritize the improvement of the nutritional status of children, including within disease control programmes (Becker et al. 1991).

In attempting to quantify the relationship between underweight status and disease, it is important to consider that undernutrition, as assessed by the underweight indicator (or a stunting indicator), is commonly associated with deficiencies of micronutrients (Bhan et al. 2001). In fact, some of these deficiencies, such as zinc, may themselves contribute to poor growth (Brown 2002). These deficiency conditions, especially of vitamin A, iron and zinc, put the child at risk of adverse outcomes, including morbidity and mortality from infectious disease and cognitive impairment. The consequences of these deficiency states can be estimated separately, as has been done in other chapters in this book. The association of underweight condition with these deficiencies means that some of the risk attributed to being underweight may be, in fact, due to specific micronutrient deficiencies. On the other hand, these other deficiencies can occur in children who are not considered underweight, so the risk of adverse outcomes is not entirely encompassed in the subset of the population who are underweight. In fact, the effect of vitamin A supplementation on reducing mortality in vitamin A-deficient populations has been found to be similar in children who were more or less well nourished at the beginning of the trial (Sommer 1986; West 1991). Likewise, zinc supplementation in populations that are presumably zinc deficient has had similar effects on reducing infectious disease morbidity in children who were classified as both "wasted" or "not wasted" (Zinc Investigators' Collaborative Group 1999). Therefore, the effects of undernutrition as identified by being underweight and those of deficiencies of vitamin A, iron and zinc cannot be simply added to determine the overall burden of disease due to nutritional risk factors, nor is it appropriate to assume that all of the consequences of micronutrient deficiencies are subsumed in the underweight calculation. Additional work is needed to determine the joint prevalence distributions of being underweight and being deficient in each of these micronutrients and to assess the joint effects of these aspects of undernutrition.

The outcomes described here represent some of the fundamental global health challenges facing populations at greatest risk for undernutrition. However, the burden of undernutrition on human health and well-being no doubt extends beyond the relatively narrow focus of this analysis. We presented findings to suggest a role for maternal malnutrition as a risk factor for maternal mortality, as well as a role for undernutrition in disability due to poor cognitive development, but the research base thus far does not allow for the calculation of burden estimates. Other considerations relating to undernutrition may include the short-term or long-term effects of underweight status on work capacity or the effect of IUGR on childhood development and morbidity. Many areas are still largely unknown or speculative, such as the role of early or ongoing undernutrition in potentiating chronic disease (Barker 1995;

Law et al. 2001; Stein et al. 1996) or the effect of undernutrition on susceptibility to infection among adult and elderly populations-questions that will only gain in importance as developing countries continue to go through demographic and epidemiological transitions.

Several reports suggest that through current programmatic efforts, rates of undernutrition among children are declining at $1 \%$ per year. In contrast, our projections indicate that over the coming decades we can expect variable changes in these prevalences. Because our analyses clearly indicate the overwhelming magnitude of the disease burden associated with child malnutrition, effective strategies to reduce child undernutrition are urgently needed. Energy supplementation for pregnant women, counselling and promotion of breastfeeding and adequate complementary food intake, and child growth monitoring are some of the more effective and affordable interventions for preventing low birth weight and improving child growth (ACC/SCN 2001; WHO 2002). Micronutrient supplementation or fortification, the use of oral rehydration therapy and childhood immunizations, have also been key elements to improving nutritional status and preventing severe childhood disease. Further innovations will be necessary in order to meet the challenge of undernutrition in all populations.

## 7. Projections of exposure: TRENDS IN CHILD UNDERWEIGHT STATUS FROM 2000 TO 2030

The estimates for 2010 and 2020 are directly derived from the model as outlined in section 2.2 , based on estimates of underweight prevalence in individual countries at multiple points in time. To extend these model estimates to 2030, we applied the lowest delta between last available trend intervals, i.e. for AFR-D and AFR-E, we used 2010-2015 and for the other subregions the deltas 2015-2020; the respective difference was multiplied by 2 (as they refer to a five-year interval) and then subtracted from or added to the estimate of 2020 to derive the value for 2030 (Table 2.37).

Table 2.37 Estimated prevalence of underweight among children aged $0-4$ years from 2000 to 2030, by subregion

|  | \% having weight-for-age below -2 SDs |  |  |  |
| :--- | ---: | :---: | :---: | :---: |
| Subregion | 2000 | 2010 | 2020 | 2030 |
| AFR-D | 32.2 | 34.2 | 36.2 | 38.2 |
| AFR-E | 31.0 | 37.3 | 44.1 | 50.7 |
| AMR-A | 2.3 | 1.5 | 0.7 | $0.0^{\mathrm{a}}$ |
| AMR-B | 5.0 | 3.3 | 2.2 | 1.1 |
| AMR-D | 12.4 | 9.5 | 7.2 | 5.0 |
| EMR-B | 8.1 | 4.3 | 2.3 | 0.5 |
| EMR-D | 25.1 | 20.4 | 16.4 | 12.6 |
| EUR-A | 2.3 | 1.5 | 0.7 | $0.0^{\mathrm{a}}$ |
| EUR-B | 7.6 |  | Overall stagnation |  |
| EUR-C | 2.6 | 18.7 | Overall declining trend |  |
| SEAR-B | 25.8 | 37.6 | 3.2 | 8.0 |
| SEAR-D | 45.9 | 2.5 | 1.2 | 22.6 |
| WPR-A | 3.8 | 16.8 | 8.6 | $0.0^{\mathrm{b}}$ |
| WPR-B |  |  | 5.6 |  |

[^6](i) EUR-B

The available data for this subregion show a diverse pattern. There are countries with decreasing rates in child underweight and parallel there are others where increase in the national prevalence of child underweight can be observed. With the information available to date it is very difficult to estimate a trend in child underweight from 2000 to 2030 . The trend pattern is expected to be driven by Turkey, which has $40 \%$ of the total $<5$ population in this subregion. However, given the available trend data for other countries in this subregion and the unfavourable conditions (demographic and economic transition associated in parts with political instability) in some of them an overall stagnation of the underweight prevalence from 2000 to 2030 is to be expected. Appendix $\mathrm{E}(\mathrm{a})$ lists references by country in alphabetical order to document the forecasted trend in this subregion.
(ii) EUR-C

Given that any trend in this subregion is likely to be dominated by Russia (which has $56 \%$ of the total population of children aged $<5$ years in this subregion) and that current evidence shows raising rates in overweight in this country we would estimate an overall declining trend of underweight. However, given the enduring unstable situation in some of the countries in EUR-C and the uncertainty about support and investments from developed countries, a quantification of the expected decline cannot be made. Appendix $\mathrm{E}(\mathrm{b})$ lists references by country in alphabetical order derived from the WHO Global Database, Medline and the Internet which contain additional information to document the forecasted trend in this subregion.

## Acknowledgements

We thank Majid Ezzati for guidance in global burden of disease comparative risk assessment methodology; Steve Vander Hoorn for comparative risk assessment analysis and burden of disease calculations; Amy Rice, Lisa Sacco and Constantine Frangakis for their analysis of malnutrition and perinatal causes of death; Andres Lescano for additional statistical analysis of morbidity data; Jeffrey McGuckin for his assistance in coordinating comparative risk assessment efforts; and Julie West and Seema Rai for their assistance with the literature search and compilation of risk data.

We are grateful to Wafaie Fawzi, Michel Garenne, Marc Andersen, Keith West, Shams el Arifeen, Fehmida Jalil, S.R. Khan, Bambang Sutrisna, and Stan Becker, for providing original data on cause-specific mortality; and K. Zaman, for providing data on pneumonia morbidity.

We are grateful for the statistical support received from Allen Shoemaker for conducting primary data analysis of raw data sets relating to underweight prevalence; Richard Morris for the modelling of the subregional estimates; and Gilda Piaggio for transforming the categorical underweight prevalences into continuous categories.

This manuscript was supported in part by the Family Health and Child Survival (FHACS) Cooperative Agreement between the United States Agency for International Development, Office of Health and Nutrition and the Johns Hopkins Bloomberg School of Public Health, Department of International Health; and by the World Health Organization, Evidence and Information for Policy Department, Department of Child and Adolescent Health and Development, and Department of Nutrition for Health and Development.

## Chapter 3

# Iron Deficiency anaemia 

Rebecca J. Stoltzfus, Luke Mullany and<br>Robert E. Black

## Summary

Iron deficiency is a highly prevalent form of undernutrition, affecting around one-fourth of the world's women and children, and is one of the most common causes of anaemia.

We conducted comprehensive reviews of published literature linking iron deficiency to disability and death for four potential outcomes: child mortality, perinatal mortality, maternal mortality and mild mental retardation. For all of these outcomes, the best available data were prospective observational studies in which anaemia or haemoglobin concentration was the risk factor. Data on child mortality were not adequate for this task, although a true risk cannot be precluded by the data. Summary relative risks for perinatal mortality ( 10 studies), maternal mortality (six studies) and mental retardation (five studies) were estimated using random effects models (both mortality outcomes) or a fixed-effects model (retardation) and weighting individual estimates by the inverse of their within-study variance. For mortality outcomes, the bivariate relations between haemoglobin and death were used. In two studies of perinatal mortality, unadjusted and multivariate adjusted odds ratios were compared to assess the potential degree of bias in the unadjusted associations. For mental retardation, published multivariate adjusted relations between haemoglobin and IQ were used. Global anaemia prevalence data were supplied by the World Health Organization (WHO), and converted to mean haemoglobin concentrations, assuming normal distribution and observed standard deviations from a large number of studies. To estimate the haemoglobin distribution if iron deficiency were corrected, we assumed the prevalence of anaemia in women and children would be reduced by $50 \%$. On average, for the world, this would increase haemoglobin concentration by about $0.45 \mathrm{~g} / \mathrm{dl}$ (range: $0.0 \mathrm{~g} / \mathrm{dl}$ to $1.28 \mathrm{~g} / \mathrm{dl}$ ).

The relative risks associated with a $1 \mathrm{~g} / \mathrm{dl}$ increase in population mean haemoglobin were 0.75 ( $95 \%$ CI $0.62-0.89$ ) for maternal mortality, 0.72 ( $0.65-0.81$ ) for perinatal mortality and 0.78 ( $0.70-0.86$ ) for mental retardation. Subgroup analyses suggested that the relative risk for perinatal mortality in malaria-endemic regions, 0.65 ( $0.56-0.75$ ), was lower than that in regions without endemic Plasmodium falciparum malaria, 0.80 (0.73-0.87). These estimates were attenuated by $20 \%$ to account for probable bias leading to overestimation of the true relationship. Based on these estimates of iron deficiency anaemia as a risk factor for mortality, iron deficiency is estimated to cause 591000 perinatal deaths and 115000 maternal deaths globally. The associated loss of healthy life years amounts to more than 19 million disability-adjusted life years (DALYs) from perinatal causes and more than 3 million from maternal causes. When the direct sequelae of iron deficiency anaemia are added, the total global burden attributed to iron deficiency anaemia amounts to 841000 deaths and 35057000 DALYs.

The available evidence suggests that iron deficiency anaemia contributes substantially to death and disability in the world. The great majority of this disease burden derives from anaemia in pregnancy and early childhood and is borne by women and children in Asia and Africa. The high global prevalence of anaemia and its potentially associated disease burden, as reflected in these estimates, constitute an urgent research agenda. Because these estimates are uncertain in many respects, their most important use may be to motivate public health scientists to provide definitive evidence.

## 1. Introduction

Iron deficiency is one of the most prevalent nutrient deficiencies in the world, affecting an estimated two billion people (Stoltzfus and Dreyfuss 1998). Young children and pregnant and postpartum women are the most commonly and severely affected because of the high iron demands of infant growth and pregnancy. However, where diets are based mostly on staple foods with little meat intake, or people are exposed to infections that cause blood loss (primarily hookworms and urinary schistosomiasis), iron deficiency may occur throughout the life span. Current WHO/International Nutritional Anemia Consultative Group/United Nations Children's fund/United Nations Children's fund (WHO/INACG/UNICEF) guidelines recommend universal iron and folic acid supplementation of young children and pregnant women where anaemia is highly prevalent (Stoltzfus and Dreyfuss 1998).

Although much is known about iron metabolism, the health consequences of iron deficiency continue to be a subject of research and debate. This is partly because in many regions of the world iron supplements are the standard of care for individuals with anaemia. Most trials of iron supplementation have measured haemoglobin concentra-
tion as the primary outcome. There is a relatively small body of clinical trials of iron repletion to humans with functional iron deficiency (i.e. iron deficiency severe enough to affect erythropoiesis) with pregnancy outcomes or mortality as primary objectives. There is surprisingly little evidence to either support or refute a causal link between iron deficiency and these important adverse health outcomes. As processes like this comparative risk assessment (CRA) bring to light the overall weakness of evidence either supporting or refuting the relationship, new research priorities may emerge.

## 2. Health outcomes considered

In May 2000, a meeting commissioned by WHO, INACG and the Edna McConnell Clark Foundation systematically reviewed the evidence of a causal relationship between iron deficiency or anaemia and six health outcomes: child mortality, maternal mortality, birth outcomes, morbidity, work productivity and child development. These papers were subsequently published in a supplement to the Journal of Nutrition (Beard and Stoltzfus 2001). We began by considering those six outcomes.

Malnutrition (in this case, iron deficiency) may contribute to death and disability through direct sequelae or as a risk factor for death and disability from other causes. The total death and disability attributed to iron deficiency is therefore the sum of its actions as a risk factor and its direct sequelae. The objective of the present paper is to consider iron deficiency as a risk factor for death and disability from other causes.

Of the six outcomes considered above, child mortality, maternal mortality, birth outcomes and morbidity were considered in the framework of iron deficiency as a risk factor. For example, women do not die in childbirth as a direct effect of iron deficiency, but rather die of heart failure due to blood loss, which is made more precipitous by iron deficiency anaemia. Similarly, babies do not die in the perinatal period from iron deficiency, but rather die of other causes, some of which are related to preterm birth, for which maternal iron deficiency is a risk factor. In contrast, decreased work productivity and altered child development (or intelligence) were considered to be direct sequelae of iron deficiency, the assumption being that iron deficiency directly causes decreased oxygen delivery to muscles and the brain.

### 2.1 Outcomes considered

## Child mortality

There is a body of observational evidence linking child mortality to anaemia. However, we could find no published or unpublished studies of reasonably large size that described the relationship between anaemia and cause-specific mortality. Furthermore, nearly all the evidence linking anaemia to overall mortality comes from sub-Saharan Africa or Papua New Guinea, where P. falciparum malaria is a major cause of anaemia,
especially severe anaemia, and malaria is also a major cause of mortality. Thus it seemed unjustified to attribute the observed relationship between anaemia and mortality to iron deficiency in this context, or to generalize to other regions of the world. Brabin et al. (2001a) summarized these data and their interpretation. There are no observational studies linking iron deficiency per se to child mortality, nor any iron supplementation trials with child mortality as outcome. For these reasons, we were unable to estimate the relationship between iron deficiency and cause-specific child mortality. However, it is important to note that the available evidence does not preclude that relationship.

## Maternal mortality

There are a number of observational studies of anaemia and maternal mortality from both Africa and Asia. None of these studies attempted to distinguish iron deficiency anaemia from other causes of anaemia, although several discussed the multiple causes of anaemia within their study population. Where P. falciparum malaria is endemic, it is an important cause of anaemia, especially in first pregnancies (Brabin 1983). However, there is no evidence that malarial infection contributes directly to maternal mortality, even in areas where $P$. falciparum is endemic (Brabin et al. 2001b). Thus in contrast to the situation with child mortality, it is less plausible that malaria would confound the observed relationship between anaemia and maternal mortality (as it likely does with anaemia and child mortality). There are no observational studies linking iron deficiency per se to maternal mortality, nor are there any iron intervention trials with maternal mortality as outcome. Thus we used the available observational data to estimate the relationship between anaemia and maternal mortality.

## Perinatal mortality

There are several observational studies of maternal anaemia and stillbirths, neonatal or perinatal mortality from Africa, Asia, North America, and the United Kingdom of Great Britain and Northern Ireland. None of these studies attempted to distinguish iron deficiency anaemia from other causes linking anaemia. There are no observational studies linking maternal iron deficiency per se to perinatal mortality, and the few published iron intervention trials with perinatal morality as outcome are small or poorly designed. As with maternal mortality, we used the available observational data to estimate the anaemia-perinatal mortality relationship.

## LOW BIRTH WEIGHT

We did not consider low birth weight as a separate outcome in these analyses, but rather assumed that the mortality risk and morbidity burden of anaemia-associated low birth weight was subsumed in our estimate of perinatal mortality as outcome. The relationship between iron status and
low birth weight has been examined in several clinical trials, and it has been the subject of two recent systematic reviews (Mahomed 2000a; Rasmussen 2001). Both concluded that causal evidence from trials is lacking. Rasmussen (2001) noted that there was insufficient evidence from these trials either to support or refute the relationship, because most trials conducted in populations with a significant burden of anaemia have suffered from poor research designs. There is however a substantial body of observational data relating pregnancy anaemia to low birth weight, similar to the observational data relating pregnancy anaemia to maternal and perinatal mortality. Scott Poe and Mary Cogswell (personal communication) have recently completed a meta-analysis of these observational studies. They found that pregnancy anaemia assessed in the first two trimesters of pregnancy was significantly associated with preterm birth (but not intrauterine growth retardation), and that the risk of preterm birth increased with increasing severity of anaemia.

### 2.2 Outcomes considered to be direct sequelae of IRON DEFICIENCY

## Work productivity

There is a substantial body of evidence in animals and humans demonstrating that iron deficiency decreases fitness and aerobic work capacity through mechanisms that include oxygen transport and respiratory efficiency within the muscle (Beard 2001; Haas and Brownlie 2001). This relationship is directly and linearly related to the severity of iron deficiency anaemia. The personal and socioeconomic consequences of this relationship are likely to be real and measurable (Horton and Levin 2001). This consequence of iron deficiency is estimated as a direct sequela of iron deficiency, and is not presented here as a risk factor.

## Intelligence or cognitive capacity

There is a growing body of evidence from animal and human studies that supports a causal relationship between iron deficiency anaemia in early childhood and intelligence in mid-childhood (Beard 2001; Grantham-McGregor and Ani 2001). Although this effect of iron deficiency will be considered as a direct sequela of iron deficiency, we used the observational studies of iron deficiency anaemia in early childhood and measures of intelligence in mid-childhood to obtain a quantitative estimate of this relationship. Different investigators used different measures of cognition, learning or intelligence, making it impossible to summarize all the results. We therefore limited the outcome to global measures of intelligence that were either IQ or on the same scale as IQ (i.e. mean of 100 with standard deviation of 15 points). However, all of these studies measured deviations in intelligence within the clinically normal range (i.e. $\geq 70$ points). In terms of the International Statistical Classification of Diseases and Related Health Problems, ninth revision
(ICD-9) classification, disability in this domain is limited to mental retardation, which these studies do not directly address. We have therefore provided an estimate of the effect of early iron deficiency on mental retardation in mid-childhood, making the controversial assumption that the reported association of iron deficiency anaemia and mean IQ does not affect the variance of IQ. Based on this assumption we can estimate the expected increased risk of $\mathrm{IQ}<70$ (i.e. mild mental retardation) associated with shifts in mean IQ.

## MORBIDITY

The bulk of experimental evidence from iron supplementation trials regards morbidity. There is evidence that sufficient iron is essential for immune function (Beard 2001), and also that excess iron may exacerbate some diseases. The evidence from experimental trials does not suggest that iron supplementation reduces morbidity; in some cases it has been associated with increased morbidity, most notably malaria and respiratory infections in malarious areas (Oppenheimer 2001). However, it is most plausible that this excess risk is associated with therapeutic iron supplementation intended to treat iron deficiency; not that iron deficiency itself is beneficial. Those trials that used low-dose oral supplementation in currently recommended dosages found no adverse effect (INACG 1999). Therefore, we did not estimate a morbidity risk associated with iron deficiency; nor does the available evidence support a risk associated with the correction of iron deficiency by currently recommended public health strategies.

To summarize, we have presented estimates of risk relationships for maternal mortality and perinatal mortality. These were based on anaemia as the indicator of iron deficiency, and only a proportion of that risk is therefore attributed to iron deficiency. We have also presented an estimate of the relationship between iron deficiency anaemia, decreased IQ and mental retardation, although we believe it should be interpreted with extreme caution.

## 3. Nature and definition of the risk factor

Iron is required in all tissues of the body for cellular respiration and many other reduction-oxidation enzyme systems, and has particular functions in muscle, brain and red cells. Critical metabolic functions in these three organs become perturbed at about the same time as animals are depleted of iron (Beard 2001). Anaemia has been used as the hallmark of iron deficiency severe enough to affect tissue function, because red cells are the tissue most amenable to sampling. Although more specific indicators of functional iron deficiency are available, notably erythrocyte protoporphyrin and serum transferrin receptor, there is insufficient data to link those indicators to the health outcomes that fit the construct of this project, namely maternal and perinatal mortality.

It is problematic that all of the available data on maternal and perinatal mortality use anaemia as the indicator, because iron deficiency is not the sole cause of anaemia in most populations. Even within individuals, anaemia may be caused by multiple factors. The available studies do not attempt to separate iron deficiency from anaemia, and there are no good regional estimates of the proportion of anaemia attributable to iron deficiency, although the topic has been discussed and debated (Gillespie and Johnston 1998).

We therefore took the approach of estimating the risk function associated with low haemoglobin, using haemoglobin as a continuous variable. Where studies reported haematocrit instead of haemoglobin, we converted to haemoglobin by dividing haematocrit by 3 .

Because our task was to estimate the burden due to iron deficiency, the counterfactual (i.e. theoretical minimum) distribution should therefore represent the haemoglobin distribution if iron deficiency were eliminated. We assumed that the change in haemoglobin distribution following a supervised period of iron supplementation was a conservative approximation of the virtual elimination of iron deficiency. ${ }^{1}$ By conservative we mean that it is more likely to underestimate the contribution of iron deficiency than to overestimate it, due to problems of noncompliance with supplementation, insufficient dosage, or insufficient duration.

We approached this calculation from two angles. The first approach was to estimate the percentage of anaemia attributable to iron deficiency. Knowing this, we could estimate the shift in the haemoglobin distribution needed to reduce anaemia by that proportion. Beaton recently summarized the per cent reduction in anaemia observed in nine controlled supplementation trials, all conducted in children (Table 3.1). The range of values was wide, $21-85 \%$. Although there is regional diversity in the studies, these data are not sufficient to generate regional estimates. They provide a global average of $51 \%$.

A second and complementary approach was to examine mean changes in haemoglobin attributable to iron supplementation in iron supplementation trials. Sloan et al. (2002) conducted a meta-analysis of haemoglobin response to iron supplementation to pregnant women in randomized controlled trials. Of 70 trials in the literature, 23 met their inclusion criteria, and 15 of those were from developing countries. In studies from developing countries, haemoglobin response was smaller in study samples with higher initial haemoglobin (summarized mean change of $1.13 \mathrm{~g} / \mathrm{dl}$ in those with initial mean haemoglobin $<10.0 \mathrm{~g} / \mathrm{dl}$ compared to $0.85 \mathrm{~g} / \mathrm{dl}$ in those with haemoglobin $11.0-11.9 \mathrm{~g} / \mathrm{dl})$. However, in studies from developed countries, the initial haemoglobin concentrations were uniformly $\geq 11.0 \mathrm{~g} / \mathrm{dl}$, and the effect size was large $(1.17 \mathrm{~g} / \mathrm{dl})$. The response to iron supplementation was strongly related to iron dose, with maximum effects observed in the eight studies that provided a daily dose $\geq 91 \mathrm{mg}$. In these studies the mean haemoglobin response was around

Table 3.1 Estimated proportion of anaemia attributable to iron deficiency

| Site | Age group | Estimated attribution to iron ${ }^{\text {a }}$ |

| Average |  | 51 |
|  |  |  |
|  | Percentage reduction in anaemia in supplemented group minus per cent age reduction in control |  |
| Source: | Beaton (2002). |  |

$1.8 \mathrm{~g} / \mathrm{dl}$. This maximal response might be considered the best theoretical basis for predicting the effect of eradicating iron deficiency. However, it is likely that the highest doses were also used in studies of more severely anaemic populations. A case can also be made for using 1.17 as the predicted effect size, as this was the average effect seen in women from developed countries, and very similar to that seen in women from developing countries with initially low haemoglobin (1.10-1.13g/dl).

An important question for the present exercise is whether the predicted haemoglobin shift should vary by region. Sloan et al. (2002) did not disaggregate their data by global region, and the studies examined by Beaton are too few to disaggregate (see Table 3.1). If significant regional differences exist in the percentage of anaemia attributed to iron deficiency, the iron-attributable portion might be smaller in Africa, where malaria contributes greatly to the burden of anaemia. Therefore iron would logically claim a smaller portion of total anaemia. Shankar recently summarized data from controlled iron supplementation trials conducted in P. falciparum malaria-endemic populations, including the haemoglobin response attributable to iron (INACG 1999). Eleven studies were included, nine of them from sub-Saharan Africa (Adam 1997; Fleming et al. 1986; Harvey et al. 1989; Lawless et al. 1994; Menendez et al. 1994, 1997; Murray et al. 1978; Oppenheimer et al. 1986; Smith et al. 1989). The studies included younger and older children, and adults, including pregnant women. The change in haemoglobin attributable to iron supplementation in individual studies ranged from 0.3 to $3.6 \mathrm{~g} / \mathrm{dl}$, yielding a weighted average of 1.24 ( $95 \%$ CI 1.16-1.33). Although malaria certainly contributed to anaemia in these populations, it is
remarkable that the haemoglobin response to iron supplementation was similar to that reported by Sloan et al. (2002). Two of the 11 studies in the Shankar analysis were in pregnant women-the subject of analysis by Sloan et al. and the group at risk for the outcomes estimated in this chapter. These two studies from the Shankar analysis both used an iron dose of $60 \mathrm{mg} /$ day, and yield a weighted average haemoglobin response of $0.83 \mathrm{~g} / \mathrm{dl}$. These studies were excluded from the analysis by Sloan et al., but are consistent with the haemoglobin responses at the dosage reported by them: 0.41 in studies of doses $\leq 60 \mathrm{mg} /$ day , and 0.86 in studies of doses $61-90 \mathrm{mg} /$ day.

Thus, the data suggest that iron deficiency is responsible for about $50 \%$ of anaemia, and that, where anaemia is prevalent, elimination of iron deficiency results in a change in mean haemoglobin of about $1.17 \mathrm{~g} / \mathrm{dl}$ or perhaps even higher. The data are lacking in several respects: notably, the studies included in these three meta-analyses did not include non-pregnant adults outside of Africa. From the data at hand, there is no strong basis for altering these values by region. We used both of these lines of evidence to estimate the proportion of the risk associated with anaemia that is attributable to iron deficiency (see section 8).

## 4. Search strategy

### 4.1 Maternal mortality

We based our work on the recent systematic review by Brabin et al. (2001b). Because there are no experimental trials of iron deficiency and maternal mortality, we estimated the risk relationship from observational data. As described by Brabin et al. (2001b), several studies from Nigeria have documented extremely high risks of maternal mortality at haemoglobin concentrations $<5 \mathrm{~g} / \mathrm{dl}$. We decided to limit our description of the haemoglobin-mortality risk relationship to the haemoglobin range of $5-12 \mathrm{~g} / \mathrm{dl}$. Values $<5 \mathrm{~g} / \mathrm{dl}$ are rare on a population basis, being more than 2 standard deviations below the mean in even the most severely anaemic communities, and we did not want those data to influence our risk estimates for the common population ranges. Pregnancy haemoglobin values $>12 \mathrm{~g} / \mathrm{dl}$ were excluded because we judged that variation in this high range is mostly unrelated to iron status, and our ultimate objective was to estimate risk associated with iron deficiency. We thus included those studies that reported mortality rates in at least two haemoglobin groups in the range of $5-12 \mathrm{~g} / \mathrm{dl}$ rates. This excluded three studies: Fullerton and Turner (1962), Johnson and Ojo (1967) and Tasker (1958). We further excluded the study of Chi et al. (1981) from Indonesia, because the haemoglobin categories presented in their Table 5 disagreed with that in the text and we had no basis for determining which was correct. In summary, 10 studies were identified, and six of these were included in the meta-analysis (see Table 3.2 for study descriptions).

| - No data. |  |  |  |  |  |
| Note: Shaded rows indicate excluded studies. |  |  |  |  |  |

### 4.2 Perinatal mortality

As with maternal mortality, we estimated the risk relationship from observational studies, using pregnancy or delivery maternal haemoglobin concentration as the risk factor. Published trials of iron supplementation that reported perinatal or neonatal mortality as an outcome were not used as a basis for our risk estimate because the women in the trial were not anaemic (Hemminki and Rimpelä 1991) or because they were small or poorly designed to test the effect of iron (Agarwal et al. 1991; Fleming et al. 1986).

We based our search on the recent systematic reviews of Brabin et al. (2001b), Rasmussen (2001) and Xiong et al. (2000). We added to this one unpublished study by Dreyfuss et al. in which one of us was involved. Xiong et al. described the relationship between pregnancy anaemia and perinatal outcomes in 16936 women in China. This study is published only as an abstract (Xiong et al. 1996); however, the authors provided the data we needed to include here. In summary, 13 studies were identified and 10 were included in the meta-analysis (see Table 3.3 for study descriptions).

### 4.3 Child development

We based our work on the recent systematic review by GranthamMcGregor and Ani (2001). We were interested in estimating the risk of continuous decrement in cognitive function or capacity in children who were iron-deficient anaemic in early childhood. Thus we limited our meta-analysis to those studies that identified iron-deficient anaemic and non-anaemic infants and toddlers and then compared their intelligence at age $2-7$ years. We further limited the meta-analysis to studies that used standardized tests on a scale of 100 with standard deviation 15 (i.e. IQ tests and the Bayley Mental Development Index). Seven different longitudinal studies were described by Grantham-McGregor and Ani (Table 3.4). The study by Hurtado et al. (1999) was excluded because the outcome measure was placement in special education, rather than a measure of intelligence. Similarly, the study by Dommergues et al. (1989) was excluded because the outcome measure (Brunet-Lezine test) did not meet our criterion for a summarizable outcome. The two longitudinal studies by Lozoff et al. followed the same cohort of children; the data from the 1991 publication were used in this analysis. The two studies of Wasserman et al. also followed the same cohort of children. The data from the 1992 publication were used in this analysis because nearly $40 \%$ of the cohort was lost to follow-up by the time of the evaluation of the children at four years of age in the 1994 publication. The five studies that were included in our meta-analysis are described in Table 3.4.
Observational studies of anaemia and perinatal mortality

| Country (reference) | Site | Period of data collection | Selection criteria | Time in pregnancy of anaemia assessment | Etiologies of anaemia |
| :---: | :---: | :---: | :---: | :---: | :---: |
| China (Xiong 1996) | Suzhou | 1989-1990 | Perinatal care monitoring records | At entry into prental care; about 12 <br> gestational weeks, and again at 32 weeks | Not described |
| India (Sarin 1995) | Punjab | 1990-1994 | Population-based survey of pregnant women | Different stages during pregnancies | Iron deficiency anaemia |
| Kenya (Macgregor 1963) | Mombasa | 1957-196\| | Patients at Lady Grigg Maternity Hospital | Within 48 hours of onset of labour | Malaria and iron deficiency are discussed |
| Malaysia <br> (Llewellyn-Jones <br> 1965) | Kuala Lumpur | 1953-1962 | Women treated in maternity hospital in given time period | Not stated | Iron deficiency anaemia: (i) hookworm; (ii) diet. Megaloblastic anaemia: (i) liver damage in malnutrition; (ii) diet-amount of folic acid, haemolytic, normoblastic anaemia |
| Malaysia (Tasker 1958) | Kuala Lumpur | 1952-1958 | Pregnant women with haemoglobin levels $<45 \%$ | At delivery, upon admission | Iron deficiency and some megaloblastic anaemia |
| Nepal (Dreyfuss and West 2001) | Sarlahi | 1994-1996 | Community-based sample of pregnant women enrolled in vitamin A trial | Mid-pregnancy | Iron deficiency, other micronutrient deficiencies, Plasmodium vivax malaria, hookworms |
| Nigeria (Harrison 1975) | Ibadan | 1957-1968 | Pregnant women with haematocrit $\leq 26 \%$ | At delivery, upon admission | Red cell haemolysis due to malaria, dietary deficiency of folates, and haemoglobinopathies |

| Nigeria (Johnson and Ojo 1967) | Ibadan | 1961 | 20-32 weeks pregnant, anaemic (haematocrit $\leq 24 \%$ ) women | 20-32 weeks | Haemolysis; folic acid deficiency |
| :---: | :---: | :---: | :---: | :---: | :---: |
| Nigeria (Harrison 1982) | Zaria | 1976 | Pregnant women who develop anaemia | Mid-pregnancy | Nutritional deficiency of iron and folates, malaria, haemoglobinopathies, blood loss, bacterial infections, and socioeconomic deprivation |
| Nigeria (Harrison et al. 1985) | Zaria | - | Pregnant women in Zaria area | First attendance at hospital to book for antenatal care or seek emergency care | Malaria, iron deficiency, haemoglobinopathies |
| Papua New Guinea (Mola et al. 1999) | Port Moresby | 1987-1992 | Pregnant women booked at antenatal clinics in or around Port Moresby and delivered in Port Moresby General Hospital | Lowest haemoglobin concentration from multiple values, mostly in second half of pregnancy | Malaria, alpha thallasemia, hookworm infection, iron and folate deficiencies |
| United Kingdom (Murphy et al. 1986) | Cardiff, Wales | 1970-1982 | All singleton births to South Glamorgan residents (Cardiff Births Study) | At first booking; 70\% within first 13 weeks, 24\% at 13-19 weeks, 5\% at 20-24 weeks | Social disadvantage |
| USA (Garn et al. 1981) | multicentre | - | National Collaborative Perinatal Project | Lowest haemoglobin concentration in pregnancy from multiple antenatal values | Not described |

Table 3.4 Longitudinal observational studies of iron deficiency anaemia and child intelligence ${ }^{a}$

| Country (reference) | Sample size | Period of follow-up | Exclusions | Study design |
| :---: | :---: | :---: | :---: | :---: |
| Chile (de Andraca et al. 1990) | Total $=77$. <br> Formerly anaemic $=4 \mathrm{I}$. <br> Formerly non-anaemic $=29$. <br> All anaemic treated at 12 months | Birth to 5-6 years | BW $<2500 \mathrm{~g}$, chronic ill health, intermediate levels of anaemia | Part of a randomized trial of iron fortification in early infancy, at one year, $25 \%$ of the non-fortified group had anaemia. The anaemic children all received 3 months of iron treatment. Selected children re-examined at 5 to 6 years of age |
| Costa Rica (Lozoff et al. 1991) | 163 of 191 children originally evaluated at 12-24 months. 30 had moderate anaemia $=\mathrm{Hb} \leq 10.0 \mathrm{~g} / \mathrm{dl}$, ferritin $\leq 12 \mathrm{mcg}$, EP $>1.77 \mathrm{mcgmol}$ or transferrin $\leq 10 \%$. 133 comparison group | 12 months to 5 years | BW $<2.5 \mathrm{~kg}$, multiple pregnancy, complicated births, acute or chronic medical problem | Follow-up at 5 years of Lozoff et al. (1987). The IDA group was initially treated for 3 months to to correct their anaemia. Current evaluators blind to original iron status. All now free of anaemia |
| Former Yugoslavia (Wasserman et al. 1992) | Children whose mothers were followed up from pregnancy in two areas of Kosovo. <br> Mitrovica $=$ lead exposed. <br> Pristina = nonlead exposed. <br> 54I agreed to participate. <br> $392(208+184)$ seen at 24 months | Birth to 24 months | Major CNS defects, chromosomal abnormalities, multiple pregnancy | Follow-up two cohorts from birth measuring serum lead, iron status and developmental indices. Related Hb at each age with DQ at 24 months. Anaemic children treated |
| Israel (Palti et al. 1983) | Routine health service screen for Hb at 9 months. <br> Tested at 2 years $=873$. <br> At 3 years $=388$. <br> At 5 years $=239$. <br> Hb only measure of iron status | 9-10 months to 5 years | Not given | Follow-up of all children from 9-10 months to 2,3 and 5 years. All with $\mathrm{Hb}<11 \mathrm{~g} / \mathrm{dl}$ treated with iron at 9 months for 3 months. At 5 years took a random sample of remaining children |
| USA (Cantwell 1974) | 6I full-term neonates from comparable socioeconomic groups: 29 given IM iron in neonatal period 32 infants developed Fe deficiency anaemia between 6-18 months. (Hb $6.1-9.5 \mathrm{~g} \%$ ) without PEM. No details of iron status | Birth to 7 years | Preterm | 29 of 61 infants received iron injections (method of assignment not given) and were not anaemic (Hb II.5-I2.9). 32 infants developed IDA. Examined at 6-7 years by examiners blind to the groups |

| Country (reference) | Outcome measures | Covariates adjusted for | Findings | Remarks |
| :---: | :---: | :---: | :---: | :---: |
| Chile (de Andraca et al. 1990) | Stanford-Binet IQ, Illinois psycholinguistic abilities test, psychoeducational abilities test, Bruininks-Osteretsky test of motor proficiency, VMI, neurological exam | Home, maternal depression and stress. Not clear if used in analysis | Hb at $I$ year $=10.1 \pm 0.7$ vs $13.0 \pm 0.8$. Hb a 15 months $=12.8 \pm 0.7$ vs $13.0 \pm 0.8$. Current Hb level not given. Formerly anaemic children performed significantly worse in IQ $(P=0.02)$, psychoeducational abilities ( $P<0.0 \mathrm{I}$ ), VMI ( $P<0.0 \mathrm{I}$ ), motor proficiency ( $P<0.0 \mathrm{I}$ ), language abilities ( $P<0.01$ ). They were more neurologically immature ( $P<0.01$ ). Their homes were significantly less stimulating and their mothers were more depressed and less affectionate |  |
| Costa Rica (Lozoff et al. 1991) | Current iron status. WISC test, Woodcock Johnson psychoeducational battery, Goodenough-Harris draw-a-man test, Beery developmental test of VMI , Bruininks-Oseretsky test of motor proficiency | Sex, birth weight, mother's IQ, height and education, breastfeeding, absence of father, home | No current difference in Hb and other measures of iron status. After controlling for covariates, previously anaemic group had lower scores on performance IQ, quantitative and visual matching subtests of the Woodcock Johnson battery, the VMI and the Bruininks-Oseretsky test of motor proficiency. In post hoc analyses, children who were non-anaemic but continued to have iron deficiency after treatment also had significantly lower scores | Good covariate control. Verbal skills less affected |
| Former Yugoslavia (Wasserman et al. 1992) | Bayley MDI at 6, 12, 18, 24 months with iron and lead status | Ethnic group, home, birth order, BW, sex, maternal IQ , education and age, lead levels | Hb at 6,12 and 24 months was not significantly associated with MDI at 24 months but Hb at 18 months was significant. Controlling for all covariates, in both | At all ages mothers' education had the most significant effect on DQ |

Table 3.4 Longitudinal observational studies of iron deficiency anaemia and child intelligence ${ }^{\text {a }}$ (continued)

| Country (reference) | Outcome measures | Covariates adjusted for | Findings | Remarks |
| :---: | :---: | :---: | :---: | :---: |
|  |  |  | Mitrovica and Pristina a change in Hb at 18 months of $2.0 \mathrm{~g} / \mathrm{dl}$ was associated with a change of 3.4 MDI points $(~ P=0.02)$. Other indices of iron deficiency not associated with development |  |
| Israel (Palti et al. 1983) | Brunet-Lezine test at 2 years. MILI test (an Israeli intelligence test) at 3 years. Wechsler with Israeli adaptation (WPSSI) at 5 years | Maternal education, father's occupation, BW, sex | When controlling for covariates: Hb at 9 months not significantly associated with DQ at 2 years ( $P=0.105$ ) and at 3 years ( $P=0.07$ ) but at 5 years had a significant effect on IQ ( $P=0.02$ ). At 5 years an increase of $1.0 \mathrm{~g} / \mathrm{dl}$ of Hb associated with 1.75 change in IQ points | A large number of cognitive tests. Previously anaemic not reported alone |
| USA (Cantwell 1974) | Neurological examination and Stanford-Binet IQ | None reported | The formerly anaemic group had a higher incidence of "soft signs" e.g. clumsiness with balancing on one foot, in tandem walking, and repetitive hand and foot movement and were more inattentive and hyperactive than the non-anaemic group. IQ scores averaged 98 in the non-anaemic and 92 in the anaemic. No significance levels levels reported |  |

[^8]
## 5. Methods for COMBINING RISK ESTIMATES FROM INDIVIDUAL STUDIES

### 5.1 Anaemia and maternal mortality

In each study, maternal mortality data were given in aggregate for each of the ranges. All ranges were converted to haemoglobin by dividing haematocrit values by 3 . The midpoint of each range was used as the independent variable. The midpoints were estimated from the information provided in the articles. A logistic regression model was then used to fit the observed data, weighting each haemoglobin midpointmortality point by the total number of women in that range. Within each study, an estimate of the risk ratio associated with a one-unit difference in haemoglobin was calculated. These individual estimates were initially combined in a fixed-effects model, weighting individual estimates by the inverse of their within-study variance, to estimate an overall risk ratio. The heterogeneity statistic indicated that individually observed effect sizes varied significantly around the overall fixed-effects model estimate. Dropping the assumption of a fixed-treatment effect, the individual effect sizes were then assumed to be normally distributed and a random-effects combined estimate was calculated using the method of DerSimonian and Laird (1986).

### 5.2 AnAEMIA and perinatal mortality

Analyses for perinatal mortality were conducted in a similar manner as that for maternal mortality. The nine studies included in the metaanalysis were sufficiently heterogeneous that a random-effects model was used to generate combined estimates (DerSimonian and Laird 1986).

### 5.3 IRON DEFICIENCY ANAEMIA AND CHILD INTELLIGENCE

The beta coefficients from multivariate regression models associated with a $1 \mathrm{~g} / \mathrm{dl}$ change in haemoglobin were obtained directly from the original published paper (Palti et al. 1983; Wasserman et al. 1992) or estimated indirectly from means and $P$-values (Cantwell 1974; de Andraca et al. 1990; Lozoff et al. 1991). Standard deviations were obtained directly from the original paper (Wasserman et al. 1992), estimated from $P$ values and beta coefficients (de Andraca et al. 1990; Lozoff et al. 1991; Palti et al. 1983), or estimated by assuming a significance level of 0.05 (Cantwell et al. 1974). As original data were not available, variability in baseline anaemia levels was not considered; rather, baseline mean haemoglobin levels were compared to follow-up IQ scores with standard deviations to estimate individual study regression coefficients. The estimates were combined in a fixed-effects model, weighting studies according to the reciprocal of their within-study variance. A chi-squared test for heterogeneity found no significant between-study variance; thus a randomeffects model was not necessary.

## 6. Results

### 6.1 Maternal mortality

We computed odd ratios for maternal mortality associated with a $1 \mathrm{~g} / \mathrm{dl}$ increase in pregnancy haemoglobin. Of the six studies included in our meta-analysis, all had individual study ORs $<1.0$, and three of those were statistically significant (Table 3.5 and Figure 3.1). The estimated OR from combining data points from all the studies was 0.75 , with a CI that clearly excluded unity ( $0.62-0.89$ ). The studies were not geographically diverse, coming from only three countries (India, Malaysia and Nigeria). However there was not a systematic difference between the risk estimates from the Nigerian vs the Asian studies. Two Nigerian studies had markedly lower ORs than the other four studies; however these two studies carried little weight in the combined OR.

### 6.2 Perinatal mortality

Ten studies were included in our meta-analysis. The individual ORs for perinatal mortality associated with a $1 \mathrm{~g} / \mathrm{dl}$ increase in haemoglobin ranged from 0.55 to 0.87 (Table 3.6 and Figure 3.2). Nine of the 10 individual study estimates were statistically different from unity. The estimated OR from the 10 studies combined was 0.72 ( $95 \%$ CI $0.65-0.81$ ).

The nine studies included in the meta-analysis were sufficiently heterogeneous that a random-effects model was used to generate combined estimates. We explored three factors that might explain this heterogeneity; these subgroup analyses are presented in Table 3.7. First, we were liberal in accepting various outcome definitions related to perinatal mortality. Only three of the 10 studies used the correct definition, which includes fetal death after 22 (or 28) weeks' gestation and neonatal mortality in the first seven days of life. Use of the correct definition of

a Adjusted ORs were adjusted for randomized supplement group (i.e. maternal supplementation with vitamin A or beta-carotene during pregnancy; this treatment did not affect neonatal death), primiparity, gestational age at Hb assessment, reported severe illness in late pregnancy, contribution of $\geq 1$ pregnancy to the data set, preterm birth. Source: M. Dreyfuss, personal communication.
b Adjusted for maternal age, gestational age, parity, hypertensive disorders of pregnancy, gestational age at enrolment into prenatal care, hospital and maternal education. Source: X. Xiong, personal communication.
perinatal mortality did not significantly change the effect estimate. Second, P. falciparum malaria contributes to anaemia in pregnancy and may also affect perinatal mortality. Five of the studies were conducted in populations with endemic $P$. falciparum malaria, and these studies had a combined risk estimate that was substantially further from unity than those studies conducted in populations not heavily exposed to this form of malaria. We concluded that the risk relationship with anaemia is greater in $P$. falciparum malaria-endemic regions. Third, two studies assessed haemoglobin at delivery whereas the other eight assessed haemoglobin earlier in gestation. Xiong et al. (2000) have suggested that anaemia early in pregnancy carries a greater risk of adverse perinatal outcomes; however this inference was based on low birth weight as outcome. We did not find this in our data. In fact, the risk relationship was slightly stronger in the two studies that assessed haemoglobin at delivery. However, those two studies were also in P. falciparum malariaendemic populations, which could bias the analysis.

The ORs presented in Table 3.6 and Figure 3.2 are unadjusted for potential confounding factors. Two of the 10 studies, Nepal 1998 and China 1996, could provide us with both unadjusted and adjusted ORs by haemoglobin category. These are displayed in Table 3.8. In the Nepal study, multivariate adjustment for a number of variables had no effect on the estimated ORs. However, in the China study, in which more

Table 3.9 Final odds ratios and confidence intervals used to generate burden of disease estimates

| Outcome | OR estimate | $95 \% \mathrm{Cl}$ |
| :--- | :---: | ---: |
| Maternal mortality | 0.80 | $0.70-0.91$ |
| Perinatal mortality, Africa | 0.72 | $0.65-0.80$ |
| Perinatal mortality, other regions | 0.84 | $0.78-0.90$ |

covariates were measured, multivariate adjustment attenuated the ORs by about $20 \%$.

We have therefore attenuated the ORs for both perinatal and maternal mortality by $20 \%$, as the evidence at hand suggests that the unadjusted estimates may be overestimated to about that degree. The final ORs and confidence intervals used to generate the burden of disease estimates are shown in Table 3.9.

### 6.3 Child intelligence

Five studies were included in our meta-analysis. The studies were geographically diverse, including Europe, Latin America, the Middle East and North America (the United States of America). However, there were no studies included from Africa or Asia. We estimated the expected change in IQ points associated with a $1 \mathrm{~g} / \mathrm{dl}$ change in haemoglobin. The individual study estimates ranged from 1.36 to 2.52 , and all were statistically different from zero (Table 3.10 and Figure 3.3). The combined estimate was 1.73 points, with a $95 \%$ CI of $1.04-2.41$. The quality of the studies was high, and all of them provided estimates that were adjusted for multiple covariates.

The relevant disease outcome for this analysis would be mild mental retardation, defined as $\mathrm{IQ}<70$, or more than 2 standard deviations below the expected population mean of 100 . The increase in risk of mental retardation can be estimated from the expected mean change in IQ if one assumes that the mean change represents a shift in the entire distribution of values with no change in variance of the distribution. These calculations are displayed in Table 3.10. The resultant relative risk associated with a $1 \mathrm{~g} / \mathrm{dl}$ increment in haemoglobin concentration is 0.78 . The relative risk estimates associated with the upper and lower confidence limits of the estimated change in IQ are 0.70 and 0.86 , respectively (Table 3.11).

## 7. DESCRIPTION OF MALNUTRITION TABLES

To describe the distribution of low haemoglobin by region we used the anaemia prevalence data that were published in the 1990 Global Burden

counterfactual haemoglobin distribution, representing the elimination of iron deficiency.

The anaemia database that we used was based on surveys conducted prior to 1990. Global monitoring of anaemia trends suggests that the prevalence of anaemia in the world has not decreased in the past decade (UNICEF 1998). However, the representativeness and reliability of these data (in terms of sample sizes) are less than we would hope for. Table 3.12 summarizes the numbers of country surveys included in the available data set, and the conversion from previous regions to the subregions used in the present analysis. Data for EUR-B and EUR-C are especially scarce. In the case of SEAR-D, the previous data source included only one country, India, but several surveys contributed to the country estimate.

Nationally representative anaemia data from the United States are available that are more recent than the data in the 1990 WHO database, and demonstrate lower anaemia prevalences (Looker et al. 1997). So as not to overestimate the burden of anaemia in economically developed regions, we used these data from the United States for three subregions, AMR-A, EUR-A and WPR-A. The haemoglobin cut-offs used to define anaemia globally have not changed since the 1990 database was created (Table 3.13). The resulting anaemia prevalence estimates are given in Table 3.14.

The second step was to convert the prevalence of anaemia to a mean haemoglobin value. We assumed all haemoglobin distributions to be approximately normal (Yip et al. 1996). We then needed to make

assumptions about the standard deviation of the distributions. The standard deviation of haemoglobin in a population depends on at least two factors. The first factor is the proportion of individuals who are at their homeostatic haemoglobin concentration (i.e. non-anaemics). There is a certain amount of variability in haemoglobin that is set by individual characteristics, including genetics. This would be represented by the standard deviation in a population with no anaemia. Added to this "inherent" variability is the variability associated with non-physiologic states,

including iron deficiency. Thus it is logical to expect the standard deviation of haemoglobin to be higher in populations with more anaemia compared to those with infrequent anaemia. The second factor is the precision of the haemoglobin assay, with greater precision yielding smaller observed standard deviations.

The variation in haemoglobin standard deviations is illustrated in Table 3.15, which relates the prevalence of anaemia to the standard deviation, using data from a draft version of the updated (but still incomplete) anaemia database for the WHO African and Eastern Mediterranean Regions (B. de Benoist, personal communication) and data from the most recent national health and nutrition examination survey in the United States, after excluding iron-deficient individuals. The standard deviations from the data from the United States are significantly smaller,

Table 3.16 Standard deviations used to convert anaemia prevalence to mean haemoglobin

| Anaemia prevalence | Standard deviation of haemoglobin |
| :--- | :---: |
| $<15 \%$ | $1.0 \mathrm{~g} / \mathrm{dl}$ |
| $15-30 \%$ | $1.2 \mathrm{~g} / \mathrm{dl}$ |
| $>30 \%$ | $1.5 \mathrm{~g} / \mathrm{dl}$ |

probably due to both of the factors discussed above. Namely, the proportion of anaemic individuals in this United States sample was very low, and the haemoglobin assessment method (venous blood collection, laboratory-based assay with rigorous quality control) was more precise than most field-based studies in developing countries.

Based on these considerations, we assumed certain standard deviations based on the anaemia prevalence of each population group. These are given in Table 3.16.

Knowing the proportion below a certain haemoglobin cut-off (i.e. prevalence of anaemia in a population) and the standard deviation of the normal distribution, we estimated the mean haemoglobin associated with the current prevalence of anaemia (Snedecor et al. 1980). These values are given in Table 3.17.

We then estimated the theoretical-minimum-risk distribution, representing the haemoglobin distribution if iron deficiency were eliminated. Assuming that $50 \%$ of anaemia in the world is attributable to iron deficiency (see section 3), we divided the current anaemia prevalences by 2. Because anaemia cut-offs are defined as the 5th percentile of a normative reference distribution (i.e. the distribution of individuals known to

be free of disease), we set the minimum prevalence of anaemia in all world subregions to be $5.0 \%$. We assumed a normal distribution, and applied the standard deviations in Table 3.15. This yields values in Table 3.18.

To check the plausibility of this theoretical minimum distribution, we examined the shift in population mean haemoglobin concentration from current reality to the theoretical minimum, representing the eradication of iron deficiency. These shifts are summarized in Table 3.19.

The predicted shifts in mean haemoglobin ranged from 0.0 , in young adult men in affluent subregions, to $1.28 \mathrm{~g} / \mathrm{dl}$ in children in SEAR-D. The predicted haemoglobin shift for young children in AFR was 1.17 , which is consistent with the evidence from iron supplementation trials in the

P. falciparum-endemic populations (1.24, $95 \%$ CI 1.16-1.33, see section 3 ). The predicted haemoglobin shifts for women of reproductive age range from 0.11 to $1.17 \mathrm{~g} / \mathrm{dl}$. These estimates were somewhat lower than the average haemoglobin response of pregnant women to iron supplementation ( 0.85 to $1.17 \mathrm{~g} / \mathrm{dl}$ ), and were substantially lower than the haemoglobin responses in women provided iron doses of $\geq 90 \mathrm{mg} /$ day (i.e. $1.8 \mathrm{~g} / \mathrm{dl}$ ) estimated by Sloan et al. (2002).

We are thus faced with some uncertainty about how to estimate the haemoglobin shift that would occur if iron deficiency were eliminated. Basing our estimates on a $50 \%$ reduction in anaemia yields a smaller shift than we would obtain if we assumed that the responses of pregnant women to maximal daily iron doses in the trials summarized by Sloan

et al. (2002) represented the true effect. We used the $50 \%$ reduction in anaemia for two reasons. First, it yields more conservative estimates for the overall burden of disease attributable to iron deficiency. Second, we expect that the responses seen in iron supplementation trials are not representative of all women in the region in which they were conducted. Researchers frequently select study populations that are unusual in their potential to respond to an intervention; in this case populations that are more anaemic than the average population. Therefore it is reasonable to expect that data from randomized trials would overestimate global or regional average effects.

Figure 3.4 Relationship between mean haemoglobin values in pregnant and non-pregnant women within populations

Note: $\quad n=43$ surveys, $r=0.84, P<0.00$ I.
Source: Data from WHO (B. de Benoist, personal communication).

A final consideration is that these global tables report values for all women in the reproductive age ranges, whereas the risks of perinatal and maternal mortality apply uniquely to pregnancy anaemia. Population surveys that include both pregnant and non-pregnant women demonstrate a strong linear correlation between the haemoglobin values in these two population subgroups, as shown in Figure 3.4. Across the range of haemoglobin for women in Table 3.17, the difference between haemoglobin values in non-pregnant and pregnant states is nearly constant (range: $1.39 \mathrm{~g} / \mathrm{dl}$ to $1.34 \mathrm{~g} / \mathrm{dl}$ ). The haemoglobin cut-off used to define anaemia is also lower in pregnancy. The WHO cut-off, for simplicity, is $1.0 \mathrm{~g} / \mathrm{dl}$ lower in pregnancy. However, the physiologic haemodilution of pregnancy reduces the haemoglobin concentration by $1.5 \mathrm{~g} / \mathrm{dl}$ in midpregnancy (Institute of Medicine 1990), when many pregnancy values are obtained in field surveys. Thus we can expect the prevalence of true anaemia to be approximately the same in pregnant and non-pregnant women. Because pregnant women are more iron-deficient than non-pregnant women, there is reason to believe that the iron-attributable fraction of anaemia would be higher in pregnancy than in other states. However, lacking firm data on this relationship, we have made the conservative assumption that the anaemia prevalence and predicted haemoglobin shift associated with the elimination of iron deficiency are the same for pregnant women as non-pregnant women.

## 8. Burden of disease estimates

The estimated deaths and DALYs attributable to iron deficiency are shown in Tables 3.20 and 3.21. Those attributed to iron deficiency as a risk factor for perinatal and maternal conditions are shown separately from those attributed directly to iron deficiency anaemia. For perinatal and maternal conditions, only mortality (as opposed to morbidity) from maternal conditions was attributed to iron deficiency. In the absence of any data on anaemia and morbidity related to childbirth or the puerperium, we assumed that such a relationship did not exist. As discussed earlier, the effects of iron deficiency anaemia on work productivity and child development and cognition are included in the direct attributions to iron deficiency anaemia (i.e. in the iron deficiency anaemia columns). These direct estimates are updated from the 1990 GBD (Murray et al. 1996a, 1996b), using 2000 demographic statistics, but otherwise the same methods.

The total burden of death and disability attributable to iron deficiency is higher than the 1990 estimate. This is due to differences in the risk estimates, not the prevalence estimates, which remain unchanged. The inclusion of iron deficiency anaemia as a risk factor for perinatal mortality is new, and contributes substantially to estimated deaths and DALYs lost. Furthermore, in the 1990 estimate, deaths from iron defi-

ciency anaemia were included only as "direct" deaths due to severe and very severe anaemia. The increased maternal mortality from iron deficiency anaemia as an underlying risk factor is newly included in these estimates.

It is apparent that while the death and especially the disability directly attributable to iron deficiency anaemia is large, death and disability attributable to iron deficiency anaemia acting as a risk factor for perinatal and maternal causes is much larger. Because of the great numbers of perinatal deaths globally, perinatal causes account for $70 \%$ of the total deaths and $56 \%$ of the total DALYs attributable to iron deficiency anaemia. Numbers of maternal deaths, while very high, are much lower than perinatal deaths. Therefore the absolute contribution of maternal causes to the totals is smaller, namely $10 \%$ of DALYs and $14 \%$ of deaths. The relative contribution of maternal and perinatal causes to the total DALYs lost is largest where death rates are high (e.g. 80\% in SEAR-D compared to only $25 \%$ in EUR-A). Indeed, as expected, the contribution of iron deficiency anaemia to maternal deaths is zero in AMR-A, EUR-A and WPR-A, where maternal mortality rates are very low.

When examined by region, the global burden of iron deficiency anaemia and its consequences are most heavily borne by those in SouthEast Asia and Africa. For maternal causes, $43 \%$ and $37 \%$ of the mater-
nal deaths (and DALYs) attributed to iron deficiency anaemia occur in Africa (AFR-D and AFR-E combined) and South-East Asia (SEAR-B and SEAR-D combined), respectively. For perinatal causes, the relative burden in the two regions is reversed, but they still suffer the greatest toll, with $34 \%$ of the iron deficiency-related perinatal deaths (and DALYs lost) in Africa and $40 \%$ in South-East Asia. WPR-B and EMR-D also bear a large burden of iron deficiency-related perinatal deaths, with approximately $10 \%$ of the global total in each of these two subregions.

## 9. Expected changes in the prevalence of IRON DEFICIENCY ANAEMIA

Based on the trends observed over the past 20 years there is no reason to expect anaemia or iron deficiency anaemia prevalence to decrease in the coming decade. The United Nations Subcommittee on Nutrition (ACC/SCN) reviewed trends in data from the 1970s and 1980s (ACC/SCN 1992). Iron density in the diet was decreasing during this period for every global region except the Near East and North Africa. Furthermore, trends in anaemia from 1977 to 1987 were increasing in the two regions where the problem is most severe: south Asia, and subSaharan Africa. In 1990, the World Summit for Children set goals for reducing malnutrition, sickness and death in children that included a goal to reduce iron deficiency anaemia by one-third by the year 2000. A progress report in 1995 (UNICEF 1995) stated:

Very few countries have so far taken nation-scale action to eliminate iron deficiency anaemia. . . . No mid-decade target was established for progress against anaemia; but the goal . . is unlikely to be met without a significant acceleration of effort over the next six years.

This needed acceleration of effort did not take place. A more recent progress report (WHO 2000) concluded the following:

> Unfortunately, there has been little appreciable change over the last two decades in the high worldwide prevalence of iron deficiency anaemia. Few active programmes in both developed and developing countries have succeeded in reducing iron deficiency and anaemia. Important factors contributing to the lack of progress include failure to recognize the causes of iron deficiency and anaemia, lack of political commitment to control it, inadequate planning of control programmes, insufficient mobilization and training of health staff, and insufficient community involvement in solving the problem.

Thus the evidence strongly suggests that under a "business-as-usual" scenario, the prevalence of iron deficiency anaemia will not decrease over the next decade. We hope that the new estimates of the burden of disease attributed to iron deficiency will result in a significant deviation from business-as-usual.

## 10. Discussion

Our analysis of the relationship between pregnancy anaemia and maternal mortality differed from that of the recent analysis by Brabin et al. (2001b), although we drew upon the same published studies. The salient difference is that we began by estimating the mortality-haemoglobin relationship within each study (expressed as an OR per g/dl increment in haemoglobin), and then used meta-analytic techniques to obtain a weighted average of those ORs. Restricting the analysis to observations between 5 and $12 \mathrm{~g} / \mathrm{dl}$ haemoglobin, the risk increased with decreasing haemoglobin within each study.

As noted previously, there are no trials of iron supplementation with maternal mortality as outcome. Furthermore, because of cost and ethical considerations, we will likely have to continue to rely on observational data to refine these estimates. However, better observational data are badly needed. The currently available data are generally quite old, are predominantly from Asia (India and Malaysia) and are not controlled for many potentially confounding or modifying factors.

This analysis differs from most previous statements about anaemia and maternal mortality by positing a continuous relationship between haemoglobin concentration and mortality risk. INACG issued the following statement about severe anaemia and death in childbirth (1989):

> At $6.0 \mathrm{~g} / \mathrm{dl}$, evidence of circulatory decompensation becomes apparent.
> Women experience breathlessness and increased cardiac output at rest.
> At this stage, added stress from labor ... can result in maternal death.
> Without effective treatment, maternal death from anemic heart failure $\ldots$ is likely with a haemoglobin concentration of $4.0 \mathrm{~g} / \mathrm{dl}$. Even a blood loss of 100 ml can cause circulatory shock and death.

A more recent summary statement (Stoltzfus 2001), based on the systematic review of Brabin et al. (2001b) also concluded that "A significant body of causal evidence exists for . . . severe anaemia and maternal mortality" but that "causal evidence is lacking or contradictory for ... mild-moderate anaemia and maternal mortality" (Table 1). However, considering that death from cardiovascular causes is a function of blood volume, blood loss, cardiac fitness and haemoglobin concentration, it seems plausible that the relationship between haemoglobin concentration and maternal death would be continuous in nature, although not necessarily linear. Indeed the relationship as we have modelled it in this analysis is log-linear, with risk increasing exponentially with decreasing haemoglobin concentration.

We are not aware of another systematic analysis of the observational data linking pregnancy anaemia to perinatal mortality. The risk estimates from geographically diverse studies were remarkably consistent, and we believe provided the best evidence available for our purpose. Rasmussen (2001) identified four controlled iron supplementation trials that reported perinatal deaths as an outcome. All four studies had major
design concerns (low rates of follow-up or lack of anaemic individuals enrolled in the trial), and all were of insufficient sample size to draw clear conclusions. Rasmussen did not draw any firm conclusion from these data.

One relatively large trial was recently completed in rural Nepal, where the incidence of pregnancy anaemia and perinatal mortality are both high. This trial has only been reported in abstract form (Christian et al. 2002) and also was not sufficiently large to draw clear conclusions about perinatal mortality. However, it represents the strongest randomized trial evidence to date, because it was placebo-controlled and had high followup rates. In this trial, all women were provided anthelminthic treatment and vitamin A supplements. Women supplemented with 60 mg iron and $400 \mu \mathrm{~g}$ folic acid had $20 \%$ ( $95 \%$ CI $0.55-1.17$ ) lower incidence of perinatal mortality than the placebo group (P. Christian, personal communication). This point estimate is larger than the per cent reduction we estimated in this analysis (i.e. $16 \%, 95 \%$ CI $10-22 \%$ ). However, the trial also included several additional treatment arms, including one group that received folic acid without iron. The folic acid-supplemented group also had lower perinatal mortality rates than the placebo group, a reduction of $11 \%$ ( $95 \%$ CI $0.63-1.26$ ). Micronutrient supplementation began after the first trimester of pregnancy, and therefore these reductions cannot be attributed to the demonstrated effects of folic acid in preventing neural tube defects. Although neither of these reductions is statistically significant, they are important public health findings. If we accept these point estimates as the best available estimates from trial data, we conclude that our perinatal risk estimates are in accord with the benefits seen with effective iron-folic acid supplementation, but that a large part of the benefit may in fact be attributable to the folic acid.

The biological mechanisms linking iron deficiency anaemia (or anaemia from any cause) to perinatal mortality remain to be elucidated. One possible pathway is through preterm delivery. Recent reviews of clinical trial evidence have found the evidence inconclusive in support of a role for iron supplementation in preventing preterm birth or low birth weight (Mahomed 2000b; Rasmussen 2001). However, the evidence for or against is remarkably weak, and does not rule out a causal relationship (Stoltzfus 2001). Scott Poe and Mary Cogswell (personal communication) have recently completed a meta-analysis of the observational evidence relating pregnancy anaemia to low birth weight, intrauterine growth retardation and preterm birth. They found that pregnancy anaemia assessed in the first two trimesters of pregnancy was more strongly associated with preterm birth than intrauterine growth retardation or low birth weight, and that the risk of preterm birth increased with increasing severity of anaemia. Thus, while controlled trial evidence is lacking, the observational evidence suggests that preterm birth is one plausible mechanism for the anaemia-related risk of perinatal mortality.

If we accept preterm birth as a plausible causal pathway, the question remains as to how iron deficiency anaemia causes preterm birth. Allen suggested three possible mechanisms (Allen 2001). Iron deficiency anaemia might activate a hormonal stress response, might increase oxidative stress or might increase the risk of maternal infections. Further research is needed to elucidate these mechanisms or to suggest alternative ones.

While preterm birth may be considered the leading hypothesis to explain the link between maternal anaemia and perinatal mortality, it is not the only hypothesis that should be pursued. If these above proposed mechanisms exist, it is plausible that they cause adverse effects on the fetus that go beyond preterm birth, for example by impairing the neonatal immune system, endocrine function, temperature regulation, or other systems critical to a successful transition from intra to extrauterine life. Additionally, the adverse effects of maternal anaemia on the mother's function and well-being may also increase risks to her neonate through her decreased capacity to actively care for and breastfeed the infant (Henly et al. 1995). In the extreme case, maternal death associated with anaemia would increase the neonate's risk of death.

We included here an estimate of the continuous relationship between iron deficiency anaemia in early childhood and later intelligence, even though this relationship is included in the direct disability score attributed to iron deficiency anaemia. The possible biological mechanisms underlying this relationship are the subject of a large body of ongoing research in animals and children (e.g. see Beard 2001). To date, two published placebo-controlled randomized trials have measured the effect of longer-term (i.e. $>2$ months) iron supplementation on cognitive development of young children in samples that included anaemic children (Idjradinata and Pollitt 1993; Stoltzfus et al. 2001). Both trials found significant benefits in the iron-supplemented group. In Indonesia (Idjradinata and Pollitt 1993), the positive effect was measured on the Bayley Scales of Infant Development, while in Zanzibar (Stoltzfus et al. 2001), parental reports of motor and language milestones were used. These trials support a causal link between iron deficiency anaemia and child development that is at least partly preventable with early treatment.

The major difficulty has been quantifying this relationship in meaningful epidemiological and socioeconomic terms, especially in the sociocultural contexts in which iron deficiency anaemia is most prevalent. Our estimated OR is an attempt to put the relationship in epidemiological terms. This estimate relies on the assumption that a mean shift in IQ can be converted into increased risk of mild mental retardation, assuming that the entire IQ distribution was shifted equally. To our knowledge there has been only one published report of the relationship between early childhood anaemia and mild mental retardation as a dichotomous outcome (as opposed to intelligence or developmental scores as continuous outcomes). Hurtado et al. (1999) assessed the association between
haemoglobin concentration of children in the United States enrolled in the Special Supplemental Program for Women, Infants, and Children, a programme of the U.S. Government that provides food supplements to low-income pregnant women and their young children (Hurtado et al. 1999). After adjusting for several important covariates, the OR for mild or moderate mental retardation at school age remained significant in their model, which treated haemoglobin concentration as a continuous risk factor (as did ours). This finding supports the plausibility of our assumption that the association between mean cognitive scores and anaemia is associated with increased risks of mild mental retardation. However, it is only a single observational study, and we believe our estimate should be interpreted with extreme caution.

In summary, the available evidence suggests that iron deficiency anaemia contributes substantially to death and disability in the world. The great majority of this disease burden is in Africa and Asia and derives from anaemia in pregnancy and early childhood. This evidence is based on critical assumptions, most importantly, that the observed prospective relationships are causal in nature, and that the relationships analysed using anaemia as the risk factor pertain equally to iron deficiency anaemia as one particular form of anaemia.

The high global prevalence of anaemia and its potentially associated disease burden, as reflected in these estimates, constitute an urgent agenda for both research and action. First, we must clarify the assumptions above, the first and foremost of these being causality, and refine these estimates with stronger evidence. Because these estimates are uncertain in many respects, their most important use may be to motivate public health scientists to provide definitive causal evidence. Second, we must establish ways to effectively reduce iron deficiency anaemia to prevent these apparent consequences. We hope these new estimates of the burden of disease due to iron deficiency will motivate these actions.

## Acknowledgements

This work was supported by the Family Health and Child Survival (FHACS) Cooperative Agreement, between the United States Agency for International Development (USAID), Office of Health and Nutrition, and the Johns Hopkins Bloomberg School of Public Health, Department of International Health and by the World Health Organization Global Programme on Evidence for Health Policy. The authors are grateful to Steve Goodman for his advice on statistical issues, and to Ines Egli and Bruno de Benoist for data used in estimation of the global anaemia prevalence. We also thank Michele Dreyfuss, Parul Christian, Xu Xiong, Mary Cogswell and Scott Poe for sharing unpublished data or analyses for inclusion in this chapter. Finally, we thank Steve Fishman, Jeffrey McGuckin and Justine Kavle for their help in facilitating communication and compiling data for this project.

## Notes

1 We recognize that iron supplementation is not the only means of shifting the haemoglobin distribution, but randomized trials of iron supplementation provide the best estimate of the distribution if dietary iron deficiency were nearly eliminated.
2 See preface for an explanation of this term.

## Chapter 4

# Vitamin A Deficiency 

Amy L. Rice, Keith P. West Jr. and Robert E. Black

## Summary

Vitamin A deficiency is a common form of micronutrient malnutrition affecting $21.1 \%$ of preschool-age children and $5.6 \%$ of pregnant women worldwide.

The published literature linking vitamin A interventions to causespecific child mortality due to measles, diarrhoea, malaria and other infectious diseases and to all-cause maternal mortality was comprehensively reviewed. Randomized controlled trial data of vitamin A interventions and survival were used to estimate the risk of mortality associated with vitamin A deficiency. The published relative risks were adjusted for the estimated prevalence of deficiency at study baseline. Summary relative risks were calculated from meta-analyses (for measles, diarrhoea, and other infectious disease causes of child mortality) or from single studies (malaria mortality among children and all-cause maternal mortality).

The estimated relative risks associated with vitamin A deficiency in children were 1.86 ( $95 \%$ CI $1.32-2.59$ ) for measles mortality, 2.15 ( $95 \%$ CI 1.83-2.58) for diarrhoea mortality, 1.78 ( $95 \%$ CI 1.43-2.19) for malaria mortality, 1.13 ( $95 \%$ CI 1.01-1.32) for other infectious disease mortality and $4.51(95 \%$ CI $2.91-6.94)$ for all-cause maternal mortality.

The available evidence suggests that nearly 800000 deaths worldwide can be attributed to vitamin A deficiency among women and children. Approximately $20-24 \%$ of child mortality from measles, diarrhoea and malaria and $20 \%$ of all-cause maternal mortality can be attributed to this preventable condition. Africa and South-East Asia have the highest burden of disease.

## 1. Introduction

The objective of this chapter is to summarize the available evidence that can be used to quantitatively estimate the risk of adverse health outcomes associated with vitamin A deficiency and to calculate the associated burden of disease for different regions of the world. Vitamin A is an essential nutrient required for maintaining immune function, eye health, vision, growth and survival in human beings. Over the years, numerous studies have been conducted to identify the biological functions of vitamin A , the health consequences associated with deficiency, and the mechanisms that explain these relationships. Causal relationships have been clearly demonstrated in some instances and comprehensive reviews on the subject have been published (Sommer and West 1996).

According to World Bank estimates, vitamin A supplementation for preschool-age children is one of the most cost-effective child survival interventions (World Bank 1993). National level public health programmes to prevent and treat vitamin A deficiency are currently being implemented in countries in Asia, Africa and elsewhere. International donors and agencies including the Canadian International Development Agency (CIDA), United Nations Children's Fund (UNICEF), the United States Agency for International Development (USAID), the World Health Organization (WHO) and others have actively supported both national and global level initiatives to raise awareness about the problem of vitamin A deficiency and to promote efforts to implement effective and affordable solutions (Mason et al. 2001). Reducing the prevalence of vitamin A deficiency will lessen disease burden by improving immune function, lowering mortality rates and preventing blindness, especially among children. This chapter will contribute to ongoing efforts to assess the global problem of vitamin A deficiency by using existing data to estimate global prevalence rates, to identify and quantify the adverse health consequences associated with deficiency, and to estimate the future health benefits that could be gained by implementing even more effective control programmes.

## 2. Definition of malnutrition and vitamin A deficiency

Malnutrition is a complex phenomenon. Broadly defined, malnutrition refers to the condition of inappropriate nutrition. In the past, discussions of malnutrition in the context of health issues in low-income countries often used this term to refer to the condition of "undernutrition" associated with what was presumed to be protein-energy malnutrition and operationally defined as a deficit in anthropometric status or by the presence of clinical signs such as oedema or altered hair colour. In more recent years, various vitamin and mineral deficiencies, including vitamin A, iron, iodine and zinc have been recognized as discrete types of mal-
nutrition that adversely affect human health and contribute to disease and mortality. Some of these nutrients affect closely related biological systems; for example both vitamin A and zinc play important roles in maintaining different aspects of immune function (Shankar 2001) and both vitamin A and iron affect haemoglobin metabolism (Semba and Bloem 2002). Ecological-level studies have demonstrated that the prevalence of these micronutrient deficiencies are high in many of the same countries, thus many individuals may suffer from multiple micronutrient deficiencies at the same time. However, relatively few data are currently available for quantifying either the joint distribution of multiple deficiencies or the impact that multiple micronutrient deficiencies have on specific health outcomes. Therefore, the comparative risk assessment (CRA) project will estimate the separate contribution of these risk factors to the global burden of disease. Individual reviews are available for the risk factors of iron deficiency (chapter 3), zinc deficiency (chapter 5) and underweight status (chapter 2) in addition to vitamin A deficiency, which is the subject of the current chapter.

Vitamin A is an essential nutrient required for maintaining immune function, eye health, vision, growth and survival in human beings (National Research Council 1989). Although animal studies that identified vitamin A as a necessary factor for rat growth were conducted in the early 1900 s and the chemical structure of the vitamin was elucidated over 20 years later, reports describing the link between xerophthalmia (signs in the eye of disease due to a severe lack of the vitamin) and successful treatment with animal liver (a rich source of the vitamin) date back to the medical writings of ancient Egypt (Olson 1996).

At present, vitamin A deficiency remains a widespread public health problem, especially in countries of South Asia and Africa. Globally, preschool-age children and women of reproductive age are the two population groups most commonly recognized to be at risk of this nutritional deficiency and its adverse health consequences. A combination of chronically lower than required dietary intakes of vitamin A-rich foods (eggs, milk, liver, deep orange fruits and dark green leafy vegetables, etc.) combined with malabsorption and increased vitamin A excretion rates associated with some common illnesses places many women and children at risk of developing vitamin A deficiency (Christian et al. 1998b; IVACG 1997; Sommer and West 1996; Stephensen 2001).

No single indicator can be reliably used to assess the full spectrum of vitamin A deficiency. Different aspects of vitamin A status are assessed using clinical indicators, biochemical indicators, functional indicators and histological indicators (WHO 1996). In humans, vitamin A is stored almost exclusively ( $>90 \%$ ) in the liver and some investigators propose liver and/or total body stores as a primary indicator of vitamin A status. Although recent isotope dilution techniques to indirectly measure liver vitamin A stores have yielded promising results (Haskell et al. 1999;

Ribaya-Mercado et al. 1999) these techniques have not yet been used in large-scale population-based surveys.

Severe vitamin A deficiency can be identified by the presence of the classical eye signs of xerophthalmia in individuals. However, because severe vitamin A deficiency is relatively rare in most populations, a large number of individuals must be surveyed in order to generate a reliable prevalence estimate. Depending on the severity of vitamin A deficiency in a population, the sample size requirement for a xerophthalmia survey may be nearly ten times higher than what would be required to generate a reliable prevalence estimate for other indicators of vitamin A status, such as low serum retinol concentrations, which may occur more frequently in the same population (Sommer and Davidson 2002; WHO 1996).

Milder vitamin A deficiency is far more common, but the assessment of vitamin A deficiency that does not result in relatively easily observable eye signs is also more problematic. One way to identify milder forms of vitamin A deficiency is to collect blood samples and measure the concentration of circulating serum retinol in an individual. Values $<0.70 \mu \mathrm{~mol} / 1$ have traditionally been considered indicative of deficiency in children, based on empirical data from population-based studies that did not exclude individuals based on measurements of acute phase proteins. In adults, appropriate cut-off levels are less firmly established, but values $<0.70 \mu \mathrm{~mol} / 1$ and $<1.05 \mu \mathrm{~mol} / \mathrm{l}$ have been used for different purposes. Because serum retinol concentrations are transiently depressed during the acute phase response to certain infections, some investigators have questioned the validity of using this indicator to assess the vitamin A status of individuals (Stephensen 2001). However, determining the prevalence of serum retinol concentrations below a defined cut-off point remains one of the most commonly used and widely accepted approaches for assessing the vitamin A status of entire populations (Sommer and Davidson 2002).

At the population level, the prevalence of vitamin A deficiency can be determined based on the prevalence of either: (i) night blindness, usually obtained by verbal recall; (ii) other eye signs of xerophthalmia (Bitot's spots or corneal lesions); or (iii) biochemical indicator values (serum retinol, breast milk retinol, relative dose-response test, modified relative dose-response test, or serum 30-day response), or histological indicator values (conjunctival impression cytology [CIC] that fall below a defined cut-off point (WHO 1996). Until recently the majority of nationally representative, large-scale surveys related to vitamin A deficiency were conducted primarily among preschool-age children. However, in the past few years some large-scale surveys, including recent demographic and health surveys, have also attempted to estimate the prevalence of night blindness among pregnant women. More limited survey findings are available for serum and breast milk retinol concentrations among women. Surveys that included data on any or all of the indicators listed above were used
as a basis for estimating the global prevalence of vitamin A deficiency as a risk factor for the CRA project. The categorical definitions chosen to represent "vitamin A deficiency" among children (aged 0-4 years) and women (aged 15-44 years) for the CRA project are described in the following sections. A description of the data, indicators, and the process used to estimate the current prevalence of vitamin A deficiency among preschool-age children and pregnant women is presented in section 3.5.

### 2.1 Definitions for children (0-4 Years)

Globally, the most reliable population-based survey data provide estimates of vitamin A deficiency among children aged <5 years, primarily because this is the most well-established high-risk age group for this nutritional risk factor. In the CRA project prevalence estimates have been developed only for the $0-4$-year age group, although there is some evidence that slightly older children also suffer from vitamin A deficiency and its adverse health consequences.

In order to calculate the attributable fraction of an adverse health outcome that is due to a risk factor, compatible definitions must be used when estimating the relative risk of the adverse outcome associated with the risk factor and the prevalence of the risk factor itself in a population. This stringent requirement for a compatible definition greatly influenced the data that were suitable for use in the CRA project. The majority of large-scale vitamin A intervention trials involving preschoolage children have been mortality studies that assumed (but did not confirm for all participants) that the children were mildly deficient (i.e. had low serum retinol concentrations). In general, very few participants in those studies exhibited eye signs of xerophthalmia, which is consistent with the expected epidemiological pattern of vitamin A deficiency. Vitamin A receipt was associated with a lower relative risk of adverse outcomes in those trials, even among children who had no eye signs of deficiency.

After considering the availability of intervention trial data and global prevalence data for vitamin A deficiency among preschool-age children, a definition of vitamin A deficiency related to low serum retinol concentrations among children in the $0-4$-year age range emerged as the most appropriate choice for use in the CRA project:

- Vitamin A deficient: serum retinol concentration $<0.70 \mu \mathrm{~mol} / 1$.
- Vitamin A sufficient: serum retinol concentration $\geq 0.70 \mu \mathrm{~mol} / \mathrm{l}$.

### 2.2 Global prevalence estimates for children

The 1995 WHO report Global prevalence of vitamin A deficiency included prevalence estimates of vitamin A deficiency among preschoolage children for two classes of indicators: (i) clinical eye signs of disease (xerophthalmia); and (ii) low serum retinol concentrations. However, data were reported only for the individual countries that met the defini-
tion of a significant public health problem, which was defined as a population prevalence of low serum retinol ( $<0.70 \mu \mathrm{~mol} / \mathrm{l}$ ) $\geq 10 \%$, of night blindness (XN) $>1 \%$, of Bitot's spots (X1B) $>0.5 \%$, of corneal xerosis and/or ulceration (X2, X3A, X3B) $>0.01 \%$, or of xerophthalmiarelated corneal scars (XS) $>0.05 \%$ (WHO 1995). Estimates for countries that did not meet those definitions were not incorporated into the global prevalence estimate. A global estimate for the total number of children at risk of vitamin A deficiency ( $\sim 254$ million) was generated by adding the estimated number of children with low serum retinol concentrations ( $\sim 251$ million) and the estimated number with clinical eye signs of vitamin A deficiency ( $\sim 3$ million).

In 1998, the Micronutrient Initiative, UNICEF and Tulane University published a joint report reviewing the recent progress of vitamin A intervention programme activities (Micronutrient Initiative/UNICEF/Tulane University 1998). To generate prevalence estimates for vitamin A deficiency among children, this group used a different approach and developed a modelling process that attempted to take into account the effects of time trends and vitamin A intervention programmes. Data from a subset of countries that had conducted prevalence surveys since the mid-1980s were used to estimate the regional and global prevalence of vitamin A deficiency among children. The number of children affected by low serum retinol concentrations was estimated to range from 75 to 140 million, while the number of children with clinical eye signs of deficiency was estimated as 3 million. The sizeable discrepancy in the estimated prevalence of vitamin A deficiency from these two sources, 254 million and 78 to 143 million children, respectively, was due in part to differences in the data and methodology used, but also to a calculation error in the WHO report (West 2002).

An updated estimate for the global prevalence of vitamin A deficiency in children appears in the 2002 publication Extent of vitamin A deficiency among preschool children and women of reproductive age (West 2002), hereafter referred to as the 2002 West report. A brief description of the methodology used in developing the estimate is described in this chapter in section 3.5. Those prevalence data served as the basis for calculating the global burden of disease attributable to vitamin A deficiency among children aged 0-4 years for the CRA project.

### 2.3 Defintitions for pregnant women (15-44 Years)

In recent years, women of reproductive age have increasingly been recognized as an important group at risk of vitamin A deficiency and the adverse health outcomes associated with this condition (West 2002). However, when compared to preschool-age children, far less information is available to quantitatively estimate the burden of disease among women. Current areas of active research include assessing the magnitude of the problem, investigating the causes of deficiency in women, describing the range of associated adverse health outcomes, and identifying
appropriate interventions for preventing and treating vitamin A deficiency.

Standardized indicators and definitions of vitamin A deficiency among women are only beginning to be developed. To date, relatively few largescale surveys have been conducted to estimate the prevalence of vitamin A deficiency in women-primarily in Asia and Africa. Although many surveys used the presence of night blindness as an indicator of poor vitamin A status among women, some survey data related to low serum retinol and breast milk vitamin A concentrations are also available. However, very few studies have been conducted to date that quantitatively relate the risk of vitamin A deficiency (defined by any indicator) to adverse health outcomes in women. Despite the inherent limitations in the current data related to vitamin A deficiency in women, the evidence was considered strong enough to generate initial estimates of the related global burden of disease. Further work in this area of research will certainly lead to a refinement of these estimates.

The requirement to have a compatible definition of vitamin A deficiency for estimating the relative risk of adverse health outcomes and the global prevalence of vitamin A deficiency among women determined which data were suitable for use in the CRA project. After considering the availability of intervention trial data and global prevalence data for vitamin A deficiency in women, a definition related to low serum retinol concentrations among pregnant women in the 15-44-year age range emerged as the most appropriate choice for use in the CRA project.

Estimates for the prevalence of vitamin A deficiency have been generated only for pregnant women in the $15-44$-year age range primarily because the strongest information is available for this particular group of women. Future projects that quantify the global burden of disease may include non-pregnant and older women as well, if stronger data have become available for quantitatively estimating the prevalence of deficiency and adverse health outcomes in these groups. Vitamin A deficiency in pregnant women aged 15-44 years was operationally defined as:

- Vitamin A deficient: Serum retinol concentration $<0.70 \mu \mathrm{~mol} /$.
- Vitamin A sufficient: Serum retinol concentration $\geq 0.70 \mu \mathrm{~mol} / \mathrm{l}$.

### 2.4 Global PREvalence estimates For pregnant women

The first comprehensive estimate for the global prevalence of vitamin A deficiency among women of reproductive age appeared in the 2002 West report (West 2002). A brief description of the methodology used in developing the estimate has been described in this chapter in section 3.5. Those prevalence data will serve as the basis for calculating the global burden of disease attributable to vitamin A deficiency among pregnant women aged 15-44 years for the CRA project.

## 3. Adverse health outcomes considered FOR REVIEW

Within the framework of the larger Global Burden of Disease (GBD) project, health states (in this case vitamin A deficiency) can contribute directly or indirectly to death and disability. The total amount of death and disability attributed to vitamin A deficiency is therefore a sum of its direct and indirect effects. The direct contribution is measured by estimating the burden associated with the sequelae assigned to vitamin A deficiency as defined by the corresponding chapter in the International Statistical Classification of Diseases and Related Health Problems, tenth revision (ICD-10), whereas the indirect contribution is measured by considering vitamin A deficiency as a risk factor for other causes of death and disability.

Adverse health outcomes generally associated with micronutrient and mineral deficiencies were initially considered for review in relation to vitamin A deficiency. These included blindness; impaired cognitive function; impaired physical work capacity; morbidity (incidence and/or severity) due to diarrhoea, measles, acute respiratory infections, malaria and other infectious diseases; cause-specific mortality related to these diseases; and all-cause mortality. Outcomes potentially associated with vitamin A deficiency in pregnant women included fetal loss, low birth weight, preterm birth, all-cause infant mortality, maternal morbidity and maternal mortality.

### 3.1 Selection criteria for adverse health outcomes

The adverse health outcomes selected for review and inclusion in the CRA project were those that fulfilled the following criteria: (i) a health outcome included in the 2000 GBD study; (ii) a health outcome where data exist to support a probable causal relationship with vitamin A deficiency; and (iii) a health outcome where data were available to quantitatively estimate the relationship with vitamin A deficiency.

Blindness and an increased risk of all-cause mortality are two of the most well-established adverse outcomes associated with vitamin A deficiency in preschool-age children (Sommer 1982; Sommer and West 1996). According to recent estimates, vitamin A deficiency that leads to corneal scarring remains one of the most common preventable causes of childhood blindness in developing countries (Gilbert and Foster 2001). In the 1980s, vitamin A supplementation was shown to significantly reduce all-cause child mortality in a series of eight large-scale trials conducted in Asia and Africa. Meta-analyses of those trial data suggest a $23 \%$ to $34 \%$ reduction in all-cause mortality among children 6 months to 5 years of age (Beaton et al. 1993; Fawzi et al. 1993; Glasziou and Mackerras 1993; Tonascia 1993). Studies that provided vitamin A supplements to newborn infants immediately after birth have also demonstrated a reduction in mortality (Humphrey et al. 1996; Tielsch et al.
2001), although other trials involving vitamin A supplementation of young infants post-neonatally through five months of age have not shown a survival benefit (Anonymous 1998b; Daulaire et al. 1992; West et al. 1995).

Blindness was excluded as a health outcome from the risk factor analysis because in the GBD study, vitamin A-related blindness is considered to be a direct functional outcome of the deficiency, and the disability associated with blindness was measured in this manner (Murray et al. 1996a, 1996b). In the case of child mortality, the contribution of vitamin A deficiency to the global burden of disease was measured primarily through its contribution as a risk factor for several types of cause-specific mortality, rather than as a risk factor for all-cause mortality. However, a small number of child deaths have also been directly attributed to vitamin A deficiency in the GBD database, because vitamin A deficiency itself appears as the underlying cause of death in some vital registration data sets. For this specific cause of death, by definition, the total number of deaths in a subregion ${ }^{1}$ was directly assigned the value obtained from the relevant child mortality statistics for that subregion (Murray et al. 2001). Thus, for the CRA project the total number of child deaths attributable to vitamin A deficiency is the sum of those that are directly and indirectly attributed to the deficiency.

Five outcomes potentially associated with maternal vitamin A deficiency during pregnancy were also excluded from the risk factor analysis because the outcomes were not assessed in the 2000 GBD study or the data were insufficient to quantitatively assess the risk of their occurrence. These were fetal loss, low birth weight, preterm birth, all-cause infant mortality and general maternal morbidity (Christian et al. 1998b, 2000, 2001; Katz et al. 2000; Semba et al. 1998). Impaired cognitive function and impaired physical work capacity were excluded from the analysis because there is little evidence to suggest a biologically plausible association with vitamin A deficiency, except for the condition of maternal night blindness, which appears to limit the time for performing household chores to daylight hours (Christian et al. 1998a). Although experimental animal data and observational human data suggest a biologically plausible role for vitamin A deficiency predisposing children to acute respiratory infections (Bloem et al. 1990; Milton et al. 1987; Sommer and West 1996; Sommer et al. 1987), morbidity and causespecific mortality related to acute respiratory infections were excluded from the analysis because the data from controlled intervention trials in humans have not, to date, consistently revealed measurable effects of vitamin A on incidence, duration or severity of acute respiratory infections (Anonymous 1995).

After excluding those outcomes from the initial list of outcomes under consideration, the following remained for a more detailed review: (i) morbidity and mortality associated with measles in children; (ii) morbidity and mortality associated with diarrhoea in children; (iii) morbid-
ity and mortality related to malaria in children; (iv) selected other infectious disease causes of death in children (other than measles, diarrhoea, malaria or acute respiratory infections); and (v) all-cause maternal mortality. All-cause maternal mortality was a compilation of three separate conditions: maternal sepsis; maternal haemorrhage; and obstructed labour. These last three outcomes related to maternal mortality were selected from the limited number of maternal health conditions that are coded separately in the ICD-10 coding scheme.

The health outcomes selected for children aged $<5$ years represent the most common preventable causes of death among this age group (Murray et al. 2001). Although some studies have also explored the link between vitamin A and other specific infectious diseases coded as individual cause of death categories in the GBD study (for example helminthic infections and tuberculosis), the strength of the current evidence was considered insufficient to demonstrate a causal link and quantitatively estimate the associated risk with these specific outcomes. HIV/AIDS was also excluded as a quantifiable health outcome for the same reason. The findings relevant to the outcomes that were chosen for inclusion are presented below.

### 3.2 Methods for identifying relevant studies and REVIEW MATERIALS

The following sources were initially consulted to identify relevant materials for this chapter: Medline database; published books about vitamin A, international health, and nutrition; International Vitamin A Consultative Group (IVACG) statements; meeting reports; abstracts and conference proceedings; and other non-peer reviewed literature sources related to vitamin A programme implementation and cost-effectiveness analyses. The Medline database was searched for literature published between 1966 and 2001 in English or with an English language abstract. Combinations of the following keywords were used: vitamin A, vitamin A deficiency, blindness, mortality, acute respiratory infection, pneumonia, diarrhoea, measles, malaria, stillbirth, fetal loss, miscarriage, low birth weight, women.

Abstracts of articles concerning the relationship between vitamin A deficiency in humans, intervention trials, and the health outcomes of interest were reviewed and copies of relevant articles were obtained. Additional publications and reference materials were identified from the citation lists in those sources and through discussions with investigators working in the field.

### 3.3 Inclusion criteria for individual studies

The individual studies and reports presented in this chapter were restricted to the results of controlled intervention trials because these findings provide strong evidence for a causal relationship and the data
can be used to quantify the risk associated with either documented or suspected vitamin A deficiency (Rothman and Greenland 1998). For the outcomes where published meta-analyses or international consensus statements from IVACG exist, the results from those sources have been included in this chapter rather than a detailed presentation of data from the individual trials.

### 3.4 Description of excluded studies

Numerous observational cohort studies, case-control studies, and caseseries investigations have been conducted over the years to explore the relationships between vitamin A and morbidity or mortality from specific diseases in children. However, the results of those studies are not presented or discussed in detail in this chapter because such designs provide weaker evidence for a causal relationship as compared to randomized controlled intervention trials. Comprehensive reviews of the numerous cohort studies, case-control studies, and case-series reports related to various adverse health outcomes can be found elsewhere (Bauernfiend 1986; Sommer and West 1996). The findings from intervention studies related to vitamin A deficiency and child morbidity have also been summarized elsewhere (Nalubola and Nestel 1999).

### 3.5 Estimating risk factor levels

The prevalence of vitamin A deficiency (defined as serum retinol concentrations $<0.70 \mu \mathrm{~mol} / 1$ ) among children aged $0-4$ years and pregnant women aged 15-44 years was estimated for each of the 14 subregions. This process involved several steps.

First, country-specific prevalence rates were estimated for each one of the 191 WHO Member States. Updated country-specific prevalence rates were obtained from the recent review, 2002 West report (West 2002), which includes the estimated prevalence and number of deficient children and pregnant women in countries where vitamin A deficiency is either documented or presumed to exist, based on non-population-based vitamin A status data or other indirect indicators. Since separate prevalence estimates were not reported for boys and girls, the same prevalence rate was applied to both of these groups in the CRA project analyses. Next, the prevalence of vitamin A deficiency for the countries not included in that review was assumed to be zero. A suitable database was created for analysis and the findings were summarized across the 14 subregions.

A detailed description of the methods used to compile the data for the 2002 West report appears in that document (West 2002), but a brief summary is presented here. In addition, a file that contains a complete listing of the contributing studies and technical notes associated with the 191 countries can be found at http://www.jhsph.edu/chn/ GlobalVAD.html.

## Data sources

A wide variety of data sources related to vitamin A deficiency were reviewed in order to obtain the most current information possible. These included: (i) the 1995 comprehensive survey report compiled by the WHO Micronutrient Deficiency Information System (MDIS) (WHO 1995); (ii) a 2001 update from the MDIS group at WHO that included national survey data published after 1995; (iii) the 1998 report published by the Micronutrient Initiative, UNICEF and Tulane University (Micronutrient Initiative/UNICEF/Tulane University 1998), which incorporated both the 1995 MDIS data and more recent country updates from 107 countries with UNICEF offices and programmes; (iv) published surveys and field studies that reported vitamin A status indicators in women or children; and (v) unpublished reports, meeting presentations and personal communication about recent field surveys and studies not included in other data sources.

## Indicators

The 2002 West report presents prevalence data for xerophthalmia rates and serum retinol concentrations $<0.70 \mu \mathrm{~mol} / \mathrm{l}$ among children and for night blindness rates and serum retinol concentrations $<0.70 \mu \mathrm{~mol} / /$ and $<1.05 \mu \mathrm{~mol} / \mathrm{l}$ among populations of pregnant women. Since the CRA project only utilized serum retinol data, the methodology used to generate xerophthalmia estimates is not discussed further in this chapter.

In preschool-age children the prevalence of serum retinol concentrations $<0.70 \mu \mathrm{~mol} / 1$ was directly estimated from survey data whenever possible. When such data were unavailable, the prevalence was assigned a value equivalent to the population prevalence of abnormal CIC results. Survey data referring to children in a narrower age than 0-4 years or surveys that included data that extended slightly beyond the fifth year of life were used as the prevalence estimate for children aged $0-4$ years.

For pregnant women the prevalence of serum retinol concentrations $<0.70 \mu \mathrm{~mol} / 1$ was directly estimated from appropriate survey data whenever possible. When such data were lacking, the prevalence was assigned a value equivalent to the prevalence among non-pregnant or lactating women in the early postpartum period or a value equivalent to the prevalence of breast milk retinol concentrations $<1.05 \mu \mathrm{~mol} / \mathrm{l}$. When serological or breast milk data were reported as a mean and SD, rather than as a prevalence rate, the prevalence was derived by assuming the data were normally distributed and calculating the standard normal deviate ( $z$ score) and the probability associated with the area under the left tail of the normal curve.

## Data extrapolation

Separate algorithms were developed for the different subregions of the world to estimate the country-specific prevalence estimates for serum retinol concentrations $<0.70 \mu \mathrm{~mol} / 1$ among children and pregnant
women (West 2002). In brief, nationally representative survey data, as deduced from individual reports or stated as such from aggregate WHO or other agency reports, were reported whenever possible. In the absence of national level data, results from sub-national or smaller surveys were used and adjustment factors were applied following the precedent of previous analysts (Micronutrient Initiative/UNICEF/Tulane University 1998; WHO 1995), although the subjective weight may have changed from the previous reports owing to new or reinterpreted results for a country. For countries where no data were available, estimates were generated by extrapolation in situations where cultural, dietary, demographic, health and development patterns as well as existing rates of adult and child mortality suggested that vitamin A deficiency is likely to exist. Prevalence rates were extrapolated either by assigning a value from a nearby country with comparable characteristics (primarily in the WHO Region of South-East Asia) or by assigning a median value from neighbouring country national surveys. Prevalence estimates among preschool-age children were also adjusted downwards in countries where the survey data preceded coverage reports from recent vitamin A supplementation programmes that reported coverage rates $>75 \%$. The prevalence data for women were not adjusted to account for any potential programmatic impact, because although postpartum maternal vitamin A supplementation programmes are slowly emerging, programmes to prevent vitamin A deficiency during pregnancy are virtually non-existent in the developing world at the present time.

The 2002 West report did not generate prevalence estimates for countries where there was no plausible evidence to suggest the presence of vitamin A deficiency. Therefore, those subregional prevalence estimates do not reflect the contribution of other countries in the world that were assumed to have a $0 \%$ prevalence rate of serum retinol concentrations $<0.70 \mu \mathrm{~mol} / /$. Over half of the countries assigned a $0 \%$ prevalence rate are located in the subregions classified as EUR-A, EUR-B, EUR-C or AMR-A, where child mortality rates are low (Murray et al. 2001).

The distribution of the 191 countries included in the CRA project is shown in Table 4.1 by the type of survey data used for estimating serum retinol prevalence rates $<0.70 \mu \mathrm{~mol} / \mathrm{l}$ in children. To calculate subregional prevalence rates of serum retinol concentrations $<0.70 \mu \mathrm{~mol} / \mathrm{l}$, the number of affected individuals was totalled for the countries in each subregion and then divided by the subregional population base. For children $<5$ years of age, the population base was obtained from the 2001 State of the world's children report (UNICEF 2001), which reported data for the year 1999. For pregnant women the annual number of live births was chosen to represent the population global base for pregnant women, and data were obtained from the same source (UNICEF 2001). The countries that were assigned $0 \%$ prevalence accounted for only approximately $17 \%$ of the base population of children (Table 4.2) and pregnant women (Table 4.3).
Table 4.I

| Country-specific data used to estimate subregional prevalence rates were based on the review article "Global prevalence of vitamin A defic of reproductive age" (West 2002). Technical notes and data for individual countries are located at www.jhsph.edu/chn/GlobalVAD.html. In the with serum retinol concentrations $<0.70 \mu \mathrm{~mol} / /$ in a country was either estimated based on existing survey data or imputed for countries wher based on cultural, dietary, demographic, health and development patterns as well as existing rates of child mortality. In order to calculate subr the CRA project, the prevalence estimate was set to $0 \%$ for the remaining 90 countries where no data on preschool child vitamin A deficien childhood vitamin A deficiency was considered unlikely to exist. These are all classified as "A" or "B" according to the WHO Comparative Rist <br> Region of the Americas $(n=18)$ Antigua and Barbuda, Argentina, Bahamas, Barbados, Canada, Chile, Cuba, Grenada, Guyana, Jamaica, P Saint Vincent and the Grenadines, Suriname, Trinidad and Tobago, United States of America and Uruguay; Eastern Mediterranean Region Lebanon, Libyan Arab Jamahiriya, Qatar, Saudi Arabia, Syria, Tunisia and United Arab Emirates; European Region ( $n=50$ ) All countries we Republic of Macedonia; Western Pacific Region $(n=1 I)$ Australia, Brunei Darussalam, Fiji, Japan, Mongolia, Nauru, New Zealand, Niue, |  |  |  |  |  |  |  |  |  |  |

### 3.6 Children (0-4 Years)

The subregional and global prevalence rates of serum retinol concentrations $<0.70 \mu \mathrm{~mol} / \mathrm{l}$ among children aged $0-4$ years are shown in Table 4.2. The prevalence estimates from the smaller number of countries that contributed to the 2002 West report are compared to the global estimates generated for the CRA project. The results indicate that globally, approximately $21 \%$ of all children have serum retinol concentrations $<0.70 \mu \mathrm{~mol} / \mathrm{l}$. The highest prevalence rates and the largest number of affected children live in the South-East Asian and African Regions. The estimated number of affected children is similar to what was reported by the Micronutrient Initiative, UNICEF and Tulane University group (Micronutrient Initiative/UNICEF/Tulane University 1998).

### 3.7 Pregnant women (15-44 Years)

The subregional and global prevalence rates of serum retinol concentrations $<0.70 \mu \mathrm{~mol} / \mathrm{l}$ among pregnant women aged $15-44$ years are shown in Table 4.3. The prevalence estimates from the smaller number of countries that contributed to the 2002 West report are compared to the global estimates generated for the CRA project. The results indicate that globally, approximately $5.6 \%$ of all pregnant women have serum retinol concentrations $<0.70 \mu \mathrm{~mol} / \mathrm{l}$. Although the prevalence rates among pregnant women are approximately one-fourth those observed in children aged $<5$ years, a similar risk distribution emerged-with the highest prevalence rates and number of affected women being located in the South-East Asian and African Regions. Although the global prevalence is low, vitamin A deficiency may be an important contributing factor to adverse health outcomes for pregnant women in selected areas of the world.

### 3.8 Other groups

There is very little, if any, information available about the global prevalence of vitamin A deficiency and the associated risk in other population groups. Therefore, the prevalence of serum retinol concentrations $<0.70 \mu \mathrm{~mol} / \mathrm{l}$ among children aged $\geq 5$ years, among non-pregnant women aged 15-44 years, among men aged 15-44 years, and among adults aged $\geq 45$ years was not estimated.

## 4. Assessing CaUsAlity And QuANTIFYING RISK FACTOR-DISEASE RELATIONSHIPS

There is often a discrepancy between the problems that motivate a study and the data available for addressing the issue. This applies to the present work, especially when identifying data to be used in estimating the relative risk of adverse health outcomes associated with vitamin A deficiency. Ideally, the results of multiple studies would be available for each outcome of interest from different countries located in different regions
Table 4.3

 reproductive age" (West 2002). Technical notes and data for individual countries are located at www.jhsph.edu/chn/GlobalVAD.html. In the review article the number of pregnant women aged $15-45$ years with serum retinol concentrations $<0.70 \mu \mathrm{~mol} / \mathrm{I}$ in a country was either estimated based on existing survey data or imputed for countries where maternal opment patterns as w ( Comparative Risk Assessment Index (WHO 2001): Region of the Americas ( $n=18$ ) Antigua and Barbuda, Argentina, Bahamas, Barbados, Canada, Chile, Cuba, Grenada, Guyana, amaica, Paraguay, Saint Kitts and Nevis, Saint Lucia, Saint Vincent and the Grenadines, Suriname, Trinidad and Tobago, United States and Uruguay; Eastern Mediterranean Region $(n=13)$ Bahrain, Cyprus, Iran, Jordan, Kuwait, Lebanon, Libyan Arab Jamahiriya, Oman, Qatar, Saudi Arabia, Syria, Tunisia and United Arab Emirates; European Region ( $n=5$ I) All countries were excluded; Western Pacific Region ( $n=11$ ) Australia, Brunei Darussalam, Fiji, Japan, Mongolia, Nauru, New Zealand, Niue, Republic of Korea, Samoa and Singapore. NA
of the world. This would allow the subregional estimates to be based on empirical data for each location. However, this type of data is simply not available. In the absence of such information the best data possible should be compiled and any important limitations recognized. There are several important limitations of the data and methodology used to estimate risk estimates for this project that deserve comment.

First, no definitive criteria exist for determining with certainty whether or not a particular risk factor is causally related to an adverse health outcome. However, many investigators have adopted the general principles that were originally proposed by Hill for use as guidelines when evaluating potential causal relationships (Hill 1965). A review of vitamin A studies conducted using different designs reveals that many of these general principles hold true when the entire body of evidence is considered together. However, experimental evidence-in this case the demonstration that a vitamin A-related intervention prevents an adverse health outcome-provides some of the strongest evidence for a causal relationship. Therefore, the present review has been restricted to the results of randomized placebo-controlled vitamin A intervention trials conducted in areas with either documented or suspected vitamin A deficiency. The inference commonly made from such a study is that if the vitamin A intervention prevents the occurrence of an adverse health outcome, then vitamin A deficiency is causally associated with it.

The design used for the prospective trials of vitamin A and child mortality was to assign the participants to either a vitamin A or control group, to implement the intervention, and to then follow the participants over time. Aside from observing the presence of clinical eye signs of deficiency, the vitamin A status (serum retinol concentration) of each and every participant was not assessed. The baseline vitamin A status of the populations under study was either inferred from prior survey data gathered in the same subregion or from a subset of the study participants.

Second, the risk estimates reported in the original publications of vitamin A and child mortality represent the protective effect of the vitamin A interventions against adverse health outcomes, rather than the relative risk of an adverse outcome associated with vitamin A deficiency per se. The risk of an adverse outcome was estimated from the original trial results as the inverse of the protective relative risk (= 1/protective relative risk). The following assumptions were made when using the intervention trial data in this manner: (i) that all children participating in the trials were vitamin A deficient at the beginning of the intervention period; and (ii) that the deficiency was corrected in all children assigned to the intervention group, while those in the placebo group remained deficient. Neither of these assumptions is likely to have been met in all of the trials. Thus the unadjusted risk estimates from the trials may underestimate the true relationship between vitamin A deficiency and an adverse health outcome.

Finally, the data from the original intervention trials were analysed on an intention-to-treat basis, rather than on the basis of achieved compliance. In reality both compliance and the biological efficacy of the particular intervention under study would influence the measured relationship between the vitamin A intervention and an adverse health outcome. Secondary analyses from one of the child mortality studies that took actual compliance into account estimated a far greater reduction in all-cause mortality than was observed in the original intention-to-treat analysis (Sommer and Zeger 1991).

On the other hand, the summary risk estimates from the metaanalyses of the individual intervention trials conducted in a variety of countries provide a certain level of built-in control for unmeasured factors that may have differed across sites. The United Nations Administrative Committee on Coordination/Subcommittee on Nutrition (ACC/SCN) meta-analysis of the child mortality trials examined the effect of age and sex on observed mortality and concluded there were no significant differences of vitamin A supplementation on all-cause mortality between males and females or by age category for children between 6 months and 5 years of age (Beaton et al. 1993). In addition, there was no detectable relationship between the effects of the vitamin A intervention and anthropometric status on child mortality.

For the purpose of the CRA project, relative risk estimates for child and maternal health outcomes used vitamin A intervention trial data as the starting point. However, the relative risk estimates were adjusted to take into account the fact that many, but not all, of the study participants had low serum retinol concentrations at the beginning of the intervention trials. The following section describes how the adjustment process was conducted. The same process was applied to data for both the child and maternal health outcomes.

The adjusted relative risks were calculated using a four-step process.

1. A quantitative estimate of the protective effect that a vitamin $A$ intervention had in preventing an adverse health outcome was found in the published literature.
2. The prevalence of serum retinol concentrations $<0.70 \mu \mathrm{~mol} / 1$ was estimated among the study population at baseline.
3. An adjusted relative risk was calculated by constructing a hypothetical population of 100000 individuals and dividing them into two strata using a serum retinol concentration cut-off of $<0.70 \mu \mathrm{~mol} / \mathrm{l}$ and the prevalence estimate obtained in the second step. The relative risk of an adverse outcome was then calculated for both strata separately by setting the background incidence rate of the adverse outcome to be equivalent among the following groups: (i) the vitamin A intervention group in the entire study population; (ii) the vitamin A intervention and control groups in the strata with serum retinol con-
centrations $\geq 0.70 \mu \mathrm{~mol} / 1$; and (iii) the vitamin A intervention group in the stratum with serum retinol concentrations $<0.70 \mu \mathrm{~mol} / \mathrm{l}$. The relative risk for children in the stratum with serum retinol concentrations $\geq 0.70 \mu \mathrm{~mol} / \mathrm{l}$ represents the effect of the vitamin A intervention among children who were not deficient before the trial began. In this stratum the relative risk is 1.0 because those children were not expected to benefit (in terms of reducing all-cause mortality) from the intervention. The relative risk for children in the other stratum is lower than the overall trial estimate (representing a greater protective effect) because those children were deficient when the trial began and all of the observed benefit (in terms of reducing all-cause mortality) associated with the vitamin A intervention was presumably observed among this subgroup of children.
4. The final step in the adjustment process was to calculate the relative risk of all-cause mortality associated with vitamin A deficiency by calculating the inverse of the adjusted protective effect (=1/protective relative risk). See Table 4.4 for an example calculation based on a $23 \%$ reduction in child deaths (protective relative risk of 0.77 ) associated with a vitamin A intervention and a $41 \%$ baseline prevalence rate of serum retinol concentrations $<0.70 \mu \mathrm{~mol} / \mathrm{l}$ in the study population. In this example, the originally reported protective effect associated with the vitamin A intervention is a relative risk of 0.77 ; the adjusted protective relative risk associated with the vitamin A intervention is 0.58 (equivalent to a $42 \%$ reduction in child deaths); and the adjusted relative risk of child death associated with vitamin A deficiency is 1.72 .

This adjustment process requires estimates for the baseline serum retinol concentrations $<0.70 \mu \mathrm{~mol} / \mathrm{l}$ for the populations contributing relative risk data to each adverse heath outcome. The baseline prevalence estimates are shown in Table 4.5. For some, but not all, adverse health outcomes, baseline prevalence data were directly available from the published reports that contributed relative risk estimates to the adjustment process. In other cases, the prevalence rates were extrapolated accordingly. The process used to derive prevalence rates for each included adverse health outcome is described below.

In order to derive estimates for the measles, diarrhoea, malaria and other infectious disease causes of death and disability in children attributable to vitamin A deficiency, it was necessary to estimate a single underlying prevalence of deficiency that existed in the southern Asian and African populations in which eight large community-based, vitamin A child-mortality intervention trials were conducted. Knowing a single, underlying prevalence of deficiency across these diverse trial populations reveals the background burden of vitamin A deficiency that is understood to account for the overall estimated reduction of $23 \%$ in
Table 4.4
Example of how to calculate the adjusted relative risk of child death associated with vitamin A deficiency assuming a published relative risk of 0.77 for child survival associated with the receipt of vitamin $A$ in a controlled intervention trial and a $41 \%$ baseline prevalence rate of 'vitamin A deficiency' among the children (defined as serum retinol concentrations $<0.70 \mu \mathrm{~mol} / \mathrm{l}$ )

| Study population | Died | Survived | Total | Incidence of death | Protective relative risk | \% reduction in deaths due to vitamin A intervention |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Entire study population |  |  |  |  |  |  |
| Vitamin A group | 385 | 49615 | 50000 | 0.0077 | 0.77 | 23 |
| Control group | 500 | 49500 | 50000 | 0.0100 |  |  |
| Total | 885 | 99115 | 100000 |  |  |  |
| Children with serum retinol concentrations $\geq 0.70 \mu \mathrm{~mol} / \mathrm{l}$ |  |  |  |  |  |  |
| Vitamin A group | 227 | 29273 | 29500 | 0.0077 | 1.00 | 0 |
| Control group | 227 | 29273 | 29500 | 0.0077 |  |  |
| Total | 454 | 58456 | 59000 |  |  |  |
| Children with serum retinol concentrations $<0.70 \mu \mathrm{~mol} / \mathrm{l}$ |  |  |  |  |  |  |
| Vitamin A group | 158 | 20342 | 20500 | 0.0077 | $0.58{ }^{\text {a }}$ | 42 |
| Control group | 273 | 20272 | 20500 | 0.0133 |  |  |
| Total | 431 | 40569 | 41000 |  |  |  |

a In the example above the relative risk of child death associated with vitamin A deficiency was calculated by using an overall observed relative risk of child survival associated with receipt of vitamin $A(0.77)$ and estimating the relative risk of child survival among the $59 \%$ of children who had serum retinol concentrations $\geq 0.70 \mu \mathrm{~mol} / \mathrm{I}$ ( I .00 ) and the $41 \%$ of children with concentrations below that cut-off ( 0.58 ). The relative risk of child death associated with vitamin $A$ deficiency was then calculated as 1.72 , which equals the inverse of the protective effect among "vitamin A deficient" children who received vitamin A: 1.72 [I.00/0.58].

preschool-age child mortality achieved with vitamin A interventions (Beaton et al. 1993).

An overall background prevalence of serum retinol concentrations $<0.70 \mu \mathrm{~mol} / \mathrm{l}$ was derived by estimating the size and prevalence of vitamin A deficiency for each national or regional population judged to be represented by each intervention trial (Table 4.6). The prevalence rate for each country as available, was applied to the estimated number of preschool-age children in order to estimate the number of vitamin A deficient preschool-age children in each population represented by a trial. These steps resulted in a subjective re-weighting of the sizes of the populations at-risk in each area that were independent of sample sizes for each trial. Finally, numbers of deficient children in each population represented by a trial were summed and divided by the sum of the population estimates of children aged $<5$ years, resulting in a prevalence that is, roughly, weighted by the sizes of populations at risk that were represented by the trials. This exercise produced prevalence rates of serum retinol $<0.70 \mu \mathrm{~mol} / \mathrm{l}$ that ranged from $28 \%$ in the Sudan, to $72 \%$ as measured during a vitamin A child mortality trial in Ghana (Ghana VAST Study Team 1993). An estimated 19 million children, or $41 \%$, among the estimated 46.5 million children living in areas at risk of vitamin A deficiency, representing the underlying, local populations of interest, were considered to be vitamin A deficient. In the absence of additional data, this underlying prevalence was further judged to represent the underlying pool of deficient children for whom death from severe episodes of diarrhoea, measles and other non-malarial infectious disease illnesses could be averted each year with vitamin A.

a Based on Table I of the State of the world's children's report (UNICEF 200I), unless otherwise noted.
b Given that the vitamin A trial in Ghana (Ghana VAST Study Team 1993) was carried out in the central part of the country, which is considered to be at higher risk than the southern, palm-oil consuming areas of the country, only one-third of the Ghanaian child population $<5$ years of age ( 3189000 , UNICEF 2001) was considered to be represented by children in the trial.
c D Ross et al., personal communication, 1995, reported in Sommer and West (1996).
${ }^{\text {d }}$ Based on government of India census data for 2001 indicating $11.5 \%$ of the country's rural population was $<5$ years, applied to statewide census estimates for both Tamil Nadu and Andra Pradesh; statewide populations were assumed to represent the at-risk population for each trial.
e In the absence of serum retinol data from the trial or from representative population surveys of Andra Pradesh, a prevalence of $31 \%$ (West 2002) was applied to the state population.
f Rahmathullah et al. (I990).
$g$ Indonesia is represented by its entire population given that the two mortality trials carried out in Aceh (Sommer et al. 1986) and West Java (Muhilal et al. 1988) were conducted in the north and central parts of the country, respectively.
h Prevalence based on the West Java trial (Muhilal et al. 1988) was assumed to represent Aceh and the rest of Indonesia in the early-mid-1980s, amidst evidence of higher subsequent prevalence rates (Kjolhede et al. 1995; West 2002).
i Because two population-based trials (Daulaire et al. 1992; West et al. 1991) were conducted in diverse and different parts of the country, the entire population of Nepalese preschool children (UNICEF 2001) was considered to be the underlying population at risk.
j In the absence of biochemical data from either child mortality trial in Sarlahi (West et al. 1991) or Jumla (Daulaire et al. 1992), a prevalence of $35 \%$ obtained from the 1998 National Micronutrient Survey (Anonymous 1998a) was taken to represent the prevalence during both trials and for the country.
k In the absence of risk differentials across different population groups of the Sudan, the entire population was assumed to be represented by children in the trial (Herrera et al. 1992).
I Median prevalence (28\%) of distribution of 33 national prevalence estimates obtained for African and Eastern Mediterranean Regions was assumed to represent the status of Sudanese preschool children.
m Calculated by dividing 19055 by 46567.

A prevalence of $55 \%$ was assigned for populations of preschool-age children whose risk of death and disability due to Plasmodium falciparum malaria could be averted by vitamin A supplementation. This prevalence estimate was based on the data reported in Table 1 from a
single, community-based randomized trial in Papua New Guinea that measured effects of vitamin A supplementation on P. falciparum malaria clinic attack rates (Shankar et al. 1999). The assigned prevalence rate was calculated based on the published mean and standard deviation serum retinol concentration for the population at baseline and applying an assumption of normally distributed data.

A prevalence of $19 \%$ was assigned to represent populations of pregnant women living in areas of the world where risk of mortality may be reduced by approximately $40 \%$ with improved, regular, supplemental intakes of vitamin A, based on the data reported in Table 2 from a single, large randomized community recently conducted in rural Nepal (West et al. 1999). The same overall adjustment process was used to calculate adjusted relative risks of adverse health outcomes for each of the included child and maternal health outcomes. For the child health outcomes, the same adjusted relative risk was reported for children aged $0-4$ years (boys and girls) for all regions of the world.

## 5. RISK FACTOR-DISEASE OUTCOME RELATIONSHIPS

The following section describes the individual studies that were used to evaluate and quantify the relative risk of an adverse health outcome associated with vitamin A deficiency. The intervention trials and results are reported separately for children aged $0-4$ years and pregnant women aged 15-44 years. Insufficient data were available to quantitatively evaluate the risks of vitamin A deficiency in other population groups. Table 4.7 describes the individual studies that were used to estimate the relative risk of adverse health outcomes for the CRA project with respect to vitamin A. The studies are listed in the same order that the outcomes are discussed in the chapter. Mortality associated with measles and diarrhoeal disease in children appears first, followed by malaria incidence and malaria mortality in children, mortality associated with other infectious causes of death in children, and finally all-cause maternal mortality among pregnant women.

Unless otherwise noted, the risk estimates cited for individual studies are the findings that were originally reported in the literature and represent the protective effect of the vitamin A intervention against adverse health outcomes. An adjusted relative risk was calculated from these data to represent the risk of adverse health outcomes associated with vitamin A deficiency following the procedure described in section 4.

### 5.1 RISK estimates for preschool children (0-4 years)

Preschool-age children have traditionally been considered to be a highrisk group for vitamin A deficiency and its consequences. Most of the large-scale controlled intervention trials that have been conducted were designed to explore the relationships between vitamin A supplementation, morbidity and mortality among children aged $<6$ years.
Table 4.7

Table 4.7 Studies used to estimate the relative risk of adverse health outcomes for the CRA project, by outcome ${ }^{\text {a }}$ (continued)

In the early 1990s the ACC/SCN commissioned a review of the existing scientific evidence to assess the effectiveness of vitamin A supplementation on child mortality and morbidity (Beaton et al. 1993). The findings from ten different community-based mortality trials conducted in Africa (Ghana and the Sudan), the Americas (Haiti) and Asia (India, Indonesia and Nepal), and 20 different morbidity trials conducted around the world were considered for inclusion in a formal metaanalysis. Sufficient data were available from five of the mortality trials (Daulaire et al. 1992; Fawzi et al. 1993; Ghana VAST Study Team 1993; Rahmathullah et al. 1990; West et al. 1991) to assess the relationship between vitamin A interventions and cause-specific mortality from measles, diarrhoea and respiratory illness. Separate relative risks were reported in the meta-analysis of these studies for all-cause mortality, mortality attributed to these three specific causes and mortality attributed to all other causes combined.

All five of those mortality trials were conducted in populations where vitamin A deficiency (both clinical and subclinical) was prevalent (assessed either as high rates of xerophthalmia or low serum retinol concentrations). In four of the trials (one in Ghana, two in Nepal and one in the Sudan), the intervention consisted of vitamin A supplementation in age appropriate doses ( 200000 IU for children $\geq 12$ months of age, 100000 IU for children 6 to 11 months of age and, for one trial in Nepal, 100000 IU for infants 1 to 11 months of age and 50000 IU for infants $<1$ month of age) every 4-6 months. In India, the intervention was a weekly supplement that contained a weekly RDA of vitamin A. In the Ghana, India and Nepal trials, a statistically significant reduction in all-cause mortality was observed among children in the vitamin A intervention group. No statistically significant effect on all-cause mortality was observed in the Sudan.

## MEASLES

Measles (and thus measles-related mortality) have nearly been eliminated in the Americas due to the implementation of successful measles control programmes over the past ten years (Hersh et al. 2000). At present, the highest rates of measles mortality occur among children aged $<1$ year in developing countries. Although unvaccinated children aged $>10$ years and adults are also susceptible to measles and measles mortality, estimates for the burden of disease associated with vitamin A deficiency were restricted to children aged 0-4 years for the CRA analysis.

## Incidence and morbidity

Measles is a highly infectious disease caused by the measles virus (Reingold and Phares 2001). Although vitamin A is involved in different aspects of the immune defence system, there is little evidence to suggest that vitamin A status affects the incidence of measles. Therefore,
the relative risk of experiencing a measles episode associated with vitamin A deficiency was not calculated for the CRA analysis.

## Mortality

Vitamin A deficiency appears to increase the risk of measles-related mortality. The ACC/SCN meta-analysis of the four prospective communitybased trials with information on measles (Ghana, India and two in Nepal) suggests that vitamin A supplementation was associated with a $26 \%$ overall reduction in measles mortality ( $\mathrm{RR}=74,95 \% \mathrm{CI}$ 0.53-1.04) (Beaton et al. 1993). In the individual trials, the reduction in measles mortality ranged from $18 \%$ in Ghana to $75 \%$ in Sarlahi, Nepal (Sommer and West 1996). A more recent study from Ghana found no difference in the acute measles case-fatality rate between vitamin A supplemented and placebo groups (Dollimore et al. 1997). Vitamin A supplementation, however, has been found to reduce measles severity. In some (Coutsoudis et al. 1991; Ellison 1932; Hussey and Klein 1990) but not all (Rosales et al. 1996) hospital-based treatment trials, the surviving children who had received vitamin A experienced complications less frequently and recovered faster than their counterparts who received placebo treatment. These findings provide supporting evidence for a causal relationship between vitamin A deficiency and measles mortality.

The relative risk of measles (GBD code U015) mortality among children aged 0-4 years with vitamin A deficiency was estimated for the CRA project from the protective effect of vitamin A interventions (RR $=0.74,95 \%$ CI $0.53-1.04$ ) observed in the ACC/SCN meta-analysis of community-based trials and a $41 \%$ estimated baseline prevalence rate of serum retinol concentrations $<0.70 \mu \mathrm{~mol} / 1$ among those study populations. The adjusted relative risk estimate derived from those data is $R R=1.86$ ( $95 \%$ CI 1.32-2.59). The calculations are shown in Table 4.8.

## Diarrhoea

Diarrhoea and diarrhoea-related mortality are prevalent among preschool-age children, particularly in low income countries. The global burden of disease related to diarrhoea mortality is widely distributed around the world.

## Incidence and morbidity

Diarrhoeal disease can be caused by a variety of bacterial, viral and parasitic agents (Reingold and Phares 2001). Although vitamin A is involved in different aspects of the immune defence system, including the maintenance of the epithelial cell border in the intestinal tract, there is little evidence from intervention trials to suggest that vitamin A status affects the incidence of diarrhoea. Therefore, the relative risk of experiencing a diarrhoea episode associated with vitamin A deficiency was not calculated. However, there is considerable evidence to link vitamin A status to the severity of diarrhoea episodes (Sommer and West 1996). Children

a The outcomes were defined using the following GBD codes: measles (UO15); diarrhoea (UOIO); malaria (U020); other infectious causes (U037); all-cause maternal mortality corresponds to the GBD code for maternal conditions (U042).
b Unadjusted for baseline prevalence of serum retinol concentrations $<0.70 \mu \mathrm{~mol} / \mathrm{l}$.
c Adjusted for baseline prevalence of serum retinol concentrations $<0.70 \mu \mathrm{~mol} / \mathrm{l}$ in trial populations.
with poor vitamin A status tend to suffer from more severe and more prolonged episodes of diarrhoea. These findings provide supporting evidence for a causal relationship between vitamin A deficiency and diarrhoea mortality.

## Mortality

Vitamin A deficiency does appear to increase the risk of diarrhoea mortality. The ACC/SCN meta-analysis of the five community-based trials with information on diarrhoea (Ghana, India, Nepal [two trials] and the Sudan) suggest that vitamin A supplementation was associated with a $32 \%$ reduction in diarrhoea mortality ( $\mathrm{RR}=0.68,95 \%$ CI $0.57-0.80$ ) (Beaton et al. 1993). In the individual trials that showed a reduction (all but the Sudan), the reduction in diarrhoea mortality ranged from $34 \%$ in Ghana to $52 \%$ in India (Sommer and West 1996).

The relative risk of diarrhoea (GBD code U010) mortality among children aged $0-4$ years with vitamin A deficiency was estimated from the protective effect of vitamin A interventions ( $\mathrm{RR}=0.68,95 \% \mathrm{CI}$ $0.57-0.80$ ) observed in the ACC/SCN meta-analysis of community-based trials and a $41 \%$ estimated baseline prevalence rate of serum retinol concentrations $<0.70 \mu \mathrm{~mol} / 1 \mathrm{l}$ among those study populations. The adjusted relative risk estimate derived from those data is $\mathrm{RR}=2.15$ ( $95 \%$ CI 1.83-2.56). The calculations are shown in Table 4.8.

## Malaria

Although malaria is endemic in several areas of the world, countries in Africa have particularly high prevalence rates and children aged $<5$ years experience much of the associated burden of disease.

## Incidence and morbidity

Malaria is caused by several species of the protozoa Plasmodium, which are transmitted by mosquitoes from one person to another (Reingold and Phares 2001). In humans, P. falciparum is the species responsible for the majority of malaria-related morbidity and mortality. Both animal and human studies have implicated specific immune mechanisms for how vitamin A could influence the incidence and severity of malarial disease (Davis et al. 1998; Krishnan et al. 1976; Serghides and Kain 2002; Stoltzfus et al. 1989). In addition, cross-sectional studies have also documented inverse associations between plasma retinol levels and P. falciparum parasitaemia in humans (Filteau et al. 1993; Friis et al. 1997; Galan et al. 1990; Samba et al. 1992; Tabone et al. 1992; Thurnham and Singkamani 1991), and one study has reported that low baseline vitamin A status was associated with an increased risk of parasitaemia (Sturchler et al. 1987).

Findings from more recent randomized controlled intervention trials suggest that vitamin A supplementation appears to reduce both the incidence and severity of malaria illness. In Ghana, cohorts of children
received high-dose vitamin A or a placebo every four months as part of either the Child Health (morbidity) or Child Survival (mortality) Study. Blood samples were collected on a monthly basis from different random subsamples of children in a series of cross-sectional surveys conducted over a one-year period. Based on the cross-sectional data, the authors reported no statistically significant differences in the incidence of fever, malaria parasitaemia, parasite density, or probable malaria illness between the two groups and concluded that vitamin A supplementation had no impact on malaria (Binka et al. 1995). However, given the relatively small sample sizes, these studies had limited statistical power and could only detect a statistically significant protective effect of vitamin A supplementation against probable malarial illness that exceeded $70 \%$ (Child Survival Study) or 95\% (Child Health Study) (Shankar 1995).

A more definitive study of vitamin A supplementation and malaria was recently conducted in Papua New Guinea. In that study children aged 6-60 months received either high-dose vitamin A or a placebo every three months and were followed over a 13 -month period. Malaria morbidity was assessed weekly using community-based case detection and surveillance of the patients who reported to the local health centre. Blood smears were prepared for children who had a fever $>37.5^{\circ} \mathrm{C}$ at the time of the weekly home visit or for any clinic visit and for all children who participated in the three cross-sectional surveys conducted at baseline, at the midpoint, and at the end of the study. Slide-confirmed cases of malaria were followed prospectively and observed for adverse health outcomes. Children in the vitamin A group had a 30\% lower frequency of $P$. falciparum febrile illnesses $(R R=0.70,95 \%$ CI $0.57-0.87$ ) and younger children (12-36 months) apparently benefited most from supplementation. The younger children in the vitamin A group also had less severe malaria morbidity, measured as fewer febrile episodes, fewer enlarged spleens and a lower parasite density (Shankar et al. 1999).

The study from Papua New Guinea used a stronger design, evaluated a greater number of disease variables, and had more statistical power to investigate a relationship between vitamin A and malaria morbidity as compared to the Ghana study. Therefore, the findings from Papua New Guinea were used to assess the relative risk of malaria incidence associated with vitamin A deficiency for the CRA project.

## Mortality

To date, no randomized trials have demonstrated a significant reduction in malaria mortality associated with the vitamin A supplementation. However, given the recently observed relationship between vitamin A supplementation and malaria severity, an equivalent relative risk was assigned for malaria mortality for the purpose of the CRA project.

The relative risk of malaria incidence (GBD code U020) among children aged $0-4$ years with vitamin A deficiency was estimated for the CRA project from the protective effect of the vitamin A intervention
( $\mathrm{RR}=0.70,95 \%$ CI $0.57-0.87$ ) observed in the Papua New Guinea trial and a $55 \%$ estimated baseline prevalence rate of serum retinol concentrations $<0.70 \mu \mathrm{~mol} / \mathrm{l}$ in that study population. The adjusted relative risk estimate derived from those data is $\mathrm{RR}=1.78$ ( $95 \%$ CI 1.43-2.19). The calculations are shown in Table 4.8.

The relative risk of malaria mortality (GBD code U020) among children aged $0-4$ years with vitamin A deficiency was estimated by extrapolation for the CRA project from the results of the vitamin A intervention on malaria incidence observed in the community-based trial in Papua New Guinea (RR $=0.70,95 \%$ CI $0.57-0.87$ ) and a $55 \%$ estimated baseline prevalence rate of serum retinol concentrations $<0.70 \mu \mathrm{~mol} / / 1$ in that study population. The adjusted relative risk estimate derived from those data is $R R=1.78$ ( $95 \%$ CI 1.43-2.19). The calculations are shown in Table 4.8.

## Other infectious diseases in children

Infectious diseases are a common cause of death among preschool-age children worldwide. The global burden of disease related to the GBD category of "other infectious diseases" among children is widely distributed around the world.

Although acute respiratory infections, diarrhoeal diseases, measles and malaria represent the most common causes of childhood illness and death, many other bacterial, viral and parasitic agents cause disease among children as well. Since vitamin A is involved in a wide variety of different biological processes, vitamin A deficiency may also increase the risk of death due to other less common causes of childhood disease, although studies to date have not specifically quantified those relationships. The GBD study included a group of "other infectious diseases" (GBD code U037) in children that captured the contribution of many low-incidence causes of death under one category. Causes of infectious diseases not explicitly listed in the other GBD categories for children are included under this code (Murray et al. 2001).

## Mortality

Data from intervention trials among children suggest that vitamin A deficiency increases the risk of mortality from causes other than diarrhoea, measles and malaria. The ACC/SCN meta-analysis of the five community-based trials (Ghana, India, Nepal [two trials] and the Sudan) with information on cause-specific mortality found that vitamin A supplementation was associated with a $5 \%$ reduction in mortality from unspecified causes of death ( $\mathrm{RR}=0.95,95 \% \mathrm{CI} 0.81-1.06$ ) (Beaton et al. 1993). This risk estimate was used for the purposes of estimation. The relative risk of mortality due to other infectious diseases (GBD code U037) among children aged 0-4 years with vitamin A deficiency was estimated for the CRA project from the protective effect of vitamin A interventions $(\mathrm{RR}=0.95,95 \% \mathrm{CI} 0.81-1.06)$ observed in the ACC/SCN
meta-analysis of community-based trials and a $41 \%$ estimated baseline prevalence rate of serum retinol concentrations $<0.70 \mu \mathrm{~mol} / \mathrm{l}$ among those study populations. The adjusted relative risk estimate derived from those data is $\mathrm{RR}=1.13$ ( $95 \%$ CI 1.01-1.32). The calculations are shown in Table 4.8.

### 5.2 RISK ESTIMATES FOR PREGNANT WOMEN (15-44 YEARS)

Over half a million women around the world die each year from causes associated with pregnancy and childbirth. Most of these maternal deaths occur in the Regions of Africa and South-East Asia.

Although data from either observational or experimental studies relating vitamin A deficiency among women of reproductive age to specific causes of mortality are limited, biologically plausible mechanisms for such relationships do exist (Faisel and Pittrof 2000). A relative risk of maternal mortality was estimated for vitamin A deficiency among pregnant women aged 15-44 years, based on the best data currently available. The risk estimate for these outcomes may be modified in the future when more data that specifically address this issue are available.

To date, the only large-scale randomized controlled trial of vitamin A supplementation among women of reproductive age has been conducted in an area of southern Nepal where high rates of maternal night blindness have been reported (West et al. 1999). More than 44000 women of reproductive age were randomized to continually receive either vitamin $\mathrm{A}(7000 \mu \mathrm{~g}$ retinol equivalents), an equivalent amount of betacarotene, or a placebo capsule on a weekly basis over an approximate three and a half year period; that is, before and during pregnancy, throughout the postpartum period and through any subsequent pregnancy until close-out of the trial. Over 22000 identified pregnancies were followed. Pregnancy-related mortality (defined as a death during pregnancy or prior to 12 weeks postpartum) was decreased by $40 \%$ $(R R=0.60,95 \%$ CI $0.37-0.97)$ in the vitamin A group and by $49 \%$ ( $\mathrm{RR}=0.51,95 \%$ CI 0.30-0.86) in the beta-carotene group (West et al. 1999). These findings provide support for a causal relationship between vitamin A deficiency and pregnancy-related mortality.

Data from the study in Nepal were used to estimate the relative risk of maternal mortality associated with vitamin A deficiency. The study presents several sets of mortality results for women stratified by time and cause of death during pregnancy and the postpartum period. The mortality results used for CRA analysis were those that excluded all deaths $>6$ weeks postpartum and all deaths attributed to reported injury which are the results that most closely conform to the ICD-10 definition of a maternal death (WHO 1992). The combined results for women in the vitamin A and beta-carotene intervention groups were used to represent non-vitamin A deficient women.

The relative risk of maternal mortality among pregnant women with vitamin A deficiency-due to a wide variety of maternal conditions (GBD
code U042)—was estimated for the CRA project from the combined protective effect of the vitamin A and beta-carotene interventions on the maternal mortality ratio ( $\mathrm{RR}=0.60,95 \%$ CI $0.39-0.93$ ) and a $19 \%$ estimated baseline prevalence rate of serum retinol concentrations $<0.70 \mu \mathrm{~mol} / \mathrm{l}$ observed among women in the Nepal trial (West et al. 1999). In the absence of other studies linking vitamin A deficiency to cause-specific deaths among women, the risk of maternal death (from a wide variety of maternal conditions) was extrapolated from the Nepal study. A maternal mortality ratio of 378 deaths per 100000 live births among women in the vitamin A and beta-carotene groups combined (West et al. 1999) was used as the starting point for the adjusted relative risk calculations. The adjusted relative risk estimate derived from those data is $\mathrm{RR}=4.51$ ( $95 \%$ CI 2.91-6.94). The calculations are shown in Table 4.8.

### 5.3 Risk estimates for all other groups

Limited information is available about the global prevalence of vitamin A deficiency or its associated adverse health effects in children aged $\geq 5$ years, in men aged 15-44 years, or in men or women aged $\geq 45$ years. Therefore, quantitative estimates for the prevalence of vitamin A deficiency and the associated risk of adverse health outcomes were not developed for these groups.

## 6. BURDEN OF DISEASE ASSOCIATED WITH VITAMIN A Deficiency

Summary estimates for three burden of disease measurements are shown in this chapter. The attributable fraction of cause-specific mortality associated with vitamin A deficiency among children aged $0-4$ years and pregnant women aged 15-44 years are shown by subregion in Table 4.9. The estimated number of cause-specific deaths and disability-adjusted life years (DALYs) attributed to vitamin A deficiency is shown in Table 4.9 and Table 4.10, respectively.

The attributable fraction results show that worldwide, vitamin A deficiency among children is associated with an estimated $20 \%$ of measlesrelated mortality, $24 \%$ of diarrhoea mortality, $20 \%$ of malaria incidence and mortality, and $3 \%$ of mortality associated with other infectious causes of disease. By definition, the attributable fraction of disease associated with vitamin A deficiency itself is $100 \%$. The attributable fractions vary widely by cause and across the different subregions. In general, the attributable fractions (for disease conditions other than vitamin A deficiency) are highest in the African and South-East Asian Regions, where vitamin A deficiency is most prevalent and child mortality rates for the causes of disease assessed in this chapter are high. Worldwide, vitamin A deficiency (serum retinol concentrations $<0.70 \mu \mathrm{~mol} / \mathrm{l}$ ) among pregnant women is associated with over $20 \%$ of maternal mortality.

a The outcomes were defined using the following GBD codes: measles ( U 015 ); diarrhoea ( U 010 ); malaria ( U 020 ); other infectious causes (U037); all-cause maternal mortality corresponds to the GBD code for maternal conditions (U042). vitamin A deficiency, by subregion other infectious diseases among children, for conditions leading to maternal mortality, and for direct sequelae of vitan A din A value for the attributable fraction is not includ
A value for the attributable fraction is not included either because the prevalence of vitamin A deficiency in the subregion was zero or the cause-specific mortality was zero or nearly
zero in the associated subregion-age-sex groups. zero in the associated subregion-age-sex groups.
The global attributable fractions are $22 \%$ (for women aged $15-29$ years) and $21 \%$ (for women aged $30-44$ years). They are slightly different because the total number of deaths among women in these age groups differ.
Table 4.I0 Deaths (000s) from measles, malaria, diarrhoea, other infectious diseases among children, from maternal conditions
attributable to vitamin A deficiency, and those directly attributed to vitamin A deficiency in vital registration systems,
The outcomes were defined using the following GBD codes: measles (UOI5); diarrhoea (UOIO); malaria (U020); other infectious causes (U037); all-cause maternal mortality corresponds to the GBD code for maternal conditions (U042).
b Among both sexes and all age groups.
Data for the measles, diarrhoea, malaria, other infectious causes, all-cause maternal mortality directly attributed to vitamin A deficiency, and the totals columns were obtained directly from annex results tables. Subregional subtotals for children aged $0-4$ years were calculated by adding across disease categories and then totalling those results. Regional subtotals for maternal causes of death were calculated by adding across the 15-29 and 30-44 year-old age categories and then totalling those results. Any discrepancies in the marginal totals in this table are attributed to differences in rounding carried over from the individual columns of the background data tables.

Again, the highest attributable fractions are found in the African and South-East Asian Regions, where vitamin A deficiency and maternal mortality rates are highest.

Worldwide the majority of deaths (see Table 4.10) and DALYs (see Table 4.11) associated with vitamin A deficiency occur in Africa and South-East Asia. However, the relative distribution of deaths and DALYs varies somewhat across subregions for the different causes of disease burden. A higher proportion of the burden of disease from measles, malaria and all-cause maternal mortality occurs in Africa, while SouthEast Asia has a higher proportion of the disease burden from diarrhoea.

The total number of maternal and child deaths and disease-related morbidity that could potentially be averted if vitamin A deficiency were eliminated depends on several factors: (i) the attributable fraction (determined by the prevalence of vitamin A deficiency and the relative risk of an adverse health outcome); (ii) the global distribution of the adverse health outcomes; and (iii) the estimated number of affected individuals in each subregion. Subregions with a higher attributable fraction but a smaller number of individuals affected by the adverse health outcomes (due to either a small population base or a low prevalence of the condition) may contribute less in absolute terms to the overall global burden of disease when compared to subregions or specific causes of death with lower attributable fractions but a larger total number of affected individuals. Conversely, subregions with similar attributable fractions but different causes of death and/or population bases will contribute different numbers of affected individuals to a global summary.

For example, the AFR-D and SEAR-D subregions have similar attributable fractions of disease for measles ( $\sim 20 \%$ ), but the number of deaths attributed to vitamin A deficiency is nearly twice as high in AFRD (41000) when compared to SEAR-D (23000) although the population base of children in the AFR-D subregion is only a third (13.5 million) of the population base of children ( 42.3 million) in the SEARD subregion. For diarrhoea, AFR-D and SEAR-D also have similar attributable fractions of disease ( $\sim 25 \%$ ), but in this case the number of deaths attributed to vitamin A deficiency is more than twice as high in SEAR-D (107000) when compared to AFR-D (46000). The relative contribution of these different factors (attributable fractions, global distribution of disease and population base) should be kept in mind when comparing the burden of disease attributed to vitamin A deficiency across subregions and specific causes of death.

## 7. Discussion

This chapter generated quantitative estimates of the global burden of disease due to vitamin A deficiency by applying the analytical framework of the CRA project to the best sources of currently available data. The results show, despite decades of achievement in paediatric detection and

control, that vitamin A deficiency remains a major public health problem among preschool-age children throughout the world. Globally, $21 \%$, or over 127 million children aged $<5$ years are vitamin A deficient. Twenty per cent to $24 \%$ of early childhood deaths due to measles, diarrhoea and malaria are attributable to vitamin A deficiency, plus an additional 3\% of deaths due to other infectious causes, accounting for 647000 deaths of preschool-age children each year. Vitamin A deficiency appears to especially put children at risk of mortality due to diarrhoea, which accounts for $50 \%$ of all childhood deaths attributable to vitamin A deficiency.

New to the global view of undernutrition is a previously unrecognized, substantial burden of maternal vitamin A deficiency. Not surprisingly the burden of disease among pregnant women appears to parallel the geographic distribution seen in young children, with Asia and Africa bearing a disproportionate burden. This first attempt to define the problem suggests, conservatively, that $5.6 \%$ of all pregnant women, or approximately 7.3 million, are vitamin A deficient in a given year. Vitamin Adeficient women are at a 4.5 -fold higher risk of pregnancy-related mortality than non-deficient women. The estimates generated for this project suggest that more than $20 \%$ of all maternal deaths in the world may be attributable to vitamin A deficiency. The method used to generate this particular estimate (applying the relative risk of death associated with vitamin A deficiency to all causes of maternal death) may somewhat overestimate the burden of disease related to vitamin A deficiency. It also does not address the prevalence, burden, or potential health consequences of vitamin A deficiency among non-pregnant women of reproductive age, which remain largely unknown.

In addition to estimating the number of preventable deaths, the results from this project suggest that approximately 27 million DALYs are associated with vitamin A deficiency. Given that DALYs provide a composite measure of disease burden associated with both fatal and non-fatal health conditions and that childhood mortality related to infectious diseases is the primary health outcome known to be associated with vitamin A deficiency, it is not surprising that the vast majority of the estimated DALYs ( $\sim 23$ million) are related to infectious disease causes of death in children.

In summary, vitamin A deficiency affects vulnerable populations throughout critical stages of life, as revealed by these estimates of disease burden in young children and pregnant women. Successful efforts to control and reduce vitamin A deficiency have the potential to improve the health and well-being of women and children around the world and to reduce the global burden of disease associated with this nutritional risk factor.

## 8. Expected changes in the prevalence of vitamin A deficiency

Based on the trends observed over the past 20 years, and more specifically on changes over the past $5-10$ years, there is reason for optimism and the expectation that the global prevalence of vitamin A deficiency (defined as serum retinol concentrations $<0.70 \mu \mathrm{~mol} / \mathrm{l}$ ) will decrease in the years leading up to 2030.

Numerous factors contribute to the current situation. In recent years a favourable global policy environment has been created and global partnerships have emerged to help guide activities aimed at the control and prevention of vitamin A deficiency. Various groups have contributed to the positive policy environment including IVACG, international organizations, bilateral agencies and individual country governments around the world.

Although these groups initially focused their attention almost exclusively on the more obvious problem of vitamin A deficiency among children, the situation is now changing. Policy-makers and programme managers are increasingly expanding their efforts in recognition of the fact that vitamin A deficiency is also prevalent among women of reproductive age and has potentially severe health consequences for them as well.

Many countries have already initiated national supplementation programmes for children (most commonly using community-based health services as a routine delivery channel or special vitamin A distribution initiatives combined with national immunization days or child health days or weeks) in an effort to prevent severe vitamin A deficiency among this age group. Although child-based supplementation programmes do not necessarily directly address the problem of vitamin A deficiency among women, other more general approaches may, if the accompanying health messages are modified to specifically encourage women as participants and programme beneficiaries. These include widespread food fortification initiatives, efforts to improve the availability of vitamin A rich foods through agricultural programmes, nutrition education programmes, etc.

Projections for the global prevalence of vitamin A deficiency for the 30 -year time period from 2000 to 2030 were developed for the CRA project based on the assumption that the policy and programming environment will remain positive and that prevention and control activities will not only keep pace, but will exceed future population growth.

The global prevalence of $21.1 \%$ for serum retinol concentrations $<0.70 \mu \mathrm{~mol} / 1$ (in preschool-age children) in the year 2000 was used as the baseline prevalence rate. Reductions of $10 \%, 20 \%$ and $30 \%$ were projected over the next three decades, resulting in estimated global prevalence rates of $19.0 \%, 16.9 \%$ and $14.8 \%$, in the years 2010,2020 and 2030, respectively. Although specific programmes to address vitamin A
deficiency in women have started much more recently, the same percentage reductions $(10 \%, 20 \%$ and $30 \%)$ in prevalence rates were assumed for the purposes of the CRA project. Starting with an assumed baseline rate of $5.6 \%$ in 2000 , prevalence rates of $5.0 \%, 4.5 \%$ and $3.9 \%$ were projected for 2010, 2020 and 2030, respectively.

## Chapter 5

## Zinc Deficiency

Laura E. Caulfield and Robert E. Black

## Summary

Research conducted during the past 10-15 years suggests that zinc deficiency is widespread and affects the health and well-being of populations worldwide. The objective of this chapter is to quantify the regional and global magnitude, distribution and disease burden implications of zinc deficiency.

We conducted a systematic literature search to identify relevant studies investigating the role of zinc in human health. This search indicated that evidence on the burden of disease related to zinc deficiency would be limited to the results of randomized controlled trials (RCTs) conducted among paediatric populations in developing countries, and would provide information on whether zinc deficiency affects the incidence of diarrhoea, pneumonia and malaria illness among children aged 0-4 years. There are no global estimates of zinc deficiency in paediatric or other populations; however, the International Zinc Nutrition Consultative Group (IZiNCG) has developed a method for estimating the prevalence of inadequate zinc intakes based on the presence and bioavailability of zinc in each country's food supply.

A systematic review of relevant epidemiological research involved meta-analysis from 11 intervention trials. Results of our review indicate that zinc deficiency in children aged $<5$ years increases the risk of incidence for diarrhoeal disease by 1.28 ( $95 \%$ CI 1.10-1.50), pneumonia by 1.52 ( $95 \%$ CI $1.20-1.89$ ) and malaria by 1.56 ( $95 \%$ CI 1.29-1.89). We extended those results as best estimates of the risk of mortality from these causes as a result of zinc deficiency. Following the IZiNCG technique, the global prevalence of zinc deficiency was estimated at $31 \%$, ranging from $4-73 \%$ across subregions. ${ }^{1}$ Based on these estimates, zinc deficiency was estimated to cause 176000 diarrhoea deaths, 406000 pneumonia deaths and 207000 malaria deaths. The associated loss of disability-adjusted life years (DALYs) attributable to zinc deficiency amounts to more than 28 million. The burden of disease due to zinc
deficiency is borne most heavily by countries in Africa, the Eastern Mediterranean and South-East Asia. The burden was approximately equally shared between males and females.

The results of this review suggest that zinc deficiency contributes substantially to the morbidity and mortality of young children throughout the world. Available evidence from RCTs on the strength of the association between zinc deficiency and morbidity from diarrhoea, pneumonia and malaria, combined with the high estimated prevalences of inadequate zinc diets, translates into a significant burden of disease attributable to deficiency of this micronutrient. Evidence relating zinc deficiency to health outcomes in children aged $>5$ years and adult men and women was not available. Given the likely high prevalence of inadequate zinc intakes in these other groups, research is needed to determine the magnitude of the potential health effects.

## 1. Introduction

Zinc is a trace mineral essential to all forms of life because of its fundamental role in gene expression, cell development and replication (Hambridge 2000). Severe or clinical zinc deficiency was defined last century, as a condition characterized by short stature, hypogonadism, impaired immune function, skin disorders, cognitive dysfunction and anorexia (Prasad 1991). Although severe zinc deficiency is considered rare, mild-to-moderate zinc deficiency is likely prevalent throughout the world today (Sandstead 1991). Lack of consensus on indicators of zinc deficiency has hampered efforts to document prevalences of zinc deficiency. Despite this, RCTs of zinc supplementation in areas with habitual low zinc intakes have begun to demonstrate how low dietary intakes of zinc adversely affect child health (Brown et al. 1998a; Zinc Investigators' Collaborative Group 1999, 2000). For this reason, it is important to attempt to quantify the prevalence of zinc deficiency and its contribution to the global burden of disease. The goal of this chapter is to describe the methods used to quantify the magnitude, distribution and disease burden implications of zinc deficiency.

## 2. Nature and definition of the risk factor

Millions of people throughout the world may have inadequate levels of zinc in the diet due to limited access to zinc-rich foods (animal products, oysters and shellfish) and the abundance of zinc inhibitors, such as phytates, common in plant-based diets (Sandstead 1991). Our understanding of the public health importance of inadequate zinc intakes has been hampered by a lack of indicators of zinc status for identifying individuals with zinc deficiency (Wood 2000).

Estimating the prevalence of zinc deficiency is difficult because plasma or serum zinc concentrations, the most widely used indicators of zinc
deficiency at the population level, have not been assessed in national or regional surveys in developing countries. Even in developed countries, such indicators are not used for methodological and cost reasons.

Zinc deficiency is largely related to inadequate intake or absorption of zinc from the diet, although excess losses of zinc during diarrhoea may also contribute (Gibson 1994; WHO 1996). The distinction between intake and absorption is important, because although some intakes of zinc may be acceptable, the levels of inhibitors (e.g. fibre and phytates) in the diet may mean that inadequate amounts of zinc are absorbed. For this reason, zinc requirements for dietary intake are adjusted upward for populations in which animal products, the best sources of zinc, are limited, and in which plant sources of zinc are similarly high in phytates. Because zinc is not well conserved in the body and because zinc deficiency is directly related to dietary zinc intake, an indirect approach to quantify the prevalence of zinc deficiency would be to examine the adequacy of zinc in the diet in various regions throughout the world.

Dietary surveys are conducted in many countries, but few such surveys exist in developing countries (Gibson 1994; Parr 1992; WHO 1996). Even when dietary intake data are available, incomplete information on the content of zinc and its bioavailability in local foods has made calculation of zinc bioavailability problematic.

### 2.1 Prevalence of Zinc deficiency

Several alternative approaches have been taken to estimate the adequacy of the diet in various regions of the world. For example, the World Health Organization (WHO) (1996) used a factorial approach to estimate the average basal and normative zinc requirements (i.e. minimum amount of zinc to cover losses in individuals adapted or not adapted to low usual dietary intakes of zinc) for population subgroups, and then considered issues of zinc bioavailability from the typical diet in various regions of the world to derive estimates of the minimal dietary intake of zinc that would meet these requirements. They then compared the estimated dietary intakes of zinc from 210 dietary surveys conducted throughout the world as a percentage of the minimal dietary intake of zinc, and identified surveys in which the mean intake of zinc did not meet the minimal basal or normative level of intake. Overall, this method led to the conclusion that populations with inadequate intakes of zinc were likely widespread throughout the world, but concentrated in areas of the world consuming plant-based diets in which zinc was only of low to moderate bioavailability. For example, of 148 surveys conducted in populations with presumed highly bioavailable zinc (mostly western Europe and the United States of America), only one dietary survey indicated a mean intake lower than the minimal zinc intake to meet average normative requirements for zinc. In contrast, among 47 surveys conducted in populations with moderate zinc bioavailability, 40 indicated average
intakes lower than the minimal normative zinc intake, and of 15 surveys conducted in populations with low zinc bioavailability, none reported mean intakes greater than the minimal normative zinc intake. Based on this approach, it was concluded that zinc nutrition in developing countries should be a priority area for research, and emphasized the need for studies of dietary intakes and dietary constituents. Although carefully constructed, this analysis could not provide us with the required data on estimated regional prevalences of zinc deficiency.

In 2001, Brown et al. published an approach that used available data on per capita food availability from 172 countries to estimate the prevalence of inadequate zinc intakes worldwide. Subsequently IZiNCG (forthcoming) revised this approach, improving on the method for assessing the bioavailability of zinc in the food supply. We used this second approach because of the improved methodology and more conservative estimates of deficiency, and were provided with estimated prevalences of inadequate intakes of zinc in the diet in each of the 14 subregions ( K . Brown, personal communication). The technique is described briefly below.

Data are available on the per capita food availability in each country based on country-level information on food production, imports and exports, as reported on food balance sheets (FBS) by the Food and Agriculture Organization of the United Nations (FAO) on an annual basis. Per capita availability of energy was estimated from this information, and population estimates for each country in 1998 (FAO 1999). Per capita zinc availability was estimated based on the zinc:energy ratio, which was derived using FAO values for energy for each food and values of the World Food Program (World Food Dietary Assessment System 1997) for the estimated zinc content of each food. To examine the bioavailability of zinc in the diet, IZiNCG gathered published information from studies of zinc absorption from test meals, and conducted a pooled analysis to derive a prediction equation for the percentage absorbable zinc based on information on the zinc, phytate, calcium and total protein content of the diet. This equation and information on the levels of zinc, phytate, calcium and total protein available per capita per meal (assuming three meals per day) calculated from the FBS database were then applied to estimate the percentage absorbable zinc for each of the 172 countries with available FBS data. The proportion of absorbable zinc ranged from $11 \%$ to $22 \%$. Countries were then categorized as having low ( $<14 \%$ ), moderate ( $15-16 \%$ ) or high ( $>17 \%$ ) mean percentage absorbable zinc in the food supply, based on their main staple food (wheat, rice, maize and other cereals, and tubers) and the contribution of animal protein to the energy available in the food supply.

The average daily zinc requirement for each country was estimated by calculating the mean of the recommended zinc intakes for low, average and high bioavailability diets for the various sexes and ages (WHO 1996), weighted by the sex and age distribution of the country's popu-
lation, as obtained from the WISTAT database (WISTAT 1994). To calculate the estimated percentage of the population with inadequate zinc intake, they assumed that the mean intake of food was equal to mean availability of food, and that the standard deviation of intake is $25 \%$ of the mean-i.e. coefficient of variation (CV) $=0.25$ (WHO 1996). Under assumptions of normality, they calculated the proportion of individuals with intakes below the country-level daily zinc requirement, and thus at risk of zinc deficiency due to inadequate zinc intake (IZiNCG forthcoming). Again, this method is conservative when compared to the previously published method using bioavailability estimates, which considered only the phytate:zinc molar ratio in the food supply (Brown et al. 2001).

The method does not account for zinc intake from breast milk or from drinking water. However, breast milk is only an adequate source of zinc in the diets of infants aged less than six months, and zinc intakes from drinking water typically increase total zinc intakes by only $2 \%$ provided a usual water intake of $2 \mathrm{l} /$ day.

A secondary consideration for our calculations was the selection of the appropriate counterfactual (i.e. theoretical minimum exposure) for zinc deficiency. Unlike some other exposures, zero prevalence of zinc deficiency is in theory possible, and would likely result in complete eradication of the zinc disease burden due to this risk factor. Thus, for purposes of the analysis, we designated the theoretical minimum exposure to be as "no inadequate intakes of zinc" or zero prevalence of inadequate intakes of zinc.

Using the method described above, the estimated global prevalence of zinc deficiency is $31 \%$, and ranges from $4 \%$ to $73 \%$ (Table 5.1). The prevalences of zinc deficiency are low ( $4-7 \%$ ) in AMR-A, EUR-A, EURC and WPR-A. Intermediate prevalences of $9-26 \%$ are found in AMRB, EUR-B and WPR-B. High prevalences are found in AMR-D (68\%), throughout South and Central Africa (37-62\%), North Africa and the Eastern Mediterranean region (25-52\%), and South and South-East Asia (34-73\%).

## 3. HeAlth outcomes Considered

To proceed with a systematic investigation of the evidence regarding the role of zinc in human health, we disaggregated and then linked both specific health outcomes and target populations. The considered health outcomes included risk and/or severity of diarrhoea, pneumonia, malaria, measles, cognitive dysfunction, physical impairment, visual impairment or blindness and mortality. The target populations consisted of the following age-sex groups: children aged 0-4 years; children 5-14 years; women $15-44$ years; men $15-44$ years; all adults $\geq 45$ years. Despite this disaggregated approach to defining risk groups, upon review of the literature described below, we concluded that there were few pub-

lished studies regarding the contribution of zinc deficiency to morbidity or mortality in any age group other than children aged $0-4$ years. For this reason, the chapter focuses on the contribution of zinc deficiency to the global burden of disease among children aged $0-4$ years.

## 4. Risk factor-Disease relationship

### 4.1 Search strategy

Evidence for the relationship between zinc deficiency and various diseases was gathered through literature searches of published studies. Articles related to zinc deficiency in human populations were identified for review based upon a Medline database search of literature published 1966-2001 in English or with an English abstract. The search was conducted using combinations of the following keywords: zinc, deficiency, mortality, death, morbidity, acute respiratory infection, pneumonia, diarrhoea, measles, malaria, child, pregnancy, infant, neonatal, fetal, premature, congenital, abortion, stillbirth, miscarriage, birth weight, retardation, development, intelligence, cognitive, psychomotor and neurological. Further searches on Medline were conducted using author names and the "related articles" option.

Abstracts were reviewed to select English-language articles that examined the effect of zinc deficiency (as defined by clinical, epidemiological or biochemical assessment) or supplementation/fortification on several health outcomes of interest in human populations. These health outcomes included infant or neonatal, child or adult mortality; incidence or severity of malaria, diarrhoea, measles or acute respiratory infection; prevalence of mental retardation or cognitive dysfunction; and risk prevalence of physical impairment such as hearing or neurological dysfunction. Once copies of articles were obtained, additional publications were identified from the reference lists of those articles. The only studies excluded from review were animal studies and case reports.

### 4.2 Methods for combining risk estimates from individual studies

The most appropriate study design to assess prospective risk for our purposes would be a prospective cohort study. Unfortunately, no such studies were identified despite an exhaustive search. Certainly this relates in part to the fundamental problem of characterizing the zinc status of individuals discussed above. There have been, however, a significant number of RCTs of zinc supplementation examining morbidity outcomes in young children living in developing countries with presumably low intakes of zinc. The studies that were identified and included in our calculations are summarized in Table 5.2.

The studies included were RCTs of zinc supplementation for the prevention of one of three health outcomes: diarrhoea, pneumonia or
Studies contributing data on the effect of zinc deficiency on morbidity among children, aged 0-4 years

malaria. In addition, there are numerous RCTs in which zinc supplements are evaluated as therapeutic agents (Zinc Investigators' Collaborative Group 2000), but these are not included. In all, nine studies contributed findings on zinc deficiency and risk of diarrhoea (Meeks-Gardner et al. 1998; Müller et al. 2001; Ninh et al. 1996; Penny et al. 1999; Rosado et al. 1997; Ruel et al. 1997; Sazawal et al. 1997; Shankar et al. 1997; Umeta et al. 2000), five contributed findings on risk of pneumonia (Bhandari et al. 2002; Meeks-Gardner et al. 1998; Ninh et al. 1996; Ruel et al. 1997; Sazawal et al. 1998), and three contributed findings on risk of malaria (Bates et al. 1993; Müller et al. 2001; Shankar et al. 2000).

The data required for this work are the risk of each health outcome associated with zinc deficiency. This was calculated as the inverse of the odds ratio or relative risk estimated from RCTs given two assumptions: subjects in the study population have some level of zinc deficiency, and supplementation with zinc eliminated zinc deficiency. Because the first of these assumptions is likely to be generally but not universally true, and the second assumption is not likely to be true, we view our results as conservative.

### 4.3 Diarrhoea

The results of the nine RCTs with findings on zinc deficiency and diarrhoea incidence are presented in Table 5.3. The results are presented for each individual study as well as a pooled estimate of all nine studies. The pooled estimate was derived using random effects models as described

| Viet Nam (Ninh et al. 1996) | 56 | 11242 | 100 | 1 242 | 1.79 (1.28-2.50) |
| All |  |  |  |  | 1.28 (1.10-1.49) |

[^10]in a previous pooled analysis (Zinc Investigators’ Collaborative Group 1999). Although each study reported the effects of zinc supplementation on the incidence of diarrhoeal illness, we have presented estimates of the relative risk of diarrhoeal disease incidence due to zinc deficiency. As shown, the pooled estimate indicates that the relative risk of diarrhoea in young children due to zinc deficiency is 1.28 ( $95 \%$ CI 1.10-1.49).

In 1999, a pooled analysis was conducted of published RCTs of zinc supplementation to reduce diarrhoea and pneumonia morbidity in young children (Zinc Investigators’ Collaborative Group 1999); at that time, seven of these studies had been published (Meeks-Gardner et al. 1998; Ninh et al. 1996; Penny et al. 1999; Rosado et al. 1997; Ruel et al. 1997; Sazawal et al. 1997; Umeta et al. 2000). The pooled estimate based on these studies indicated that zinc deficiency increases the risk of diarrhoea in young children by 1.33 ( $95 \%$ CI 1.14-1.59).

### 4.4 Pneumonia

The results of the five RCTs with findings on zinc deficiency and pneumonia incidence are presented in Table 5.4. The results are presented for each individual study as well as a pooled estimate across all five studies. As shown, it is estimated that zinc deficiency increased the risk of pneumonia in young children by 1.52 ( $95 \%$ CI 1.20-1.89).

With the exception of the study by Bhandari et al. (2002), the studies had been included in a published pooled analysis of the effects of zinc supplementation on pneumonia (Zinc Investigators' Collaborative Group 1999). The summary estimate from that analysis was of similar magnitude: the relative risk of pneumonia due to zinc deficiency in young children was 1.69 (95\% CI 1.20-2.45).

| Follow-up refers to the total number of child-days of follow-up or disease surveillance in each study. |  |  |  |  |  |

### 4.5 Malaria

Three RCTs of zinc supplementation to prevent malaria morbidity were identified. In Papua New Guinea, Shankar et al. (2000) found a $38 \%$ ( $95 \%$ CI $3-60 \%$ ) reduction in malarial attacks based on clinic visits for malaria or fever with confirmed parasitaemia above a predefined threshold. Using an analogous definition, Bates et al. (1993) also found an approximately one-third reduction in malarial attacks, but it was not statistically significant $(P=0.09)$, and the authors concluded there was no effect of zinc deficiency on malarial attack rates. However, Shankar et al. (2000) obtained the original data from the study (Bates et al. 1993) and utilized random effects models to derive a pooled estimate of a $36 \%$ ( $95 \%$ CI $9-55 \%)$ reduction in clinic-based malarial attacks with parasitaemia with zinc supplementation. The paper by Müller et al. (2001) utilized a different methodology to detect malarial illness-communitybased daily surveillance-and thus, examined a different aspect of malarial illness. They found no significant reduction in malarial incidence by treatment, with a zinc treatment odds ratio of 0.98 ( $95 \%$ CI 0.86-1.11). Studies with community-based malaria surveillance largely detect associations with early manifestations of a malaria episode, and on episodes tending to be less severe, whereas studies focusing on clinical malaria episodes detect effects on the progression of a malaria episode, and on cases perceived to be severe enough to warrant a visit to the health centre (Cox et al. 1994). Because of the heterogeneity of outcomes studied, and our desire to focus on malarial morbidity that contributes to the global disease burden estimates (Snow et al. 1999), we excluded the study by Müller et al. (2001) from further analysis. Instead we used Shankar's pooled analysis to derive a relative risk for malaria morbidity associated with zinc deficiency in young children of 1.56 ( $95 \%$ CI 1.29-1.89).

### 4.6 Mortality

Clearly, zinc deficiency contributes to increased risk of incidence for important childhood diseases that are predominant causes of death among children. Direct estimation of the risk of cause-specific mortality among children due to zinc deficiency is not available from the literature. Unless there were an expectation that zinc deficiency reduced casefatality or severity of these diseases, the risk of mortality due to zinc deficiency should be at least equivalent to the risk of disease occurrence due to zinc deficiency. For this reason, we have proposed that the relative risk of mortality related to diarrhoea, pneumonia and malaria associated with zinc deficiency, are $1.28,1.52$ and 1.56 , respectively (Table 5.5). These might well be conservative estimates, given the high likelihood that zinc deficiency increases the risk of severity and death during illness with diarrhoea or pneumonia (Zinc Investigators' Collaborative Group 1999, 2000). There are three pieces of direct evidence that zinc deficiency increases mortality in young children. First, Indian infants

Table 5.5 Estimated effect of zinc deficiency on morbidity and mortality due to diarrhoea, pneumonia and malaria in children aged 0-4 years

|  | Morbidity |  |
| :--- | :---: | :---: |
| IIIness | Relative risk (95\% Cl) | Mortality |
| Diarrhoea | $1.28(1.10-1.49)$ | $1.28(1.10-1.49)$ |
| Pneumonia | $1.52(1.20-1.89)$ | $1.52(1.20-1.89)$ |
| Malaria | $1.56(1.29-1.89)$ | $1.56(1.29-1.89)$ |

born small for gestation who received zinc supplements six days a week were $0.32(95 \%$ CI $0.12-0.89)$ less likely to die during infancy than those receiving the control supplement (Sazawal et al. 2001). Second, Bangladeshi children who received supplements of $20 \mathrm{mg} / \mathrm{d}$ zinc as adjuvant to oral rehydration solution (ORS) during diarrhoea, were half as likely to die than those receiving ORS alone (Baqui et al. unpublished data). Third, zinc supplementation was associated with a marginally significant reduction in all-cause mortality ( 5 deaths vs 12 deaths, $P=0.10$ ) in the study by Müller et al. (2001). With respect to malarial deaths, it should be reiterated that the reduction in malaria attacks attributable to zinc supplementation was based on clinic attack rates, that is, more severe malaria morbidity rather than less severe illness that would be detected through community-based surveillance, as conducted in the study by Müller et al. (2001). Finally, it should be noted that infections themselves cause secondary zinc deficiency because zinc is sequestered by the liver as part of the acute phase response and is thus less available for many cellular functions (Keen et al. 1993). This point provides additional rationale as to why zinc deficiency may be more strongly related to deaths than to illness incidence. This may also partially explain findings that zinc supplementation reduces the duration of diarrhoeal episodes in prospective trials, as well as in trials in which zinc supplements are provided therapeutically (Zinc Investigators' Collaborative Group 1999, 2000).

### 4.7 DISEASE CAUSATION MECHANISMS

The results of this body of research do not define the explicit biological mechanisms through which zinc deficiency increases disease risk in young children. There is no doubt, however, that zinc is a critical nutrient for cell replication and function and thus, critical for normal functioning of all body systems. The first system known to be compromised with even mild deficiencies of zinc is the immune system, reflecting the profound and ubiquitous role zinc plays in immune function. As recently reviewed by Shankar and Prasad (1998), zinc deficiency impairs multiple aspects of immune function, including barrier and non-specific immunity, spe-
cific immune components (lymphyocytes, monocytes and macrophages, neutrophils, natural killer cells), and mediators of immune function such as glucocorticoid and thymulin activity, and cytokine function. Given the multiple roles of zinc in the immune function, it is not surprising that zinc deficiency should confer increased risk of morbidity and mortality due to infectious diseases.

Zinc deficiency also results in reduced growth rates in animals, and there is ample evidence from RCTs that the provision of supplemental zinc to young children can reduce growth faltering in preschool-aged children. Recently, Brown et al. (1998a) published a meta-analysis of more than 52 RCTs investigating the effect of supplemental zinc on anthropometric status or growth in children. The results of their analysis indicate that improvements in zinc intakes achieved with supplemental zinc (at dosages similar to those reported here) improve the weight-for-age and height-for-age $z$-scores by 0.26 SD and 0.22 SD, respectively. It is heuristic to conclude that some of the improved growth is due to zinc-related effects which reduce morbidity incidence and duration/severity.

## 5. Burden of disease estimates

The estimated deaths and DALYs attributable to zinc deficiency are shown in Tables $5.6-5.7$. When examined by region, the burden of zinc

deficiency and its consequences are borne most heavily by Africa, the Eastern Mediterranean and South-East Asia. This is true for both diarrhoea and pneumonia. The burden of malarial disease attributable to zinc deficiency is borne almost exclusively by those in the African Region.

## 6. Discussion

We estimated that zinc deficiency in children aged $<5$ years caused 176000 diarrhoea deaths, 406000 pneumonia deaths, and 207000 malaria deaths. The associated DALYs attributable to zinc deficiency were more than 28 million. This was because the risks of morbidity and mortality associated with zinc deficiency are relatively high, and because available data suggest that zinc deficiency-as defined by inadequate dietary zinc-is highly prevalent in many parts of the world, and particularly in parts of the world where the majority of deaths due to diarrhoea, pneumonia and malaria occur. This places zinc deficiency as a key factor conferring risk of morbidity and mortality to young children, one that is ostensibly preventable through public health action.

The evidence that zinc deficiency increases incidence risk is strong because it results from RCTs conducted in areas of the world with limited zinc available in the diet and where pneumonia, diarrhoea and malaria are public health problems. The risk estimates for diarrhoea and
pneumonia are particularly strong, based on results from nine and five RCTs, respectively. The estimated increased risk for malaria is less well studied. Our risk estimate was based on two RCTs with similar risk estimates in which clinic attack rates were the outcome of interest. We excluded the only other published RCT in which the effect of supplemental zinc on less severe malaria morbidity (detected through community surveillance) was studied and in which no increased risk of malaria was found. Clearly more research on the relation between zinc deficiency and malaria is needed to substantiate the risk estimates provided here.

The use of experimental designs has allowed for the characterization of the consequences of zinc deficiency, yet much work needs to be done in order to describe the magnitude and distribution of zinc deficiency throughout the world. This is an important task because the placement of zinc deficiency as a major contributor to the global burden of disease rests in its ubiquitous presence throughout the world. The approach used to characterize zinc deficiency was to estimate the proportion of the population living in areas with inadequate zinc in their food supply as determined from food balance sheet data compiled by FAO. This is far from the traditional approach of characterizing nutrient deficiencies using biochemical indicators. As stated earlier, however, there is no clear choice of biochemical indicator for zinc status, and the information available on zinc status based on plasma zinc concentration (the most commonly cited indicator of zinc status) would be limited to restricted samples of study participants conducted in selected regions of the world. To our knowledge, there are few if any national nutrition surveys utilizing biochemical indicators of zinc status and few laboratories capable of conducting trace mineral assays in developing countries due to the difficulties in eliminating contamination.

The advantage of the approach developed by IZiNCG is that a common methodology could be applied across similarly collected data from 172 countries, representing all 14 subregions. Further, because zinc is stored in the body in only limited amounts, and because certain key features of the diet (total energy content, animal protein availability, fibre/phytate content associated with the principal grain) largely determine the bioavailability of the zinc present in the food supply, the adequacy of dietary zinc intakes is an appropriate indicator to approximate the prevalence of zinc deficiency. There are multiple uncertainties inherent in this approach, and key assumptions include the following: (i) that per capita food availability data relates to actual dietary intake and ultimately to zinc status; (ii) that foods not included in the data (e.g. foraged foods) are not rich sources of zinc; (iii) that our knowledge of the composition of foods with respect to zinc, calcium, fibre and phytate is adequate for our purposes; (iv) that characterization of the bioavailability of zinc is correct; and (v) that we have the appropriate zinc requirement distribution and cut-point for defining adequacy of
intake. It is only through further research that we can determine the validity of the assumptions made, and judge the certainty with which we have characterized the prevalences of zinc deficiency in young children.

There are reasons to believe that the estimates presented here are conservative. First, food availability is usually greater than food intake. This effect, however, may be countered by underestimation of intake in the FAO data which do not always account for subsistence production. Second, the groups for which these numbers are likely to be most conservative are women of reproductive age and small children who may be particularly disadvantaged in terms of obtaining the best sources of zinc (animal products) in their diet. Third, dietary intake surveys, which more directly estimate the prevalence of inadequate intakes in populations, typically have estimated higher prevalences of inadequate zinc intakes than those depicted here (Parr 1992, 1996). On the other hand, because breastfeeding is an adequate source of zinc in the diets of infants aged less than six months, the same age when a large proportion of childhood mortality is concentrated, applying the risks to all children aged 0-4 years may result in substantial overestimation of disease burden in some populations.

It is also important to note that maternal or gestational zinc deficiency may affect immunological development in the newborn in ways that compromise immune function throughout the lifespan irrespective of zinc status (Caulfield et al. 1998; Shankar and Prasad 1998). Although this is well demonstrated in certain animal models, it has not been well characterized in humans, but a recent study by Osendarp et al. (2001) provides intriguing evidence of potential long-term effects on infant health in the first year of life due to maternal prenatal zinc deficiency. Fetal accumulation of zinc is a function of maternal zinc status, and therefore, newborn zinc deficiency (assessed as low serum zinc concentration) is likely among women with inadequate dietary zinc intakes during pregnancy (Caulfield et al. 1999). This deficiency is likely transitory for all but the most vulnerable (preterm or low-birth-weight infants) because the zinc content of colostrum is high and some zinc becomes available to the infant as part of the haematological changes accompanying the transition to extrauterine life (WHO 1996). Beginning at around six months of age, however, breast milk intake no longer provides sufficient zinc to meet requirements (Krebs 2000), making zinc-rich complementary foods necessary (Brown et al. 1998b). If zinc-rich sources are not available on a routine basis, zinc deficiency develops over time and persists until changes in the diet are made. Thus, it must be recognized that removal of the global burden of disease due to zinc deficiency will likely require improvements in child and maternal zinc intakes. In this chapter, we have considered only the burden of disease for children aged 0-4 years since no available evidence on the role of zinc in morbidity and mortality among other age groups was available. Thus, it may
be true that zinc deficiency contributes greatly to death and disability among other age groups. Defining these risk relations should be a priority area for future research.

Because low weight-for-age (usually described as underweight) also increases risk of morbidity and mortality from diarrhoea, pneumonia and malaria (see chapter 2), there is overlap between zinc deficiency and underweight as risk factors for morbidity and mortality from these causes in young children. The degree of overlap cannot be quantified empirically, but evidence from studies can provide insight in this issue. In the meta-analysis of zinc RCTs (Zinc Investigators' Collaborative Group 1999), the authors found that the effects of zinc supplementation on risk of diarrhoea and pneumonia across studies did not depend on the underlying level of malnutrition as characterized by the average $z$ score in the study subjects. However, the study by Umeta et al. (2000) did find greater reductions in morbidity in stunted as opposed to nonstunted children. Zinc supplementation has reduced morbidity with no detectable changes in growth rates (Meeks-Gardner et al. 1998). Overall, limited evidence shows that the efficacy of zinc supplementation for reducing morbidity is more substantial than for reducing growth faltering in studies in which both outcomes have been characterized. There are also studies in the literature in which improvements in immune function have been observed with zinc supplementation in well-nourished subjects (e.g. those with adequate weight); thus, although most of the research on the benefits to health from zinc supplements has been conducted in populations similarly characterized by underweight or stunting, the potential reductions in the global burden of disease due to zinc deficiency should not be limited to those who are also underweight or stunted. In the case of malaria, Shankar (2000) describes how zinc deficiency exerts fairly specific effects on malaria morbidity (increasing febrile illness accompanied by hyperparasitaemia), whereas low anthropometric status appears to exert more generalized effects. With these considerations, we conclude that although zinc deficiency and underweight co-exist in many populations, and both are risk factors for the disease outcomes described here, the majority of the disease burden attributable to zinc deficiency is not restricted to children who are generally malnourished.

In summary, the available evidence suggests that zinc deficiency contributes substantially to death and disability throughout the world, and particularly in Africa, the Eastern Mediterranean, and South-East Asia. Because epidemiological evidence is limited to studies conducted among preschool children and this analysis considers only three causes of death and disability, it is clear that further research on the role of zinc in morbidity, mortality and disability due to other causes and in other age groups is urgently needed. Further research is needed to identify indicators of exposure to zinc deficiency as well as effective strategies to reduce zinc deficiency and its consequences.

## 7. PROJECTIONS OF EXPOSURE

Currently, there are no programmes or policy initiatives in place to specifically improve the zinc intakes of human populations. This is true with respect to improving the zinc supply in foods (e.g. interventions to improve intakes of animal products which are good sources of zinc or to reduce phytates in foods which impair zinc absorption). Further, there are no examples of programmes utilizing supplemental zinc to improve zinc status, although some are beginning to use supplemental zinc as adjuvant therapy during diarrhoeal illness, based on research demonstrating the efficacy of zinc in shortening the duration of the current episode and prolonging the time until the next episode in paediatric populations with heavy disease burden. Because of the general lack of policy or programmatic initiatives to address zinc deficiency, we project that the magnitude and distribution of zinc deficiency will remain the same for the years 2010 and 2020, as presented here.

## Acknowledgements

We are grateful for the support of Kenneth H. Brown in providing us with the data on the prevalence of inadequate zinc intakes in 172 countries; Sunil Sazawal for updating the pooled analyses of zinc and risk of diarrhoea and pneumonia, and Anuraj H. Shankar for conducting the pooled analysis of zinc and malaria and for his insights into the various dimensions of malarial morbidity.

This manuscript was supported in part by the Family Health and Child Survival (FHACS) Cooperative Agreement between the United States Agency for International Development, Office of Health and Nutrition, the Johns Hopkins Bloomberg School of Public Health, Department of International Health, and by the World Health Organization.

## Chapter 6

# High blood pressure 

Carlene M.M. Lawes, Stephen Vander Hoorn, Malcolm R. Law, Paul Elliott, Stephen MacMahon and Anthony Rodgers

## Summary

This chapter aims to estimate the burden of disease attributable to raised blood pressure in 2000, and the burden avoidable by distributional shifts of blood pressure. The key initial steps were to define the blood pressure variable, choose disease outcomes to be assessed, estimate current global blood pressure levels, choose a theoretical minimum and estimate risk factor-disease relationships.

Blood pressure was defined as systolic blood pressure (SBP) in mmHg. SBP was chosen principally because data are widely available for this index of blood pressure, and it appears to be at least as good a predictor of cardiovascular disease as other indices.

Based on consistent direct, continuous associations in cohort studies and evidence from randomized clinical trials, the outcomes assessed were stroke, ischaemic heart disease (IHD), hypertensive disease and other cardiac disease. Similar data suggested causal relationships with renal failure, but this could not be mapped to a Global Burden of Disease (GBD) study outcome.

Raw SBP data were obtained from studies after a systematic review of population-based surveys, and included data from about 230 surveys and over 650000 participants. Sex-specific associations of SBP with age were estimated for each of the subregions ${ }^{1}$ separately, based on populationweighted (by country) study estimates of mean values. There was moderate variation in the final age-specific and sex-specific estimates of mean blood pressure across the 14 subregions, with the range between the highest and lowest age-specific mean SBP levels across subregions typically being about 20 mmHg . Confidence intervals around mean SBP and standard deviations were calculated to reflect uncertainty. Trends in mean SBP over time were extrapolated from published epidemiological data.

The theoretical minimum of SBP was estimated to be mean 115 mmHg and standard deviation 6 mmHg (usual SBP), for all age, sex and subregional groups. The main basis for this estimate was the level of SBP down to which epidemiological relationships with cardiovascular disease outcomes are observed. This theoretical minimum is also consistent with the levels of SBP in populations with little or no cardiovascular disease. Furthermore, recent clinical trial data have indicated reductions in stroke after lowering blood pressure by about 10 mmHg SBP in those with mean SBP 125 mmHg .

Data on the risk factor-disease relationship were obtained from the Asia-Pacific Cohort Studies Collaboration (APCSC), an individual participant meta-analysis that combined data from 37 prospective observational cohorts involving over 425000 individuals with $2-27$ years of follow-up (mean 7 years), and in total over 3 million person-years of observation. Data from this meta-analysis were complemented by data from other overviews and large cohort studies. The main findings were direct, positive and continuous associations of usual SBP with the risks of all end-points of interest. The risks were similar by sex and subregion, except there was possibly a stronger association of blood pressure with stroke in Asian compared to non-Asian populations, due partly to the higher proportion of haemorrhagic strokes. Overall, each 10 mmHg below-usual SBP was associated with $38 \%$ ( $95 \%$ CI 37-39\%) lower stroke risk and a $26 \% ~(95 \%$ CI $24-29 \%)$ lower risk of IHD. Each 10 mmHg below-usual SBP was associated with $46 \%$ ( $95 \%$ CI $40-51 \%$ ) and $18 \% ~(95 \%$ CI $15-20 \%)$ lower risks of hypertensive disease and other cardiac disease. Few data were available for the GBD end-point "other cardiac disease", so, given some uncertainty about causality and the varying composition for this end-point around the world, the relative risks were halved for this outcome. There was attenuation of proportional associations with age for all these outcomes.

Data on risk reversibility came from meta-analyses of randomized controlled trials of blood pressure lowering. In total 23 trials were reviewed, which included over 71000 participants allocated a variety of blood-pressure-lowering agents or placebo. The mean overall SBP reduction was 10 mmHg , and a total of 2632 strokes and 3693 IHD events were observed. Overall the trials confirmed the size of the reductions expected from epidemiological relationships in middle age. However, the reductions in risk in old age were larger than expected from the cohort study data.

We used the observational epidemiological data for relative risk estimates and the trial overviews for the time frame of risk reversibility. For example, in middle age the epidemiology suggests a 10 mmHg increase in SBP is associated with about $40 \%$ more stroke and $25 \%$ more IHD. The trials suggested that within 3-5 years of lowering SBP by 10 mmHg , most or all of this increased risk for stroke and hypertensive disease and
approximately two thirds for IHD and other cardiovascular disease are reversed.

The foregoing methods and assumptions allowed estimates of burden attributable to mean SBP levels of more than 115 mmHg . The analysis showed that:

- forty-nine per cent of IHD is attributable to SBP $>115 \mathrm{mmHg}$ worldwide (range of $40-64 \%$ by subregion), which translates into 2991000 deaths and 28.2 million disability-adjusted life years (DALYs) in the year 2000;
- sixty-two per cent of stroke is attributable to SBP $>115 \mathrm{mmHg}$ worldwide (range of $52-78 \%$ by subregion), which translates into 3149000 deaths and 27.8 million DALYs in the year 2000;
- seventy-six per cent of hypertensive disease is attributable to SBP $>115 \mathrm{mmHg}$ worldwide (range of $64-90 \%$ by subregion), which translates into 663000 deaths and 5.4 million DALYs in the year 2000; and
- fourteen per cent of other cardiovascular disease is attributable to SBP $>115 \mathrm{mmHg}$ worldwide (range of $8-22 \%$ by subregion), which translates into 338000 deaths and 2.8 million DALYs in the year 2000.

Worldwide, 7.1 million deaths (about $12.8 \%$ of the total) and 64.3 million DALYs ( $4.4 \%$ of the total) were estimated to be due to nonoptimal blood pressure. The proportion of DALYs was lower than the proportion of deaths as most blood pressure-related cardiovascular disease events occurred in middle or old age, so the years of life lost due to premature mortality and years of life lost due to disability is a smaller percentage of the total DALYs than of the total deaths. Overall, the results suggest that a considerable proportion of cardiovascular disease is related to non-optimal blood pressure, and this translates into an important portion of deaths and years of life lost to deaths and disability worldwide. Approximately one third of the blood pressure-related attributable burden occurred in developed subregions, one third in lower mortality developing subregions (AMR-B, EMR-B, EUR-B, EUR-C, SEAR-B, WPR-B) and a further third in high mortality developing subregions (AFR-D, AFR-E, AMR-D, EMR-D, SEAR-D).

The estimates of burden attributable to non-optimal blood pressure are approximately double those from the World Health Organization (WHO) GBD study in 1990. However, the 1990 estimates did not correct for regression dilution bias, which means there was underestimation of risk of cardiovascular disease by a factor of about two. This therefore explains the almost doubling of burden attributable to blood pressure in current estimates.

## 1. Introduction

### 1.1 Defining the blood pressure variable

Blood pressure is a measure of the force that the circulating blood exerts on the walls of the main arteries. The pressure wave transmitted along the arteries with each heartbeat is easily felt as the pulse-the highest (systolic) pressure is created by the heart contracting and the lowest (diastolic) pressure is measured as the heart fills.

Blood pressure is described as a continuous variable as it is commonly reported in this manner, with mean and standard deviation values. Relative risk values for the risk factor-disease relationship are also available for this format. The standard unit for measuring blood pressure is mmHg , which may be applied to SBP, diastolic blood pressure (DBP), or alternative measurements such as mean arterial pressure and pulse pressure ( PP ).

Historically, many classification systems and treatment recommendations placed more emphasis on DBP, as elevated DBP was thought to confer greater risk for cardiovascular disease than elevated SBP (Kannel 1999, 2000; Lloyd-Jones et al. 1999). There is, however, now evidence for a paradigm shift to consider SBP as well as DBP (Black 1999b). Both the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC-VI) (Anonymous 1997) in 1997 and the 1999 guidelines from the WHO-International Society of Hypertension (WHO/ISH) (Anonymous 1999) now agree that both SBP and DBP should be used to classify hypertension (Black 1999a).

Prospective observational studies have provided data on whether, over the long term, there appears to be an association between blood pressure and disease end-points. Therefore, comparisons of the strength of associations for both DBP and SBP may be made. Data published from the Framingham study over the past 30 years have suggested that cardiovascular consequences do not necessarily derive principally from DBP (Kannel et al. 1969). While DBP may be a better predictor of cardiovascular disease in those aged $<45$ years, SBP is a better predictor of stroke and cardiovascular disease in those aged $>60$ years (Kannel et al. 1970, 1971). Overall, the risk of cardiovascular events was greater in the presence of isolated systolic hypertension than diastolic hypertension. For each standard deviation increase in mean SBP, the cardiovascular disease risk increased by $40-50 \%$, whereas for DBP the increment was $30-35 \%$. (This persisted after adjusting for age, and occurred in both men and women.) Combined systolic and diastolic hypertension carried only marginally greater risk than isolated systolic hypertension (Kannel 1996).

Other prospective studies corroborate these results with evidence that, in both sexes, the overall association between blood pressure and cardiovascular end-points is stronger for SBP than DBP (Franklin et al.

1999, 2001; Lichtenstein et al. 1985; Miall 1982; Mitchell et al. 1997; Miura et al. 2001; Sesso et al. 2000; Stamler et al. 1993). Within each level of DBP, a higher SBP was related to increased risk of IHD in a continuous and graded fashion. There was also an increase in risk with higher DBP within each SBP level, but in this latter scenario, the increases were not as steep or consistent (Stamler et al. 1993). Subjects who subsequently died from IHD were better identified by their SBP than by their DBP. Overall, SBP was a better predictor of outcome (Lichtenstein et al. 1985).

There are some data to suggest that PP (the difference between SBP and DBP) is a good predictor of cardiovascular risk (Abernethy et al. 1986; Black 1999b; Domanski et al. 1999; Frohlich 2000). However, it has not been consistently shown to be superior to SBP (Abernethy et al. 1986; Franklin 1999; Franklin et al. 1999, 2001; Sesso et al. 2000), and it was not a better predictor than SBP in the Asia-Pacific Cohort Studies Collaboration overview (APCSC 2003b); further, estimates of relative risk are available for SBP rather than PP. SBP was therefore used in preference to PP for the purposes of these analyses.

### 1.2 Disease outcomes

There are a number of potential disease outcomes associated with blood pressure. Blood pressure is generally accepted to have a role in accelerating atherosclerosis of the blood vessels and thereby influencing cardiovascular disease. Atherosclerosis is believed to start with "fatty streaks" on the intimal surface of blood vessels. Over time the intima is invaded by "foam cells" (lipid-laden macrophages) and plaques develop (Warlow et al. 1996). These plaques may be complicated by platelet adhesion, activation and aggregation, and formation of a thrombus. Many ischaemic cardiovascular disease events are due to "atherothromboembolism", where a fibrous plaque may obstruct blood vessel lumen resulting in infarction, or the thrombotic component of the plaque may break down and embolize (Warlow et al. 1996). It is proposed that haemorrhagic events (e.g. strokes) are due to degenerative atherosclerotic changes in blood vessels, which may cause formation of microaneurysms and fibroid necrosis, both of which may weaken the artery wall and lead to rupture (Leppala et al. 1999; MacKenzie 1996; Swales 1994; Warlow et al. 1996). Potential outcomes considered for blood pressure are as follows.

## Stroke

Data from a variety of prospective cohort studies and overviews have demonstrated a strong, continuous temporal association between blood pressure and stroke (Anonymous 1998; APCSC 2003a; MacMahon and Rodgers 1993a; MacMahon et al. 1990; PSC 1995). Further, a causal association is biologically plausible and clinical trials have demonstrated reversibility (Collins et al. 1990; Neal and MacMahon 1999; Neal et al.
2000). More recent prospective studies have also assessed the association between blood pressure (BP) and stroke subtypes, such as haemorrhagic and ischaemic stroke. However, the GBD classification system for diseases and injuries has only one category for total stroke (end-point 108 G4 cerebrovascular disease, International Statistical Classification of Diseases, ninth revision [ICD-9] codes 430-438). Thus, it was not possible to analyse stroke subtypes individually in this work. Epidemiological studies show a positive association between blood pressure and fatal, non-fatal and total strokes, and total strokes were included in the analyses.

## ISCHAEMIC HEART DISEASE

As with stroke, a variety of prospective cohort studies and overviews have demonstrated a strong, continuous temporal association between blood pressure and IHD (APCSC 2003a; MacMahon and Rodgers 1993a; MacMahon et al. 1990); a causal association is biologically plausible and clinical trials have demonstrated reversibility (Collins et al. 1990; Neal and MacMahon 1999; Neal et al. 2000). The GBD classification system for diseases and injuries has a category for total IHD (endpoint 107 G3 ischaemic heart disease, ICD-9 codes 410-414).

## RENAL DISEASE

Cohort study data on mortality in association with hypertension do not often include renal disease as an end-point (Whelton and Klag 1989). However, the largest cohort to date, the Multiple Risk Factor Intervention Trial (MRFIT) study assessed the development of end-stage renal disease in men followed for 16 years. This study identified a strong, graded relation between both systolic and DBP and end-stage renal disease, independent of other disease associations (Klag et al. 1996). There were several limitations in this study, but many of these could potentially be addressed in analyses. Only baseline blood pressure measurements were taken, which would underestimate associations substantially, but correction factors could be applied. No women were included, but the proportional effect is the same in males and females for other disease associations, so it could be assumed to be consistent here. No information was available on anti-hypertensive agents, which could weaken the association, but would not negate it. The major limitation was that renal function was not assessed at baseline in all participants (Klag et al. 1996). This makes the issue of temporality difficult to establish, as renal disease could predispose to high blood pressure rather than the reverse.

Additional limited, but consistent, data about the relationship between blood pressure and renal failure are available from other prospective observational studies and hypertension treatment trials (MacMahon 1994; Whelton and Klag 1989). While this evidence is suggestive, it is not conclusive (Whelton and Klag 1989).

The above evidence is suggestive of an etiological role for blood pressure in the progression of renal failure. However, there is a further major consideration in choosing disease outcomes for this project. All disease outcomes must map to GBD end-points, and there is no end-point that is equivalent to renal failure. The "nephritis and nephrosis" category (end-point 121 J1, ICD-9 codes 580-589) includes a wide range of more diverse renal conditions. Therefore, apart from the more restricted "hypertensive renal disease" incorporated in the GBD end-point, hypertensive disease (below) analyses of renal failure could not be conducted.

## Hypertensive disease

The GBD classification system end-point "hypertensive disease" (endpoint 106 G2, ICD-9 codes 401-405) includes essential hypertension, hypertensive heart disease, hypertensive renal disease, hypertensive heart and renal disease and secondary hypertension. To some extent this is not an ideal disease outcome category. The evidence suggests continuous associations between blood pressure and disease end-points, so partitioning off those with hypertension is somewhat artificial as they are more likely to be part of a continuum rather than a distinct group. It would be preferable to have more specific disease categories that were not specifically labelled as "hypertensive". If any disease is selectively diagnosed in people with high blood pressure, the strong association with blood pressure becomes self-fulfilling. However, the choice of end-points for analyses is limited to those classified in the GBD classification system for diseases. As there are direct and positive associations with blood pressure and these outcomes, it is necessary to include this end-point, despite its shortcomings.

## Other Cardiovascular Disease

The final end-point included in the GBD classification system associated with blood pressure is "other cardiac disease". This compromises a miscellany of cardiovascular conditions including heart failure, pulmonary heart disease, diseases of the pericardium and endocardium, conduction disorders, cardiac dysrhythmias, diseases of arteries, arterioles and capillaries, and diseases of veins and lymphatics. Numerically, one of the most important is likely to be heart failure. Data from the Framingham study suggest that for those with hypertension, the incidence of heart failure is increased sixfold relative to those who are not hypertensive (Stokes et al. 1989). The risk of congestive heart failure for highest:lowest blood pressure quintiles was two-three times (Kannel and Belanger 1991). This positive association was also apparent in analyses of data from the APCSC (APCSC secretariat, personal communication, 2001), and the risk of heart failure appears to rise continuously and steeply with increasing levels of blood pressure (Stokes et al. 1989). Clinical trials also suggest reversibility of heart failure with blood pressure lowering (Neal et al. 2000). Data from APCSC also indicate strong
positive associations with all cardiovascular deaths that are not due to stroke, IHD or hypertensive disease.

Ideally, the disease end-points would have more specific categories rather than this heterogeneous group. Unfortunately, available data do not allow for analyses by specific diagnostic category within this group. Due to the substantial number of deaths that were likely to be associated with blood pressure, it was not appropriate to drop this category altogether. Analyses, therefore, included this end-point, but as discussed later in this chapter, relative risk estimates were modified to take into account the varying composition and uncertainty of causality of all diseases within this "other cardiovascular disease" group.

### 1.3 Theoretical minimum

## LOWEST RELATIVE RISK OF END-POINTS——OBSERVATIONAL STUDIES

APCSC combined data from 37 prospective observational cohorts involving over 425000 individuals with 2-27 years of follow-up (mean 7 years), and in total over 3 million person-years of observation (APCSC 1999). Analyses of the relationship between SBP and relative risk of cardiovascular disease in the Asia-Pacific region illustrate a continuous log linear relationship for both end-points. The lowest demonstrated relative risk for stroke and IHD occurred at approximately 115 mmHg (Figure 6.1), which suggests that this would be an appropriate level for a theoretical minimum.

Figure 6.I Usual SBP and risk of stroke and IHD in the Asia-Pacific region

[^11]
## RECENT DATA FROM BLOOD-PRESSURE-LOWERING TRIALS

Recently available data from a large trial of blood pressure lowering (PROGRESS, involving 6105 participants with cerebrovascular disease) indicated benefits of blood pressure lowering even in the group with baseline SBP $<140 \mathrm{mmHg}$ (mean 125 mmHg ) (Progress Collaborative Group 2001).

## LOW BLOOD PRESSURE POPULATIONS

An alternative source of data relevant to setting a theoretical minimum comes from studies on populations with little or no cardiovascular disease, based on research since the 1930s and 1940s (Poulter and Sever 1994). These include populations that are relatively isolated and have preserved their lifestyle for many generations. In many of these populations there is no, or very low prevalence of cardiovascular disease, including studies of autopsy findings (Poulter and Sever 1994). A further feature common to these populations is low blood pressure, and no or limited increase in blood pressure with age. This pattern is consistent in isolated populations throughout the world (Table 6.1).

These studies do have limitations. In most studies, there was no discussion of how age was assessed in these remote populations; in some surveys, other criteria were used when age was unknown, such as physical appearance, number and age of children, personal knowledge of interpreters and calendars of local events such as initiation at puberty (Carvalho et al. 1989; Mann et al. 1964). Despite this, the data suggest that "low blood pressure" populations do exist (mean SBP $\leq 115 \mathrm{mmHg}$ ) where hypertension is absent or rare (Carvalho et al. 1989; He et al. 1991a, 1991b; Poulter and Sever 1994). Cardiovascular disease also tends to have a very low prevalence in these populations (Poulter and Sever 1994). Typically these populations have diets low in salt, cholesterol and fat (particularly animal fat), a lifestyle requiring heavy physical labour, and an absence of obesity (Barnes 1965; Carvalho et al. 1989; Connor et al. 1978; He et al. 1991a, 1991b; Page et al. 1974; Poulter and Sever 1994; Sever et al. 1980). Low salt intake appears to be particularly relevant to the blood pressure differences. There is also evidence from studies conducted in a variety of settings (Poulter and Sever 1994), such as Africa (Poulter et al. 1988, 1990), China (He et al. 1991a, 1991b) and the Pacific (Joseph et al. 1983; Salmond et al. 1985, 1989), that blood pressure levels rise after migration to more urbanized "acculturated" settings and the slope of the age-BP relationship increases. In addition to changes in blood pressure, body mass index and heart rate tend to increase (Poulter and Sever 1994). Pre-migration data suggest that these changes are not due to selective migration (Poulter et al. 1988). Instead, it is likely that factors such as dietary changes of increased intake of sodium, animal protein, fat and processed foods, and decreased intake of potassium and vegetable protein are important (He et al. 1991a, 1991b; Poulter and Sever 1994; Poulter et al. 1988).

| Country or area (reference) | Population | Mean SBP levels | Patterns with age |
| :---: | :---: | :---: | :---: |
| Africa |  |  |  |
| Tanganyika ${ }^{\text {a }}$ (Mann et al. 1964) | Masai tribe (mostly men) with virtually no cardiovascular disease | $\begin{aligned} & 120-125 \mathrm{mmHg} \text { SBP } \\ & >160 \mathrm{mmHg} \text { rare } \end{aligned}$ | No age-related rise in BP |
| Southern Africa (Sever et al. 1980) | Tribal and urban Xhosa people | $\begin{aligned} & 120-130 \mathrm{mmHg} \\ & \text { rural } 130-140 \mathrm{mmHg} \\ & \text { urban } \end{aligned}$ |  |
| Kenya (Carvalho et al. 1989) | Rural villagers in remote areas (INTERSALT study) | $108-114 \mathrm{mmHg}$ in males and females |  |
| Americas |  |  |  |
| Mexico (Connor et al. 1978) | Tarahumara Indians who lived in the mountains | $105-110 \mathrm{mmHg}$ | No age-related rise in BP |
| Brazil (Carvalho et al. 1989) | Yanamamo Indians of the Amazon rain forest and Xingu Indians (INTERSALT study) | $90-105 \mathrm{mmHg}$ | Virtually no increase in BP with age |
| Western Pacific |  |  |  |
| China (He et al. 1991a, 1991b) | Rural Yi farmers in isolated areas | $100-110 \mathrm{mmHg}$ | BP does not tend to rise after puberty |
| Papua New Guinea (Barnes 1965) | The isolated Bomai and Yongamuggi people | $105-110 \mathrm{mmHg}$ for males and females | No age-related rise in BP |
| Papua New Guinea (Carvalho et al. 1989) | Rural villagers in remote areas (INTERSALT study) | $105-110 \mathrm{mmHg}$ | No age-related rise in BP |
| Solomon Islands (Page et al. 1974) | Six tribal societies with varying levels of acculturation | $110-120 \mathrm{mmHg}$, lowest in least acculturated groups | No age-related rise in BP |

[^12]Data from these studies indicate that populations do exist that have mean SBP levels of about 115 mmHg or even lower. The final decision on theoretical minimum, based on all the data, was that it would be set at 115 mmHg . This level correlated with data from cohort studies on the lowest level where accurate data are available on the association between SBP and cardiovascular disease.

## Standard deviation around the theoretical minimum

The choice of standard deviation around the theoretical minimum was based on examining the relationship of the standard deviation and mean of SBP using all available data obtained from the review of blood pressure surveys discussed in the following section (Figure 6.2). From this illustration, a distribution with a mean of 115 mmHg would typically

Figure 6.2 Association between mean SBP and standard deviation

have a standard deviation of 12 mmHg (baseline) which, when correcting for regression dilution bias, would be equivalent to 6 mmHg "usual".

## 2. Risk factor exposure

### 2.1 Data on blood pressure levels

Data on global blood pressure levels were collated from three major sources. The first source was data from the MONICA (Anonymous 1989b) and INTERSALT (Anonymous 1989a) studies. These studies collected blood pressure data from a variety of world regions. The MONICA study involved surveys at 39 collaborating centres in 22 countries carried out between 1979 and 1987 (Anonymous 1989b). The INTERSALT study involved surveys at 52 collaborating centres in 32 countries carried out between 1985 and 1987 (Anonymous 1989a). These two studies provide important information about blood pressure patterns, but do not provide a truly global overview of blood pressure
distributions. The MONICA study included populations that were predominantly European in origin, neither study included populations from the Eastern Mediterranean Region, and there were limited data from South-East Asia (other than India) and Africa. It was therefore necessary to include additional blood pressure data for comparative risk assessment (CRA) analyses.

The second major source of data were obtained through a literature search using Medline and the key words "blood pressure", "hypertension", "survey", "health survey" and "cross sectional survey". Studies were reviewed and included in analyses if they fulfilled the following criteria:

- conducted from 1980 onwards;
- included randomly-selected or representative participants;
- included a sample size of over 1000 in developed countries (a smaller sample size was acceptable in other countries if other criteria were fulfilled);
- described sample size and age group of participants;
- presented mean values of blood pressure by age and sex; and
- utilized a standard protocol for blood pressure measurement.

The final sources of data were personal communications with researchers and study investigators. The authors had access to data from APCSC-a collaboration involving 37 cohorts in the Asia-Pacific region. This collaboration includes prospective cohort studies undertaken in the Asia-Pacific region with at least 5000 person-years of follow-up recorded or planned, and data on date of birth or age, sex and blood pressure have been collated (APCSC 1999). Blood pressure data from eligible studies that had been collected from 1980 onwards were included in the SBP database. Data were also available from a previous global review of blood pressure levels for the last round of GBD, and these data were also included where the above criteria were fulfilled (P. Elliott, personal communication, 2001). Finally, authors of surveys/studies were contacted and age-specific and sex-specific data requested, where they had not been published in this format.

Many studies have not published data in the format required for this project (e.g. age-specific and sex-specific mean SBP level), and unfortunately time and resource constraints limited attempts to obtain all of these data from researchers. It was also very difficult to obtain results of surveys that have, for example, been published only in local/national reports but not in peer-reviewed journals. Access to these data would have been greatly improved if these reports were more widely available in electronic format, such as on the Internet. Details of studies currently included are presented in Table 6.2.
Table 6.2 Studies currently included in blood pressure data review

| Subregion | Country or area | Study (reference) | Year published | Sample size | Age range (years) |

Figure 6.3 SBP data coverage expressed as total study sample size, by geographical region

Figure 6.3 illustrates data coverage by geographical region. Data from about 230 studies (total sample size of over 660000 participants) have been included.

The subregions with the most data-studies including a total of more than 50000 participants-were AMR-A, EUR-A, WPR-A and WPR-B. All other subregions had data on a total of $>2000$ participants.

Approximately half of the studies from which data were obtained utilized random sampling of individuals or households (54\%) -including stratified random sampling (see Appendix A). Forty-six per cent of studies obtained samples by other methods such as house-to-house or workplace surveys. Response rates were documented in half of the studies. Of those studies that did provide these data, the response rate was $>80 \%$ in $42 \%$ of studies, between $50-80 \%$ in $54 \%$ of studies, and documented to be $<50 \%$ in only five studies. For completeness, full documentation of sampling method, response rate and blood pressure measuring techniques is presented in Appendix A. A summary is given in Table 6.3.

### 2.2 Methodology to estimate mean and standard deviation of blood pressure

Study summary data were taken from all data sources (i.e. summary statistics and not individual participant data were available for analysis). Mean SBP, standard deviation, sample size and age ranges from all data sources were extracted and entered into an Excel database. Scatter plots of these SBP data for each subregion, utilizing the midpoints in study age categories, are presented in Figures 6.4-6.7.

NA Not applicable.

The SBP data obtained from the literature came from studies that included different age ranges and were presented broken down by different age categories from that required for the CRA project. For this reason a method was needed that made complete use of all the available data. First, exploratory data analysis techniques were utilized to assess the general shape of association as well as to check for data errors. Secondly, models were fit to the data and country-level blood pressure estimates were made. Finally, subregional estimates were obtained by pooling across the country-level estimates. This approach is explained in greater detail below.

## SBP-AGE RELATIONSHIPS

The data from the surveys were used to assess the shape of the association of SBP with age for all data combined and for each subregion and sex separately using Splus software. At this stage no assumptions were made about the shape of association, and therefore non-parametric methods were applied (i.e. the generalized additive model). When the shape of the association was examined using all of the blood pressure data, there appeared to be an approximately linear association from the age of about $30-70$ years in males and females (Figure 6.8). When the analyses were repeated by subregion, the association increased approximately linearly from age 30 years for females ( 20 years for males) until approximately 70 years in all subregions, despite variation in the slope and overall starting SBP level.

In many subregions, SBP levels appeared to flatten for those aged $>70$ years, although there was some variation between the subregions in the point at which the association levelled off. In a few subregions, particularly the "A" subregions, there was no obvious levelling out of SBP in the 70-79 year age group; however, data for those aged $\geq 80$ years were particularly scarce, so a flattening out of SBP is still possible in these subregions. The shape of the association in those aged $>70$ years within each subregion was influenced by the fact that there were considerably less

Figure 6.4 Mean SBP-age relationship for input data by subregion, for females

Figure 6.6 The relationship of standard deviation of mean SBP with age by subregion, for females

Figure 6.7 The relationship of standard deviation of mean SBP with age by subregion, for males

Figure 6.8 The SBP-age association for all studies combined

survey data available for females and males aged $>70$ years. The literature clearly indicates that SBP tends to rise linearly until the eighth or ninth decade (Franklin et al. 1997; Kannel 1996, 1999; Whelton 1994; Whelton et al. 1994), after which it levels out (Franklin et al. 1997; Kannel 1996, 1999; Whelton 1994; Whelton et al. 1994). Therefore, it was assumed that in all subregions SBP levels increased linearly to 70 years of age in both males and females, after which (i.e. the $\geq 70$ year groups) levels flattened out. This approach was appropriate given the limitations of the data for those aged $>70$ years, and the information from the literature indicating that this pattern is widespread. It was also more conservative than assuming that the levels of SBP continue to increase with age.

The trend with age in industrialized subregions such as AMR-A, EURA, WPR-A corresponds with evidence in the literature, which shows a consistency of relationship between age and blood pressure in surveys in industrialized countries (Kannel 1999; Whelton et al. 1994). The literature suggests that between the third, fourth and seventh decades the rate of rise in SBP is approximately $0.6-0.8 \mathrm{mmHg} /$ year for women and approximately $0.3-0.5 \mathrm{mmHg} /$ year for men in industrialized populations
(Whelton et al. 1994). By the seventh decade women tend to have levels of SBP equal or exceeding those in men (Whelton et al. 1994). These findings concur with those for industrialized subregions in the current analyses. There were similar patterns in most developing countries, that is, an age-related rise in blood pressure which is consistently higher for systolic than DBP. SBP tends to rise linearly, and the age-related rise in blood pressure during adulthood is steeper for women than men (Kannel 1999; Whelton et al. 1994). However, the size of the age-related increase in blood pressure varies by subregion.

## Country-level estimates

After gathering all country-level studies, we obtained country-level estimates for countries where data were available. There were studies available that were nationally representative and these were used solely to derive the respective country-level estimates. In these cases any additional studies from those countries were not utilized as they only contributed additional heterogeneity to the best estimates obtained from the nationally representative data. There were eight countries where this was possible: Australia, Canada, Egypt, Germany, Japan, Paraguay, the United Kingdom of Great Britain and Northern Ireland and the United States of America. There were sufficient data to assess SBP in 61 additional countries and for these a regression approach was required so that all remaining study-level data could be described as well as extrapolated within countries where data did not cover all age groups. The following model was applied to both males and females:

$$
Y_{i j}=\beta_{1 i} \text { subregion }+\beta_{2 i} \text { age }+\beta_{3 i} \text { subregion } \times \text { age }+\beta_{4 j} \text { country }
$$

This equation expresses how the study summary data were modelled to estimate blood pressure levels for each country separately. SBP was regressed against several explanatory covariates: age was included as a continuous variable, linear between 30 and 70 as described in the previous section. Subregion was categorical and the "subregion $x$ age" interaction term included allowing for differing slopes of SBP with age between subregions. Country was included as a dummy variable and in this way the resulting beta coefficients can be used to assess the intercountry variation after controlling for age and subregional differences. The $i$ and $j$ subscripts denote the $i$ th subregion and $j$ th country within each subregion. Finally, the model was weighted by the sample size collected within each age group in each study to make the mean blood pressure estimates.

The modelling process is illustrated in Figure 6.9 where study level data within EUR-A were available for 18 of the 26 countries. The figure also shows, for the purpose of illustration only, the overall relationship of blood pressure with age in this subregion. It is clear from this figure that there is significant variation around the overall relationship with age

Figure 6.9 SBP data from studies in EUR-A

and also that a great deal of this variation is due to the differing patterns of blood pressure between countries. This occurred in most of the other subregions, especially where there were a large number of countries. In this example, each of the 18 countries within EUR-A was estimated to have the same overall slope within this subregion but at differing absolute levels.

Mean SBP was estimated for each country for each of the five relevant GBD age groups ( $>30$ years) by using the fitted regression model to predict the best estimates within each country at the midpoints of each age group. A similar approach was used to estimate the standard deviations for each age, sex and country combination.

## Subregional level estimates

Estimates for each of the 14 subregions were made by weighting across the country-level estimates by their respective population sizes. For example, the following estimates for females were made for countries within WPR-A (Table 6.4). The weight given to each country within this subregion is equal to the percentage of total subregional population for each of the three respective countries.

Table 6.4 Estimates of age-specific mean SBP levels ( mmHg ) for females in WPR-A by country and pooled for the whole subregion

|  | Age group (years) |  |  |  |
| :--- | ---: | ---: | ---: | ---: |
| Country | $30-44$ | $45-59$ | $60-69$ | $70-79$ |

Country-level estimates were possible in 69 countries (with 61 of these derived from the model described above) for both sexes representing all 14 subregions. For most of the subregions there was reasonable data coverage based on the literature review. However, there were some subregions for which very few data were found and estimation at the country level proved difficult. Therefore, high level of coverage, as in the example above, was not possible for all of the subregions. The two South-East Asian subregions are an example of this: data on only one country in each of these two subregions were obtained (N.B. India was the country

Note: Reported standard deviations are derived from baseline SBP (i.e. one-off measures), which when corrected for regression dilution bias were used in all calculations on the "usual" scale.
for which estimation was possible in SEAR-D). It was assumed that in these data-sparse subregions, any country-level estimates belonging to those subregions were representative of the respective overall subregional blood pressure levels. Estimates of SBP distribution are presented in Tables 6.5 and 6.6.

### 2.3 Methodology to estimate uncertainty around mean and standard deviation SBP

The level of uncertainty around the means and standard deviations also had to be estimated. The approach described in the previous section to estimate the means and standard deviations makes as complete use as possible of all available data. However, there will always be increased uncertainty associated when generalizing from the data collected. Assessing the uncertainty in SBP estimation involved considering three main sources:

1. countries with nationally representative survey data;
2. countries that had multiple studies that were heterogeneous; and
3. countries with little or no data.

First, for the eight countries where very reliable large-scale nationally representative data were available, the standard errors were taken
directly from those study data. This uncertainty reflects, almost entirely, sampling variation in those studies and was generally small.

Second, for each of the 61 countries for which data were modelled, standard errors were obtained from the model predictions made for each country, age and sex combination. These standard errors reflected the variability of the data at the study level within each country. Significant interstudy variation within a particular country resulted in a larger standard error for that country. Conversely, in cases where studies consistently provided similar blood pressure levels, standard errors were very small.

Finally, an additional type of uncertainty was incorporated to reflect that when pooling country-level estimates to the subregional level there were varying degrees of missing information between the subregions. The "A" subregions all had excellent coverage with greater than $95 \%$ of the populations in these subregions represented in the available study data. On the other hand, only data on Sri Lanka were available in SEAR-B with no study data available on all remaining countries in that subregion, providing only $6 \%$ coverage. To allow for this varying coverage, an additional factor was introduced that depended on the proportion of total subregional population covered. The regression modelling approach described earlier provided a way of summarizing how much variability between countries was unaccounted for by age, sex and subregional differences. For example, the country coefficients ranged approximately $20-25 \mathrm{mmHg}$ for females across all the countries included in the model. The degree of inter-country variation provided an indication of uncertainty in countries without data and therefore provided a basis from which to determine a suitable level of uncertainty within each subregion. One way to achieve this was to assume that the proportion of the subregion without any data had uncertainty equal to the intercountry variation. In effect, missing countries are assigned an uncertainty equivalent to choosing a country at random from the distribution of country effects (i.e. similar to a random effects approach).

The uncertainty for countries with complete, partial and no data, each obtained as described above, were then used in the relationship for pooled standard error of the mean weighted by population size. The following example illustrates how this was achieved for females aged 30-44 years in AMR-A.

```
\(\operatorname{Var}(\) Pooled mean SBP in AMR-A \()=\)
    \(w_{1}^{2} \operatorname{var}(\) mean SBP - USA \()+w_{2}^{2} \operatorname{var}(\) mean SBP - Canada \()+w_{3}^{2}\)
    var(mean SBP - Cuba)
```

where $w_{1}, w_{2}$ and $w_{3}$ are the weights equal to proportion of total subregional population in each of the three countries in AMR-A. In this example, variance estimates (i.e. square of the standard error) were derived directly from existing estimates for the United States and Canada, as there were data available for these two countries. There were no data available for Cuba and therefore the final term depended on all the other
Values of $95 \% \mathrm{Cl}$ around mean SBP $(\mathrm{mmHg})$ by subregion, sex and age

countries in the regression model and the variance in this case was equal to 20 mmHg . For subregions with low population coverage, this approach would result in much larger uncertainty. Having calculated the overall variance of the mean for a subregion, it was then converted into a $95 \%$ CI. A similar approach was taken to estimate the uncertainty for blood pressure standard deviations. Results are shown in Tables 6.7 and 6.8.

## 3. Blood pressure-disease relationships

Data on the relationship between blood pressure and disease outcomes come from two main types of study (MacMahon 1994). Prospective observational studies provide data from which the effects of prolonged blood pressure differences can be estimated (MacMahon et al. 1990). Trials provide data about the effects of short-term blood pressure reduction (Collins et al. 1990) or risk reversal. Results from prospective observational studies are discussed in this section.

### 3.1 Risk accumulation

A large number of observational studies have been conducted in a variety of settings that examine the association between blood pressure and disease. However, the results of many of these individual studies are limited. Many observational studies had small sample sizes, or an insufficient number of end-points and therefore lacked the power required to provide reliable estimates of associations for different population subgroups (e.g. sex and age groups) and/or specific diagnostic categories (MacMahon et al. 1990). Individual studies have not always provided information on the direction of the association at lower blood pressure levels, making it difficult to assess whether the observed association is continuous or has a threshold level. In addition, these studies frequently do not standardize the size of the association for bias and confoundingin particular regression dilution bias (MacMahon et al. 1990). This bias occurs when associations are calculated from "one-off" measures of blood pressure (i.e. measures taken once on one occasion) rather than "usual" blood pressure. (There is further discussion of this bias in the next section.) Overviews of observational studies, or meta-analyses of trials, overcome many of the size limitations of individual studies. At the time of writing, four major overviews have been conducted, and their main design features are summarized in Table 6.9. In contrast to the first three overviews, which utilized tabular data, the APCSC (1999) involved analyses of individual participant data. Therefore, it could more reliably adjust for confounding and provide more reliable risk estimates.

Of the four overviews, all included the stroke end-point, but only two included analyses for the IHD end-point (MacMahon et al. 1990; APCSC 2003a). Only APCSC included analyses for hypertensive disease and other cardiovascular disease (APCSC 2003a). Further advantages with this study are that all analyses were based on individual participant
Table 6.9 Characteristics of major cohort study overviews

| - No data. |  |  |  |  |

data and provided age-specific analyses of all end-points. APCSC was therefore used as the primary data source for relative risk estimates of all end-points.

## ANALYTICAL ISSUES

Regression dilution bias has particular relevance in observational studies of blood pressure, and must be accounted for in analyses. This bias occurs as baseline or one-off measures of blood pressure are subject to random fluctuations, due partly to the measurement process and partly to any real but temporary deviations at the baseline visit from the usual blood pressure level (MacMahon et al. 1990). Therefore, baseline blood pressure values have a wider distribution than the "usual" blood pressure values. With repeated measures there is a "regression to the mean" of values (MacMahon 1994) whereby an initially extreme observation tends to become less extreme with replication (Strachan and Rose 1991). This imprecision in measurement not only influences distribution, but will also affect the association with disease outcomes (MacMahon et al. 1990) (Figure 6.10).

The baseline distribution has a shallower slope on the curve relation of blood pressure to relative risk of stroke and IHD, which means there is an underestimation of the strength of the association between blood pressure and disease incidence ("regression dilution bias") (MacMahon 1994). If not corrected for, this bias systematically dilutes the apparent importance of blood pressure and can result in systematic and substantial underestimation of risk of disease with usual blood pressure (MacMahon et al. 1990).

The size of the dilution is directly related to the extent to which blood pressure measurements are subject to regression to the mean. Several

Figure 6.10 Effects of regression dilution bias on the association between SBP and relative risk of cardiovascular disease

major meta-analyses conducted in recent years aimed to address these limitations with correction for regression dilution bias (Anonymous 1998; APCSC 2003a; MacMahon et al. 1990; PSC 1995). It is possible to use repeated measures of blood pressure to obtain an estimate of the attenuation factor in order to correct for this bias in the analysis. Data from cohort studies suggest that for DBP, the relationship with stroke/IHD is about $60 \%$ steeper if 4 -year mean blood pressure values are used rather than mean values at baseline (Garcia-Palmieri and Costas 1986; Paul et al. 1963). As a result, a correction factor of 1.6 was used in early meta-analyses (MacMahon et al. 1990). However, other studies suggest that the association with usual blood pressure is twice as strong as that with baseline DBP (Aromaa 1981; Hughes and Pocock 1992) and a correction factor of 2.1 overall has been applied in the subsequent prospective studies collaboration (PSC) and Eastern meta-analyses (Anonymous 1998; PSC 1995). The APCSC meta-analyses primarily used SBP rather than DBP. The overall attenuation factor was 1.84 (APCSC 2003a). This concurs with other un-published data (PSC secretariat, personal communication) and these later meta-analyses are the most reliable source of estimates for risk accumulation.

A summary of the main results of the four prospective study overviews is presented in Table 6.10. While SBP is primarily being used to classify blood pressure in these analyses, some analyses have only published risk estimates in terms of DBP; therefore data for both indices have been presented for completeness. The risk estimates do appear slightly different across overviews, partly explained by different age distributions within the overviews.

## Stroke

There is evidence of a positive association between blood pressure and all types of stroke (Anonymous 1998; APCSC 2003a; MacMahon et al. 1990; PSC 1995). All of the overviews have demonstrated heterogeneity among studies in the strength of the association between blood pressure and stroke risk, and a major factor contributing to this variability is attenuation with age (APCSC 2003a; PSC 1995).

The slope of the association between relative risk of stroke (plotted on a log scale) and mean usual blood pressure is roughly constant, implying a log-linear relationship (Figure 6.11). This means that the relative difference in risk associated with an absolute difference in usual blood pressure is similar at all levels of blood pressure, at least within the range studied. There is no good evidence of a threshold level below which lower levels of blood pressure were no longer associated with lower relative risks of stroke (down to SBP 115 mmHg ). Likewise, there was no evidence of a threshold level above which the relative risk of stroke increases much more rapidly (Anonymous 1998; APCSC 2003a; MacMahon et al. 1990; PSC 1995). The strength of the overall relation was not altered by restricting analyses to those with and without a
Table 6.10 Summary results of major cohort study overviews

history of cardiovascular disease at baseline (APCSC 2003a; PSC 1995).

There has been no evidence in any of the overviews that the strength of association between blood pressure and stroke varies by sex (Figure 6.12). This is consistent for all age subgroups, so it is not necessary to have sex-specific estimates for CRA.

Age has an important influence on the size of the SBP-stroke relationship, as the associations are steeper for those in younger age groups (Figure 6.13). While the proportional change in stroke risk per unit change in blood pressure is less extreme in old age than in middle age, the relationship remains positive for all age groups (APCSC 2003a; PSC 1995).

The different age distributions within the four overviews therefore explain the slightly different relative risk estimates. This limits the ability to directly compare the overall relative risk estimates across the overviews, as it is only appropriate to compare age-specific results. It is therefore necessary to use age-specific risk estimates for blood pressure, provided by the APCSC data. There were no statistically significant differences in the age-specific relative risk for blood pressure and stroke between subgroups, or for stroke subtypes in APCSC analyses (2003a).

Risk estimates for the association between blood pressure and total stroke are shown in Table 6.11. These estimates of relative risk were vir-

tually unchanged when analyses adjusted for cholesterol, smoking, alcohol or past history of cardiovascular disease in the APCSC cohorts that provided these additional data.

## Ischaemic heart disease

Two overviews have published data on the association between blood pressure and risk of IHD. As with stroke, the relationship between blood pressure and IHD was log-linear with no apparent threshold levels of blood pressure (Figure 6.14).

The slope of the association of blood pressure with IHD is less than that for stroke, each 10 mmHg decrease in usual SBP was associated with about a $25 \%$ lower risk of IHD. However, in most studies the absolute effects of IHD tended to be greater because IHD was so much more common than stroke (MacMahon et al. 1990).

The blood pressure IHD association was attenuated with age (Figure 6.15), and did not differ significantly between males and females (APCSC 2003a; PSC secretariat, personal communication). A comparison of the strength of the SBP association with IHD between Asia and Australasia demonstrated that there were no differences between the age-specific relative risks in the two subgroups.

Age-specific relative risk estimates for IHD from the APCSC cohort are presented in Table 6.12. These estimates are consistent with unpublished data from PSC. They were virtually unchanged when analyses adjusted for potential confounders such as cholesterol, smoking, alcohol or past history of cardiovascular disease in the APCSC cohorts that provided these additional data.

## Hypertensive disease

The APCSC project provides the only age-specific estimates for this endpoint, and each 10 mmHg decrease in usual SBP was associated with

$46 \% ~(95 \%$ CI $40-51 \%$ ) lower risk of hypertensive disease. There were no statistically significant differences between males and females or Asia and Australasia for this end-point. As with other cardiovascular endpoints, there was attenuation with age. Age-specific relative risk estimates are shown in Table 6.13.

## Other cardiovascular end-points

The category "other cardiac disease" includes end-points such as heart failure. Overall, each 10 mmHg decrease in usual SBP was associated with $18 \% ~(95 \%$ CI $15-20 \%$ ) lower risk of other cardiac disease. The age-specific APCSC associations for this composite end-point are shown in Table 6.14.

There were no statistically significant differences in associations by sex or subregion, although there were relatively few data to assess this reliably. This end-point was defined as all cardiovascular deaths other than those due to stroke, IHD or hypertensive disease. Numerically most of these were ascribed to heart failure. Given some uncertainty about causality and the varying composition for this end-point around the world, the relative risk reductions were halved for this outcome to avoid any potential overestimation of effects.

Table 6.14 Relative risk of death from "other cardiac disease" with a 10 mmHg decrease in usual SBP

| Age group (years) | Relative risk $(95 \%$ CI) | Events |

### 3.2 RISK REVERSIBILITY

As already alluded to, prospective observational studies provide data on the association between blood pressure and stroke and IHD, but they do not provide data on the impact of blood pressure lowering on these outcomes (MacMahon et al. 1990). From prospective studies alone it is not possible to tell whether outcomes are reversible, or whether the association reflects, to some extent, irreversible cumulative effects of blood pressure differences that have persisted for years (Collins and Peto 1994).

The results from randomized clinical trials do provide data on reversibility. They are relevant to assessing how rapidly, and to what extent, the epidemiologically expected reductions in stroke and IHD are produced by lowering blood pressure (Collins and Peto 1994; Collins et al. 1990). They therefore provide estimates of the proportion of the potential long-term benefit from a particular blood pressure difference that may be expected within a few years of blood pressure lowering. This section will discuss how results from trials can be utilized in CRA analyses.

## Data sources on risk reversal

A variety of trials have studied the impact of blood pressure lowering. However, as with prospective studies, individual studies usually lack sufficient power to reliably detect moderate changes in events (Collins and Peto 1994; Collins et al. 1990; He and Whelton 2000). To accurately detect small but potentially important differences in risk reduction of cardiovascular disease (e.g. 10-15\%), it is necessary for trials to record many hundreds of end-points. At least 1000 events would be necessary to reliably detect a $15 \%$ difference in risk of myocardial infarction (MacMahon and Neal 2000). Since most have not achieved this, overviews are necessary to provide more accurate estimates of the impact of blood pressure lowering on stroke and IHD. Results from these overviews will contribute to estimates of "risk reversibility".

A variety of overviews of trials have been published. These include:

- an overview of 14 randomized trials including nearly 37000 individuals and almost 190000 patient years of follow-up (Collins and Peto 1994; Collins et al. 1990). This overview was subsequently updated including three additional trials (MacMahon and Rodgers 1993a, 1993b). The updated review included 17 trials (four large, 13 small) of pharmacological treatment including over 47000 individuals with over 12000 aged over 60 years, mean follow-up 4.9 years (MacMahon and Rodgers 1993a, 1993b).
- a review by He and Whelton (1999) included 10 trials, a total of 18542 participants, and an average follow-up of four years (He and Whelton 1999).
- Psaty et al. (1997) included 18 long-term randomized trials in their review, which included over 48000 patients followed up for an average of five years in the United States, Europe, Scandinavia, Australia and Japan (Psaty et al. 1997).
- the analyses from the Blood Pressure Lowering Treatment Trialists' Collaboration (BPLT) included data from 15 trials, 74696 individuals, mean age 62 years and $53 \%$ male (Neal et al. 2000).
- a review by Pahor et al. (2000) included nine trials and 27743 individuals (Pahor et al. 2000).
- an updated meta-analysis conducted on all trials included in previous overviews.

## Estimates of risk reversibility

## Stroke

Overviews of randomized controlled trials have all confirmed the reversibility of stroke with blood pressure lowering (Collins and Peto 1994; Collins et al. 1990; He and Whelton 1999; MacMahon and Rodgers 1993a, 1993b; Neal et al. 2000; Pahor et al. 2000; Psaty et al. 1997). The cohort study overviews already discussed suggested that a 10 mmHg lower SBP (or a 5 mmHg lower DBP) was associated with about a $30-40 \%$ lower risk of stroke. A major overview of clinical trials has demonstrated a quantitatively similar result with this level of blood pressure reduction (Collins and Peto 1994; Collins et al. 1990; MacMahon and Rodgers 1993a, 1993b). Analyses of additional trials in subsequent published overviews have had similar results (He and Whelton 1999; Neal et al. 2000; Psaty et al. 1997). The updated meta-analysis categorized trials of drugs vs placebo by drug classes, and found consistent results for each class of drug vs placebo and all trials combined (Table 6.15).

These results suggest that potentially all of the excess risk of stroke due to blood pressure can be reversed. The trial overviews also concur with cohort studies in that the reductions were similar for fatal and

Net BP reduction = blood pressure difference between the randomized groups (i.e. BP change in treatment group minus BP change in placebo group).
These trials also included older classes of drugs such as methyldopa and alkaloid
Summary mean age, \% male and net SBP and DBP change are weighted by study size for those studies that provided data on net changes in both SBP and DBP. Weighting by number of IHD events made little material difference.
non-fatal strokes, and for males and females (He and Whelton 1999). The recently completed PROGRESS trial also demonstrated similar relative risk reductions for those classified as hypertensive and non-hypertensive at the start of the trial (Progress Collaborative Group 2001). In contrast to the treatment effect demonstrated in drug vs placebo trials, the treatment effect of one drug class vs another was relatively minor. Another important piece of information from the trial overviews is the time frame of this risk reversal: the data suggest that these reductions in risk of stroke occurred after only 2-3 years of blood pressure treatment (He and Whelton 1999; MacMahon and Rodgers 1993a).

## Ischaemic heart disease

Overviews of randomized controlled trials have also confirmed the reversibility of IHD with blood pressure lowering (Collins and Peto 1994; Collins et al. 1990; He and Whelton 1999; MacMahon and Rodgers 1993a, 1993b; Neal et al. 2000; Pahor et al. 2000; Psaty et al. 1997). The cohort studies suggested that a 10 mmHg lower SBP (or a 5 mmHg lower DBP) was associated with about a $20-25 \%$ lower risk of IHD. Overviews of clinical trials have demonstrated that this magnitude of blood pressure reduction is associated with about a $15-20 \%$ reduction in IHD (Collins et al. 1990; He and Whelton 1999; MacMahon and Rodgers 1993a), which was confirmed by the updated meta-analysis (Table 6.15).

There were similar reductions for fatal and non-fatal strokes, for males and females (He and Whelton 1999), and for those with and without hypertension (Progress Collaborative Group 2001). As with stroke, these reductions in risk occurred after 2-3 years of blood pressure treatment (He and Whelton 1999; MacMahon and Rodgers 1993a). These data suggest that approximately two thirds of blood pressure related risk of IHD (not all) was reversed in this time frame.

The data indicate that within $3-5$ years, 10 mmHg lower SBP resulted in reversal of most or all of the epidemiologically expected risk for stroke events and approximately two thirds of IHD. Likewise, it will be assumed that most or all of the expected risk for hypertensive disease and approximately two thirds of other cardiovascular disease will be reversed in this time frame. The time frames for reversibility from trials are important for estimating avoidable burden, but the trial relative risk estimates will not be used. There are a variety of problems with the generalizability of trial relative risk data, which make it less appropriate than prospective study data. These limitations include the fact that many trials only used mortality as an end-point (Linjer and Hansson 1997) and they were not powered for adequate subgroup analyses (e.g. age and sex subgroups). Overall, using relative risks from cohort studies will lead to conservative estimates of relative risk and avoidable burden because the clinical trial data have not to date demonstrated the age attenuation in relative risks that is observed in the epidemiological data.

In summary, data from the APCSC will be used for risk accumulation complemented by data from other overviews such as PSC. The main findings were direct, positive and continuous associations of usual SBP with the risks of all end-points of interest. The risks were similar by sex and subregion, except for a stronger association of blood pressure with stroke in Asian compared to non-Asian populations, due partly to the higher proportion of haemorrhagic strokes. Few data were available for the GBD end-point "other cardiac disease" and so given some uncertainty about causality and the varying composition for this end-point around the world, the relative risks will be halved for this outcome. There was attenuation of proportional associations with age for all these outcomes.

Data on risk reversibility come from overviews of all unconfounded randomized trials of blood pressure lowering. For the CRA analyses, it is proposed to use the observational epidemiological data for risk accumulation and use the trial overviews for the time frame of risk reversibility. For example, in middle age the epidemiology suggests that a 10 mmHg increase in SBP is associated with about $40 \%$ more stroke and $25 \%$ more IHD. The trials suggest that within $3-5$ years of lowering SBP by 10 mmHg , most or all of this increased risk for stroke and hypertensive disease is reversed and approximately two thirds for IHD and cardiovascular disease.

## 4. Results

### 4.1 Attributable fraction

The "attributable fraction" refers to the proportion of disease burden that would theoretically not have occurred if the population distribution of blood pressure had been equal to that of the theoretical minimum (mean SBP of 115 mmHg ). The attributable fractions for each of the endpoints increased initially with age in males and females, but then declined for the oldest age groups, reflecting the balance between increasing mean SBP, and decreasing relative risks with age.

## Stroke

Globally, $62 \%$ of stroke is attributable to $\mathrm{SBP}>115 \mathrm{mmHg}$ (range of $52-78 \%$ by subregion). Subregions with the lowest attributable fractions included AFR-E, AMR-D, SEAR-D and EMR-D. In contrast, EUR-B and EUR-C had the highest values. In most subregions the attributable fraction for males and females were similar (within $5 \%$ ).

## ISCHAEMIC HEART DISEASE

Globally, $49 \%$ of IHD is attributable to $\mathrm{SBP}>115 \mathrm{mmHg}$ (range of $40-64 \%$ by subregion). Subregions with the lowest attributable fractions included AMR-A, AMR-D, SEAR-D and WPR-B. In contrast, EUR-B and EUR-C had the highest values.

## Hypertensive disease

Globally, $76 \%$ of hypertensive disease is attributable to SBP $>115 \mathrm{mmHg}$ (range of $64-90 \%$ by subregion). Subregions with the lowest attributable fractions included AFR-E, EMR-D, AMR-D and SEAR-D. In contrast, EUR-B and EUR-C had the highest values.

## OTHER CARDIOVASCULAR DISEASE

Globally, $14 \%$ of other cardiovascular disease is attributable to SBP $>115 \mathrm{mmHg}$ (range of $8-22 \%$ by subregion). Subregions with the lowest attributable fractions included AMR-D, EMR-D, SEAR-D and WPR-B. In contrast, EUR-B and EUR-C had the highest values.

### 4.2 Attributable burden

For the year 2000, WHO estimated that there were 55.9 million deaths and 1455 million DALYs worldwide; about $22 \%$ of these deaths and $7 \%$ of these DALYs were due to ischaemic heart disease and stroke. The burden of disease was distributed across the developed and developing world (e.g. about one quarter of all stroke deaths and one third of IHD deaths occurred in the least developed subregions), and predominantly affected those aged $>60$ years.

The "attributable burden" refers to the number of deaths or DALYs that would theoretically not have occurred if the population distribution of blood pressure had been equal to that of the theoretical minimum (mean SBP of 115 mmHg ). In total, the attributable burden equated to 3.1 million stroke deaths, just under 3.0 million IHD deaths, about 0.7 million hypertensive disease deaths and 0.3 million other cardiovascular disease deaths. For DALYs these figures were 27.8 million stroke DALYs, 28.2 million IHD DALYs, 5.4 million hypertensive disease DALYs and 2.8 million other cardiovascular disease DALYs (Table 6.16).

Worldwide this means that 7.1 million deaths (about $12.8 \%$ of the total) and 64.3 million DALYs ( $4.4 \%$ of the total) were estimated to be due to non-optimal blood pressure. The proportion of DALYs was lower than the proportion of deaths, as most blood pressure-related cardiovascular disease events occurred in middle or old age, so the years of life lost due to premature mortality and years of life lost due to disability is a smaller percentage of the total DALYs than of the total deaths.

The age group with the greatest attributable deaths for both males and females was 70-79 years. The number of attributable deaths then declined, reflecting the smaller denominator population, and the smaller total number of events in the oldest age group. For DALYs, this decline occurred sooner, as there are less years of life lost and years of life lived with disability with advancing age. For example, $48 \%$ of excess IHD deaths were in those aged $\geq 70$ years, compared to $24 \%$ of excess DALYs.

For each end-point, the attributable deaths were higher for males than females for the age categories $30-44,45-59$ and $60-69$ years. In
Table 6.16 Attributable deaths and DALYs for systolic blood pressure $>115 \mathrm{mmHg}$, by cardiocvascular end-point and subregion

| EUR-C | 513 | 603 | 35 | 35 | 4134 | 5239 | 312 | 333 |
| SEAR-B | 115 | 100 | 48 | 9 | 1185 | 1050 | 458 | 103 |
| SEAR-D | 451 | 650 | 49 | 36 | 4262 | 7080 | 539 | 446 |
| WPR-A | 91 | 51 | 7 | 11 | 736 | 400 | 33 | 63 |
| WPR-B | 944 | 291 | 198 | 35 | 8315 | 2664 | 1601 | 247 |
| World | 3149 | 2991 | 663 | 338 | 27829 | 28201 | 5440 | 2801 |

contrast, attributable deaths were higher for females in the oldest age groups: 70-79 and $\geq 80$ years. There was a similar trend for attributable DALYs. This was due to older females having higher mean SBP (and therefore greater attributable fraction) than males, and there are also a larger number of cardiovascular deaths occurring in older females compared to older males.

## Stroke

The subregion with the highest attributable stroke burden was WPR-B ( 944000 deaths, 8.3 million DALYs), followed by EUR-C ( 513000 deaths, 4.1 million DALYs) and SEAR-D ( 451000 deaths, 4.3 million DALYs).

## ISCHAEMIC HEART DISEASE

SEAR-D had the highest attributable IHD burden ( 650000 deaths, 7.1 million DALYs), followed by EUR-C ( 603000 deaths, 5.2 million DALYs), EUR-A (290000 deaths, 2.1 million DALYs) and WPR-B (291000 deaths, 2.6 million DALYs).

## Hypertensive disease

The attributable burden for hypertensive disease, was highest in WPRB (198000 deaths, 1.6 million DALYs), followed by EUR-B and A for deaths ( 58000 and 56000, respectively) and SEAR-D and B for DALYs ( 539000 and 458000 , respectively).

## Other cardiovascular disease

The highest attributable burden for other cardiovascular disease was in EUR-A ( 70000 deaths, 381000 DALYs), SEAR-D (36000 deaths, 446000 DALYs) and EUR-B ( 40000 deaths, 272000 DALYs).

Overall, approximately one third of attributable DALYs occurred in the most developed subregions ( 23.3 million), a further third (20.3 million) in low mortality developing subregions and a final third (20.7 million) in high mortality developing subregions. A higher proportion of these deaths and DALYs were from IHD than stroke in developed and high mortality developing subregions, but more were stroke than IHD in low mortality developing subregions.

These results indicate where most of the worldwide attributable cardiovascular disease burden occurred, and provide any given subregion with an indication of absolute size of the attributable burden. However, the age structure, population size and the number of estimated events occurring in a subregion, influences the ranking of subregions by absolute number of attributable deaths and DALYs. The relative impact of the attributable DALYs indicates that between 3-33\% of all deaths and $1-17 \%$ of all DALYs across the subregions were attributable to nonoptimal blood pressure. Approximately $22 \%$ of all deaths and $11 \%$ of
all DALYs were attributable to non-optimal blood pressure in developed subregions, $14 \%$ and $5.0 \%$, respectively, in low mortality developing subregions, and $7.5 \%$ and $2.5 \%$, respectively, in high mortality developing subregions.

## 5. Discussion

### 5.1 Attributable deaths and DALYs

The analyses in this chapter suggest that globally, a substantial proportion of cardiovascular disease is attributable to non-optimal blood pressure, defined as mean SBP $>115 \mathrm{mmHg}$. Overall, about two thirds of stroke, one half of IHD, and about three quarters of hypertensive disease were attributable to non-optimal blood pressure. The attributable fractions were higher in the more developed parts of the world than the least developed regions, as would be expected given the higher blood pressure levels.

Worldwide, 7.1 million deaths (about $12.8 \%$ of the total) and 64.3 million DALYs $(4.4 \%$ of the total) were estimated to be due to nonoptimal blood pressure. Overall, the results suggest that a considerable proportion of cardiovascular disease is related to non-optimal blood pressure and this translates into an important portion of deaths and years of life lost to deaths and disability worldwide.

### 5.2 Attributable deaths and DALYs by subregion

In absolute terms, most of the excess burden of cardiovascular disease occurred in the populous subregions of WPR-B, SEAR-D and EUR-C; each subregion accounted for approximately $15-20 \%$ of worldwide attributable deaths and DALYs. The relative impact that attributable deaths and DALYs have in different subregions may also be calulcated as the proportion of all deaths and DALYs attributable to non-optimal SBP (i.e. mean $>115 \mathrm{mmHg}$ ) within each specific subregion. Overall, between $3-33 \%$ of all deaths and $1-17 \%$ of all DALYs across the subregions were attributable to non-optimal blood pressure. Excess cardiovascular disease burden was highest in European subregions where mean blood pressure levels were highest.

### 5.3 Comparison with the first WHO GBD study

The WHO GBD study in 1990 estimated that $8.7 \%$ of all deaths were due to stroke and $12.4 \%$ were due to IHD worldwide, compared to $9.5 \%$ and $12.5 \%$ in the current 2000 WHO estimates. Worldwide, $2.8 \%$ of all DALYs were from stroke in 1990 and $2.9 \%$ in 2000, and for IHD these percentages were $3.4 \%$ in 1990 and $3.8 \%$ in 2000 . These percentages relate to worldwide estimates, and will vary across subregions. The 2000 WHO estimates indicated that about $5.8 \%$ of DALYs were due to stroke in developed subregions, which compares to $5.0 \%$, and
the percentage of DALYs attributed to IHD across these studies was $9.2 \%$ (2000), compared to $9.0 \%$ in 1990. (Murray and Lopez 1996).

In terms of attributable burden, both GBD studies have estimated the total number of deaths and DALYs attributable to non-optimal blood pressure. A key difference is that the current estimates of burden attributable to blood pressure are approximately double those of the 1990 estimates. Worldwide $5.8 \%$ of deaths and $1.4 \%$ of DALYs were attributable to blood pressure in 1990, compared to $12.8 \%$ of deaths and $4.4 \%$ of DALYs in these analyses.

Potential reasons for the increases in the estimates include differences in the estimates of blood pressure prevalence; the theoretical minimum or comparison blood pressure group; the relative risk estimates; and in the way that DALYs were estimated. There were some differences in the studies used to estimate blood pressure prevalence and the comparison blood pressure level ( 110 vs 115 mmHg ), but these would not have been sufficient to account for an approximate doubling of the burden attributable to blood pressure. A particularly important difference however, relates to the relative risk estimates used. The 1990 estimates did not correct for regression dilution bias. As discussed earlier, this bias occurs when relative risk estimates are based on one-off measures of blood pressure, which are subject to random fluctuations. Correcting for this bias with re-measurement data results in "regression to the mean" of blood pressure values, and a steeper association between blood pressure and disease outcomes. Without correction for this bias there will be systematic underestimation of risk of cardiovascular disease by a factor of about two. This therefore explains the almost doubling of burden attributable to blood pressure in the current estimates, and also indicates that the current estimates are the most comprehensive, accurate and robust.

## 6. Estimating future exposure

We used the following basic steps for estimating future exposure, with each step to some extent dictating the following step.

1. The literature was reviewed to assess what is already known about trends in blood pressure in different populations.
2. Regions were categorized into broad groupings based on likely direction of changes in blood pressure levels over time.
3. The future trends in blood pressure distribution were estimated.

### 6.1 Literature review of blood pressure trends over time

There is considerable evidence in the literature that changes in risk factors such as blood pressure occur over time. For example, a variety of studies from different world regions and populations have demonstrated increases and decreases in blood pressure levels.

## Established market economies (AMR-A, EUR-A, WPR-A)

A large number of studies have documented reductions in mean blood pressure levels in populations in "A" subregions over the past 30 years. These studies have included populations in countries such as the United Kingdom (Capewell et al. 1999; McCarron et al. 2001), New Zealand and Australia (Bonita 1993; Bonita and Beaglehole 1986, 1987; Capewell et al. 2000; Dobson et al. 1999), the United States (Burt et al. 1995; Garraway and Whisnant 1987; McGovern et al. 1996), Finland (Tuomilehto et al. 1991; Vartiainen et al. 1994), Iceland (Sigfusson et al. 1991), Switzerland (Wietlisbach et al. 1997) and Japan (Okayama et al. 1993; Sakata and Labarthe 1996; Shimamoto et al. 1989; Ueshima et al. 2000).

The populations surveyed, the methodologies used, and the time periods and durations covered varied greatly between studies, however, mean SBP levels have decreased by up to $5-10 \mathrm{mmHg}$ for a 10 -year period (Bonita 1993; Bonita and Beaglehole 1986, 1987; Capewell et al. 1999, 2000; McCarron et al. 2001; Shimamoto et al. 1989; Sigfusson et al. 1991; Vartiainen et al. 1994; Ueshima et al. 2000). However, in more recent studies (from the mid-1980s onwards) these decreases have been less than 5 mmHg per 10 years (Dobson et al. 1999; McGovern et al. 1996; Okayama et al. 1993; Sakata and Labarthe 1996; Wietlisbach et al. 1997). Data also indicate that the reduction in mean SBP levels has been greatest in the oldest age groups (e.g. mean SBP levels from national Japanese survey data declined by about 2 mmHg in those aged $30-39$ and $40-49$ years between 1980 and 1990 , but by $3-5 \mathrm{mmHg}$ in those aged $>70$ years) (Sakata and Labarthe 1996).

Low mortality subregions (AMR-B, EMR-B, EUR-B, EUR-C, SEAR-B, WPR-B)
These subregions are quite varied and there are little reliable time trend data. Survey data from the Czech Republic demonstrated only small changes in blood pressure between 1985 and 1992 (Bobak et al. 1997). In China, there is some evidence of increasing blood pressure levels in the past 10 years (Chow and Muyinda 1999; Wu et al. 1996), and in the Republic of Korea, between 1984 and 1999 there were only small changes in the prevalence of hypertension (Suh 2001).

```
High mortality subregions (AFR-D, AFR-E, AMR-D, EMR-D,
SEAR-D)
```

Very little reliable longitudinal survey data are available in these subregions. However, data from a variety of more "traditional" populations with lower blood pressure have demonstrated that as those populations become more industrialized, risk factor profiles such as blood pressure change. This is particularly evident in migration studies where there is evidence from studies conducted in a variety of settings (Poulter and Sever 1994), such as Africa (Poulter et al. 1988, 1990), China (He et al.

1991a, 1991b) and the Pacific (Joseph et al. 1983; Salmond et al. 1985, 1989), that blood pressure levels rise after migration to more urbanized settings. Pre-migration data suggest that these changes are not due to selective migration (Poulter et al. 1988). Instead, it is likely that factors such as dietary changes of increased intake of sodium, animal protein, fat, and processed foods, and decreased intake of potassium, and vegetable protein are important (He et al. 1991a, 1991b; Poulter and Sever 1994; Poulter et al. 1988). Obviously, the lifestyle and blood pressure changes in an entire population will be slower than those that occur in migrant groups.

## Potential categories of blood pressure change

Data presented above indicate that subregions may be classified into three broad groups, and changes in blood pressure over the next 10,20 and 30 years may be based on trends already documented. Assuming that the absolute increases and decreases in SBP are similar for males and females but greater in the older age groups, the following general scenario was considered.

These changes suggest that:

- the A subregions will experience small decreases in mean SBP levels over the next 30 years, which is consistent with recent literature (Dobson et al. 1999; McGovern et al. 1996; Okayama et al. 1993; Sakata and Labarthe 1996; Wietlisbach et al. 1997). However, with time these reductions attenuate.
- in the case of $B$ and $C$ subregions, there is no change initially in mean SBP levels, but in the following 10-year and 20-year periods there are small decreases in SBP as improvements in lifestyle occur.
- in the case of D and E subregions, small increases in mean SBP levels occur over the entire 30-year period; however these are greater at the beginning (2000-2010) and then start to lessen and level out (See Table 6.17).

Due to the limited data available, these estimates are susceptible to a high degree of uncertainty. There is a wide range of factors that could influence future risk factor levels, and it is difficult to capture these factors even with sophisticated modelling. A decision was therefore made to use a relatively simple, but transparent method for the purposes of these analyses.

Estimates of mean blood pressure levels over time
Tables 6.18-6.20 summarize mean SBP levels by subregion, sex and age in 2010, 2020 and 2030.

Table 6.I7 Scenario for changes in mean SBP levels $(\mathrm{mmHg})$ by age and subregion over the next IO, 20 and 30 years

|  | $30-44$ years | $45-59$ years | $60-69$ years | $70-79$ years | $\geq 80$ years |

## Acknowledgements

Particular thanks are due to the Asia-Pacific Cohort Studies Collaboration secretariat, and all study collaborators for allowing us to access and analyse their data for estimates of relative risk. The Prospective Studies Collaboration assisted with analyses and provided unpublished data on relative risk estimates that could be compared with those presented here.

The authors are grateful to Varsha Parag and Derrick Bennett for biostatistical support, including analyses of data from the Asia-Pacific Cohort Studies Collaboration. Angela Hurley provided valuable research assistance and Clarissa Gould-Thorpe lent much appreciated secretarial support.

## Note

1 See the preface for an explanation of this term.

IN THE REVIEW
Africa

| Subregion | Country or area | Study (reference) | Sampling methods | Response rate | BP measurement |
| :---: | :---: | :---: | :---: | :---: | :---: |
| AFR-D | Gambia | van der Sande et al. (1997) | Multi-stage stratified cluster sampling based on the 1993 census | 94.9\% | ?Trained \& certified staff <br> Automated electronic sphg ?cuff <br> 2 measures taken ?position after ?mins rest, ?arm |
|  | Ghana | Nyarko et al. (1994) | Employees from the University of Ghana were randomly selected | Not stated | Trained \& certified staff ?sphg ?cuff <br> ?measure taken ?position after ?mins rest, ?arm |
|  | Liberia | Giles et al. (1994) | House-to-house survey of adults in rural area | 84\% | ?Trained \& certified staff <br> Automated digital sphg ?cuff <br> 2 measures taken sitting after 5 mins rest, $L$ arm |
|  | Mauritius | Nan et al. (1991) | Population clusters were selected randomly by 2stage process based on census | $\begin{aligned} & 83.4-88.9 \% \\ & (M \text { and } F) \end{aligned}$ | ?Trained \& certified staff Standard sphg one cuff 2 measures taken sitting after 5 mins rest, R arm |
|  | Nigeria | Akinkug (P. Elliot, personal communication, 2001) | Community sample | Not stated | Trained \& certified staff Standard sphg one cuff 2 measures taken sitting after 5 mins rest, ? arm |
|  | Nigeria | Bunker et al. (1992) | Sample of urban civil servants from six ministries of Bendel State | Not stated | Trained \& certified staff Standard sphg various cuffs 3 measures taken sitting after 5 mins rest, ?arm |
|  | Nigeria | Idahosa (1985) | Sample of males from the Edos tribal group in Benin | Not stated | Trained \& certified staff Automated sphg various cuffs 3 measures taken sitting after 5 mins rest, ?arm |

Africa (continued)

| Subregion | Country or area | Study (reference) | Sampling methods | Response rate | BP measurement |
| :---: | :---: | :---: | :---: | :---: | :---: |
|  | Nigeria | Idahosa (1987) | Cross sectional survey in Bendel, Nigeria | Not stated | Trained \& certified staff <br> Automated digital sphg one cuff <br> 2 measures taken sitting after 5 mins rest, R arm |
|  | Nigeria | Idahosa and Llwawole (1984) | Survey of Corps members stationed in Bendel State | Not stated | Trained \& certified staff Standard sphg one cuff 3 measures taken sitting after 5 mins rest, R arm |
|  | Nigeria | Ogunlesi et al. (1991) | Sample taken from male employees at a factory in Ibadan, Nigeria | Not stated | Trained \& certified staff Automated sphg various cuffs ?measure taken sitting after 5 mins rest, R arm |
|  | Nigeria | Okesina et al. (1999) | Houses in villages selected randomly, then individuals randomly selected | Not stated | ?Trained \& certified staff Standard sphg ?cuff ?measures taken sitting after ?mins rest, ?arm |
|  | Nigeria | Oviasu and Okupa (1980a, 1980b) | Cross sectional survey of workers in state capital secretariat | 95\% | Trained \& certified staff Standard sphg one cuff 2 measures taken sitting after 5 mins rest, $L$ arm |
|  | Senegal | Astagneau et al. (1992) | Random inclusion of households using a town map | 96\% <br> households then 86\% individuals | Trained \& certified staff Standard sphg one cuff 2 measures taken sitting after 5 mins rest, ?arm |
|  | Senegal | Lang et al. (1988) | Sample taken from crosssectional survey of employees of six companies in Dakar, Senegal | 97\% | Trained \& certified staff Standard mercury sphg ?cuff ?measure taken sitting after 5 mins rest, ?arm |
|  | Seychelles | Bovet et al. (1991) | Age and sex strata random sampling from national census | 84-89\% | Trained \& certified staff Standard sphg various cuffs 2 measures taken sitting after 5 mins rest, R arm |

|  | Sierra Leone | Lisk et al. (1999) | Multistage random sampling from census | Not stated | Trained \& certified staff Standard sphg one cuff 2 measures taken sitting after 5 mins rest, $L$ arm |
| :---: | :---: | :---: | :---: | :---: | :---: |
| AFR-E | Democratic <br> Republic of the Congo | M'Buyamba-Kabangu et al. (I986, I987) | Rural population sampled from one village and compared to random sample of urban population | Not stated | Trained \& certified staff Standard aneroid sphg one cuff 5 measures taken sitting after 5 mins rest, R arm |
|  | Ethiopia | Pauletto et al. (1994) | From the outpatient department of a rural hospital | Not stated | Trained \& certified staff Standard sphg various cuffs 2 measures taken sitting after 5 mins rest, R arm |
|  | Kenya | INTERSALT study (Anonymous 1989a) | A stratified random sample representative of population | Not stated | Trained \& certified staff RZ sphg various cuffs 2 measures taken sitting after 5 mins rest, R arm |
|  | Kenya | Poulter et al. (1984) | Random from census | Not stated | Trained \& certified staff <br> Standard sphg ?cuff <br> 2 measures taken ?position after 5 mins rest, ?arm |
|  | Malawi | Simmons et al. (1986) | Two cross sectional surveys of an urban estate and "typical" rural villages | 96.9\% | Trained \& certified staff Standard sphg various cuffs 2 measures taken sitting after 5 mins rest, R arm |
|  | South Africa | CORIS study (P. Elliot, personal communication, 2001) | A stratified sample by age and sex from census data | Not stated | Trained \& certified staff Standard sphg various cuffs 2 measures taken sitting after 5 mins rest, R arm |
|  | South Africa | Mollen (P. Elliot, personal communication, 2001) | Community sample | Not stated | Trained \& certified staff <br> Standard sphg one cuff 2 measures taken sitting after 5 mins rest, ? arm |

Africa (continued)

| Subregion | Country or area | Study (reference) | Sampling methods | Response rate | BP measurement |
| :---: | :---: | :---: | :---: | :---: | :---: |
|  | South Africa | Morbid (P. Elliot, personal communication, 2001) | Community sample | Not stated | Trained \& certified staff Standard sphg one cuff 2 measures taken sitting after 5 mins rest, ? arm |
|  | South Africa | Seedat (P. Elliot, personal communication, 2001) | Community sample | Not stated | Trained \& certified staff Standard sphg one cuff 2 measures taken sitting after 5 mins rest, ? arm |
|  | South Africa | Seedat et al. (1982) | House-to-house study of urban and rural population | Not stated | Trained \& certified staff Standard aneroid sphg various cuffs 3 measures taken sitting after 5 mins rest, ?arm |
|  | South Africa | Steyn et al. (1985) | A stratified sample by age and sex from census data | Not stated | Trained \& certified staff Standard sphg various cuffs 2 measures taken sitting after 5 mins rest, R arm |
|  | South Africa | Steyn et al. (1996) | A stratified proportional sample from target population using census data | Not stated | Trained \& certified staff Standard sphg various cuffs 2 measures taken sitting after 5 mins rest, R arm |
|  | United Republic of Tanzania | Edwards et al. (2000) | Randomized cluster sampling based on households from censusall adults in house | $\begin{aligned} & \text { 80-85\% (Shari) } \\ & \text { 64-79\% (Ilala) } \end{aligned}$ | Trained \& certified staff Standard sphg various cuffs 2 measures taken sitting after 5 mins rest, R arm |

|  | United Republic of Tanzania | Kitange et al. (1993) | Whole population in four villages, random sample in four | 60-94\% | ?Trained \& certified staff <br> Standard sphg ?cuff <br> 2 measures taken sitting after 5 mins rest, R arm |
| :---: | :---: | :---: | :---: | :---: | :---: |
|  | United Republic of Tanzania | Swai et al. (1993) | Community based survey of eight villages in three areas in rural United Republic of Tanzania | 90.9-96\% | Trained \& certified staff <br> Standard mercury sphg ?cuff <br> 2 measures taken sitting after ?mins rest, R arm |
|  | Zimbabwe | Allain and Matenga (T. Allain, personal communication, 2001) | Stratified sampling | Not stated | Trained \& certified staff Standard sphg ? various cuffs 2 measures taken sitting after 5 mins rest, R arm |
|  | Zimbabwe | Hunter et al. (2000) | From health facilities | Not stated | Trained \& certified staff RZ sphg various cuffs 2 measures taken sitting after 5 mins rest, R arm |
|  | Zimbabwe | INTERSALT study <br> (Anonymous 1989a) | A stratified random sample representative of population | Not stated | Trained \& certified staff RZ sphg various cuffs 2 measures taken sitting after 5 mins rest, R arm |
|  | Zimbabwe | Mufunda et al. (2000) | Random sampling of household clusters, then sampled adults according to "probability proportionate to size"over sampling of older age groups | 56\% of potentially eligible, 79\% of those contacted | Trained \& certified staff Automated and standard sphg various cuffs 2 measures taken sitting after 5 mins rest, R arm |

## Chapter 7

# High cholesterol 

Carlene M.M. Lawes, Stephen Vander Hoorn, Malcolm R. Law and Anthony Rodgers

## Summary

Cholesterol is a fat-like substance, found in the blood stream and also in bodily organs and nerve fibres. While there are different etiological roles for various types of cholesterol, such as high and low density lipoprotein, the large majority of descriptive and epidemiological data are available only for total cholesterol levels. Therefore, in this analysis, cholesterol was defined as total serum cholesterol expressed in millimoles per litre of blood ( $\mathrm{mmol} / \mathrm{l}$ ) a continuous variable with mean and standard deviation.

The primary outcomes assessed were ischaemic heart disease (Global Burden of Disease [GBD] study end-point 107) and non-fatal stroke (end-point 108). Ischaemic heart disease (IHD) was chosen on the basis of clear and consistent positive associations observed in cohort studies and evidence of reversibility in clinical trials of cholesterol lowering treatments. Cholesterol is positively associated with ischaemic stroke, but has a qualitatively different association with haemorrhagic stroke. As endpoints must all be mapped to the GBD classification system for disease, total stroke was used in the analyses. However, application of relative risk estimates to the 14 subregions ${ }^{1}$ were adjusted to reflect differences in stroke subtypes. Cholesterol has been observed to be inversely associated with a number of other outcomes such as cancer and chronic respiratory disease. However, evidence suggests that these associations are due to the effects of disease on cholesterol, rather than vice versa. Consequently these outcomes were not included.

Raw cholesterol data were obtained from studies after a systematic review of population-based surveys, which included about 160 surveys and almost 640000 participants. Sex-specific associations of cholesterol with age were estimated for each of the subregions separately, based on country-weighted study estimates of mean values. There was moderate variation in the final age- and sex-specific estimates of mean cholesterol
across the 14 subregions, with the range between the highest and lowest age-specific mean cholesterol levels typically being about $2 \mathrm{mmol} / \mathrm{l}$.

A theoretical-minimum-risk distribution of cholesterol (i.e. one that would yield the lowest population risk of adverse health outcomes) was taken as 3.8 standard deviation $0.6 \mathrm{mmol} / \mathrm{l}$ (usual) for all age, sex and subregional groups. The main basis for this estimate was the level of cholesterol down to which epidemiological relationships with cardiovascular disease outcomes are observed, and clinical trial data showing benefits from cholesterol lowering among those with below-average cholesterol levels. This theoretical minimum was also consistent with the levels of cholesterol in populations with little cardiovascular disease.

For the comparative risk assessment (CRA) analyses, observational epidemiological data were used to estimate the hazard ratios for the risk factor-disease relationship and trial meta-analyses for the time frame of risk reversibility. Data on hazard ratios for IHD were included from an overview of the ten largest observational studies conducted in populations from industrialized countries. This overview included data from 494804 participants followed for 7-23 years, among whom 18811 IHD events were observed. There was evidence of differences in the strength of the association by age but no difference between males and females. These data were closely similar in size and shape to the associations seen in an overview of 29 cohorts involving 353065 participants from the Asia-Pacific region. In this individual participant meta-analysis, 2937 strokes were observed as well as 2838 IHD events. Overall, each $0.6 \mathrm{mmol} / \mathrm{l}$ lowering of usual cholesterol was associated a $27 \%$ reduction in IHD. A $1 \mathrm{mmol} / / \mathrm{lowering}$ of cholesterol was associated with a $13 \%$ (range $6-19 \%$ ) reduction in total stroke, predominantly due to the effect on ischaemic stroke.

An overview of 49 trials of cholesterol lowering indicated that risk reductions in IHD of $11 \%, 24 \%, 33 \%$ and $36 \%$ are associated with a $1 \mathrm{mmol} / \mathrm{l}$ reduction in cholesterol after $1,2,3-5$ and $>5$ years, respectively. Taking into account the size of the reduction in cholesterol, there was no clear difference in effects according to how the cholesterol reduction was achieved, either by diet or any one of several classes of drugs. These data indicated that in middle age, the risks associated with high cholesterol are reversed within a few years of cholesterol lowering. A meta-analysis of cholesterol lowering trials also confirmed a reduction in risk of stroke with cholesterol lowering.

The foregoing methods and assumptions allowed estimates of burden attributable to cholesterol levels of more than $3.8 \mathrm{mmol} / \mathrm{l}$. Overall, $56 \%$ of IHD mortality and disease burden was attributable to cholesterol $>3.8 \mathrm{mmol} / \mathrm{l}$ worldwide (range of $44-68 \%$ by subregion). This translated into 3609000 deaths in the year 2000 . Also $32 \%$ of ischaemic stroke was attributable to cholesterol $>3.8 \mathrm{mmol} / \mathrm{l}$ worldwide (range of $25-45 \%$ by subregion), which translated into 805000 deaths in the year 2000 .

Worldwide, 4.4 million deaths (about $7.9 \%$ of the total) and 40.4 million disability-adjusted life years (DALYs) $(2.8 \%$ of the total) were estimated to be due to non-optimal cholesterol. The proportion of DALYs was lower than the proportion of deaths as most cholesterolrelated cardiovascular disease events occurred in middle or old age, so the years of life lost due to premature mortality and years of life lost due to disability is a smaller percentage of the total DALYs than of the total deaths. Overall, the results suggest that a considerable proportion of cardiovascular disease is attributable to non-optimal cholesterol, defined as mean cholesterol $>3.8 \mathrm{mmol} / 1$, and this translates into an important portion of deaths and years of life lost to deaths and disability worldwide. Approximately $40 \%$ of the cholesterol-related attributable burden occurred in developed subregions, $20 \%$ in low mortality developing subregions (AMR-B, EMR-B, EUR-B, EUR-C, SEAR-B, WPR-B), and a further $40 \%$ in high mortality developing subregions (AFR-D, AFR-E, AMR-D, EMR-D, SEAR-D).

In absolute terms, most of the excess burden of cardiovascular disease occurred in the populous regions, as would be expected. The relative impact of attributable deaths and DALYs-calculated as the proportion of all deaths and DALYs attributable to non-optimal cholesterol (i.e. mean $>3.8 \mathrm{mmol} / \mathrm{l}$-was highest in the European subregions, where mean cholesterol levels were highest.

## 1. Introduction

Cholesterol is a fat-like substance, found in the blood stream and also in bodily organs and nerve fibres. Most cholesterol in the body is made by the liver from a wide variety of foods, but especially from saturated fats, such as those found in animal products. A diet high in saturated fat content, heredity, and various metabolic conditions such as type II diabetes, influence an individual's level of cholesterol.

### 1.1 Choice of exposure variable

Cholesterol was described as a continuous variable, as it is commonly reported in this manner with mean and standard deviation values. The System Internationale (SI) unit for measuring cholesterol is millimoles per litre of blood ( $\mathrm{mmol} / \mathrm{l}$ ), but in some studies, particularly those from the United States of America and Japan, it is reported in milligrams per decilitre of blood (conversion factor $1 \mathrm{mg} / \mathrm{dl}=0.02586 \mathrm{mmol} / \mathrm{l}$ ). Total cholesterol was chosen in preference to other potential measures of risk associated with blood lipids (e.g. high density lipoprotein [HDL cholesterol] and low density lipoprotein [LDL cholesterol]) as more data and information were available on both risk factor levels and the risk-factor-disease relationship (relative risk values) for total cholesterol.

### 1.2 Disease outcomes

A number of diseases are associated with non-optimal cholesterol levels. Cholesterol is thought to amplify and accelerate atherosclerosis, and influence IHD and ischaemic stroke events, but the exact mechanisms are unclear. It has been proposed that cholesterol, particularly LDL cholesterol which accounts for about $60 \%$ of total cholesterol in the circulation, is taken up by macrophages. When cholesterol levels are high, macrophages take up more cholesterol than they can metabolize and become "foam cells". These cells are important in the early stages of atheromatous plaque formation (Bronner et al. 1995; Gorelick et al. 1997; Warlow et al. 1996).

By contrast, there is no positive association between cholesterol and haemorrhagic stroke, and some research indicates that those people with lower levels of cholesterol are at greater risk of haemorrhagic stroke (Leppala et al. 1999; Neaton et al. 1992; Yano et al. 1994). The mechanisms are unclear, but low levels of cholesterol may weaken the endothelium of small intracranial vessels which, in combination with high blood pressure, may rupture, and/or result in "osmotic fragility" of red blood cells, thereby increasing the risk of haemorrhage (Bronner et al. 1995; Iso et al. 1989; Tanaka et al. 1982; Warlow et al. 1996). Potential outcomes considered as affected by cholesterol are described below.

## ISCHAEMIC HEART DISEASE

Data from prospective cohort studies have demonstrated a strong, continuous temporal association between cholesterol and IHD (APCSC 2003; Law et al. 1994b, 1994c; Lewington and MacMahon 1999; Neaton and Wentworth 1992; Neaton et al. 1992). Further, a causal association is biologically plausible and clinical trials have demonstrated reversibility (Bucher et al. 1998; LaRosa et al. 1999; Law et al. 1994b; Pignone et al. 2000; Ross et al. 1999). The GBD classification system for diseases and injuries has a category for total IHD (end-point 107 G3 ischaemic heart disease, the International Statistical Classification of Diseases, ninth revision [ICD-9] codes 410-414) (Bucher et al. 1998; LaRosa et al. 1999; Pignone et al. 2000; Ross et al. 1999).

## Stroke

Data on the association between cholesterol and stroke are more complex. Most major cohort studies and overviews have shown that cholesterol is positively associated with ischaemic stroke (Anonymous 1998a; Neaton et al. 1992; PSC 1995). However, there appears to be a qualitatively different association with haemorrhagic stroke, with some studies observing a negative association (APCSC 2003; Neaton et al. 1992) and others a null association with this outcome (Suh et al. 2001). There are no specific GBD end-points for stroke subtypes, only for total
stroke (end-point 108 G4 cerebrovascular disease, ICD-9 codes 430-438). However, application of RR estimates to the subregions will reflect differences in stroke subtypes, as discussed later in this chapter.

## Other disease and injury outcomes

Cholesterol has been observed to be inversely associated with a number of other outcomes such as cancer and chronic respiratory disease (Law et al. 1994a). However, evidence suggests that these associations are due to the effects of disease on cholesterol, rather than vice versa (Law et al. 1994a). Consequently these outcomes were not included.

## 2. Risk FACTOR EXPOSURE

### 2.1 Data on cholesterol levels

Data on global cholesterol levels were collated from three major sources. The first source was the MONICA study (Anonymous 1989), which collected cholesterol data from 39 collaborating centres in 22 countries and was carried out between 1979 and 1987. This study provides important information about cholesterol patterns, but does not provide a truly global overview of cholesterol distributions. It included populations that were predominantly European in origin, and did not include populations from the Eastern Mediterranean, South-East Asian or African Regions. Further, MONICA data were collected in the early 1980s, and more recent data are also available now. We therefore found it necessary to include additional cholesterol data for this analysis.

The second major source of data was a literature search using Medline and the key words "cholesterol", "survey" "health survey" and "crosssectional survey". Studies were reviewed, and included in analyses if they fulfilled the following criteria:

- conducted from 1980 onwards;
- included randomly selected or representative participants;
- had a sample size of over 1000 —however, a smaller sample size was acceptable in specific regions, or age groups where data were limited, if the study fulfilled the other criteria;
- described sample size and age group of participants;
- presented mean values of cholesterol by age and sex; and
- utilized a standard protocol for cholesterol measurement.

The final source of data was personal communications with researchers and study investigators. The authors had access to data from the Asia-Pacific Cohort Studies Collaboration (APCSC), a collaboration involving 37 cohorts in the Asia-Pacific region, which includes at least 5000 person-years of follow-up recorded or planned. Data on date of
birth or age, sex, and cholesterol have been recorded and collated (APCSC 1999). Cholesterol data from eligible studies that had been collected from 1980 onwards were included in the cholesterol database. In addition, authors of surveys/studies were contacted and age and sexspecific data requested, where these had not been available in the published format.

Many studies did not publish data in the format required for this project (e.g. omitting age- and sex-specific mean cholesterol levels), and unfortunately time and resource constraints limited attempts to obtain all of these data from researchers. It was also very difficult to obtain results of surveys that have only been published in local/national reports but not in peer-reviewed journals. Access to these data would have been greatly improved had these reports been more widely available in electronic formats such as on the Internet. Details of studies currently included are presented in Table 7.1.

In total, approximately 1900 abstracts were reviewed. Data from about 160 surveys (total sample size of almost 640000 participants) have been included. Figure 7.1 illustrates data coverage by geographical region.

No data were available for AMR-D comprising Bolivia, Ecuador, Guatemala, Haiti, Nicaragua and Peru, and very limited data (studies totalling $<2000$ participants) for SEAR-B and EMR-D. Data on more than 50000 participants were obtained for AMR-A, EUR-A, WPR-A and WPR-B, owing to many studies being available and large sample sizes.

Figure 7.I Cholesterol data coverage expressed as total study sample size, by geographical region

a Laboratory associated with a hospital, university or research institution.

Approximately half of the studies utilized random sampling of individuals or households, including stratified random sampling; the other half used methods such as house-to-house or workplace surveys. Response rates were documented in $72 \%$ of the studies, of which response rate was $>80 \%$ in $32 \%$ of them, between $50 \%$ and $80 \%$ (including those where response was $>80 \%$ in some subcategories) in $63 \%$ of them, and documented to be lower than $50 \%$ in only six studies. For completeness, full documentation of sampling method, response rate and cholesterol measuring techniques are presented in Appendix A, which is intended only for those who require more data on individual studies. A summary is given in Table 7.2.

In most studies, a laboratory was associated with a hospital, university or research institution, and the staff appeared to have received appropriate training. Whether the blood sample was taken after the individual had fasted has an impact on lipid subfractions such as triglycerides rather than on total cholesterol, but this information also provides an indication of the consistency with which samples were taken, and the degree of detail given in publications. The majority of analyses were performed using newer enzymatic techniques, rather than the older extraction analyses.

### 2.2 Methodology to estimate mean and standard deviation of Cholesterol data

Mean cholesterol, standard deviation, sample size and age ranges from all reviewed data sources were extracted and entered into an Excel database. Scatter plots of these cholesterol data for each subregion, utilizing the midpoints in study age categories, are presented below in Figures 7.2-7.5.

The cholesterol data obtained from published studies including various age ranges were presented by age categories that were different from those required for the CRA project. For this reason, a method was needed which would make complete use of the available data and then combine them to produce estimates for subregions and age groups. The first step was to assess the general shape of association using all the available data. Second, associations were estimated for each subregion separately where sufficient data were available. For subregions with limited data, the association was estimated using complete data available from other subregions. Finally, these subregional age-cholesterol associations for males and females were used to predict subregional cholesterol levels.

It should be noted that no step specifically estimates mean cholesterol at the country level; this approach is explained in greater detail below.

## Age-Cholesterol relationships

The data from the literature were first used to assess the shape of the association of cholesterol with age using SPLUS software. At this stage no assumptions were made about the shape of association and therefore non-parametric methods were applied.

Figures 7.2 and 7.3 demonstrate that there were variable amounts of data available among the different subregions, so initially analyses were limited to those subregions with the most data spread across all age groups. The six subregions thus examined were AMR-A, AMR-B, EMRB, EUR-A, WPR-A and WPR-B. Previous analyses had demonstrated that the shape of the age-cholesterol relationship may vary depending on absolute level of cholesterol (APCSC secretariat, personal communication, 2001). Therefore, analyses of pooled data from the six subregions were stratified by overall cholesterol levels into plausible low $(<4.7 \mathrm{mmol} / \mathrm{l})$, medium ( $4.7-5.5 \mathrm{mmol} / \mathrm{l}$ ) and high ( $>5.5 \mathrm{mmol} / \mathrm{l}$ ) groups (Figure 7.6), as we describe below using the example of WPR-A.

The purpose of determining the overall shape of the association between cholesterol and age was to enable extrapolation to other subregions where only limited data were available. The method utilized for subregions with sparse data is detailed below. The associations between age and cholesterol for both females and males were non-linear. The association for females increased between the ages of 30 and 65 years, and then fell slightly afterwards. For males, the association increased

Figure 7.2 Scatter plots of mean cholesterol (mmol/l) against age by subregion, for females

Figure 7.3 Scatter plots of mean cholesterol (mmol/l) against age by subregion, for males

Figure 7.4 Scatter plots of mean cholesterol standard deviation (mmol/l) against age by subregion, for females

Figure 7.5 Scatter plots of mean cholesterol standard deviation (mmol/l) against age by subregion, for males

Figure 7.6 The cholesterol-age association from pooled data of six subregions ${ }^{\text {a }}$ for populations with high, medium and low cholesterol levels

Females
a AMR-A, AMR-B, EMR-B, EUR-A, WPR-A and WPR-B.
Note: Overall cholesterol levels-Low $=<4.7 \mathrm{mmol} / /$; Medium $=4.7-5.5 \mathrm{mmol} / /$; High $=>5.5 \mathrm{mmol} / \mathrm{l}$.
between the ages of 30 and 50 years, and then flattened before declining slightly in older age. Very little data were available in the populations aged $>80$ years, and therefore it is unclear whether cholesterol continues to decrease beyond the age of 70-79 years. These patterns were consistent among high, medium and low cholesterol subgroups; however, the gradient of the increase was greatest in the high cholesterol groups, and least in the low cholesterol groups.

Having established the non-linear association between age and mean cholesterol, the second step involved estimating the shape and level of this association for males and females in each subregion separately. The methodology differed by subregion depending on the available data. There were sufficient data to estimate the associations for males and females in six of the 14 subregions (AMR-A, AMR-B, EUR-A, EMR-B,

Figure 7.7 Combining cholesterol data (mmol/l) from country studies in WPR-A

WPR-A and WPR-B). For example, for males in WPR-A, data were available from four countries (Australia, Japan, New Zealand and Singapore). The scatter plot in Figure 7.7 presents these cholesterol data at the country level.

Cholesterol data differed among and between these countries, with the size of the plot circles proportional to the population size and study size where more than one study was available within a country (Figure 7.7). Cholesterol levels were consistently lower for Japan across all age groups. The curve of best fit through these data weighted by study size within each country and by country population size within each subregion was estimated (i.e. a weighted regression line). Clearly, the fitted curve is weighted mostly to the Japanese studies due to Japan having the largest population size.

Although there was significant variation in the overall cholesterol levels between the different subregions, the shape of association across age groups was consistent for the six subregions where sufficient data were available (Figure 7.8).

For six of the remaining subregions (AFR-D, AFR-E, EUR-B, EUR-C, SEAR-B and SEAR-D), insufficient data were available to draw the age-cholesterol association accurately. Within these subregions, the available cholesterol data were pooled together to give age standardized mean levels weighted by country. That is, a single mean cholesterol level was estimated for each subregion with sparse data for males and females separately. Based on this level, one of three "age-cholesterol curves" was

Figure 7.8 The association of cholesterol with age for males and females in six subregions

chosen (Figure 7.6), and this curve was then shifted (up or down) to correspond with the calculated age adjusted mean cholesterol level for that subregion. Using this methodology, the "low cholesterol" curve (overall cholesterol $<4.7 \mathrm{mmol} / \mathrm{l}$ ) was used for AFR-D and AFR-E, the "middle cholesterol" curve (overall cholesterol $4.7-5.5 \mathrm{mmol} / \mathrm{l}$ ) was used for EUR-B, SEAR-B and SEAR-D, and the "high cholesterol" curve (overall cholesterol $>5.5 \mathrm{mmol} / \mathrm{l}$ ) was used for EUR-C.

Of the two remaining subregions, no data were collected in this review for AMR-D, so data from AMR-B were used to estimate the mean cholesterol levels. In the one study for EMR-D, which included only 634 individuals, the overall mean cholesterol level was skewed by particularly high cholesterol levels in the oldest age group, compared to age patterns observed in other subregions. This was thought not to be representative of that subregion, therefore data from EMR-B were used to estimate cholesterol levels for EMR-D.

## Estimates of mean cholesterol and standard deviation

Estimates of mean cholesterol for each of the age groups were made using the age-cholesterol associations outlined above for each subregion and sex separately. Utilizing these associations, age-specific estimates for each subregion were obtained by using midpoints of each GBD age group and predicting the subregional average cholesterol levels. Cholesterol values for those aged $>80$ years were assumed to be the same as the $70-79$ age group due to the extremely limited availability of cholesterol levels in the populations studied with a mean age $>80$ years. (Figures 7.2 and 7.3 demonstrate that very few subregions had any data for those with a mean age of $>80$ years.) A similar approach was used to estimate the standard deviations for each age, sex and subregion category. Current mean cholesterol results are presented in Table 7.3, and standard deviations are in Table 7.4.

### 2.3 UnCERTAINTY OF MEAN AND STANDARD DEVIATION OF Cholesterol levels

The uncertainty of the means and standard deviations of population distributions of cholesterol also had to be estimated. The approach described in the previous section to estimate the means and standard deviations makes as complete use as possible of all available data.

Table 7.3 Estimates of mean cholesterol levels (mmol/l) by subregion, sex and age

| Subregion | Sex and age group (years) |  |  |  |  |  |  |  |  |  |

| WPR-B | 1.0 | 1.1 | 1.3 | 1.2 | 1.2 | 1.1 | 1.1 | 1.2 | 1.1 | 1.1 |

Note: Reported standard deviations are derived from baseline cholesterol (i.e. one-off measures), which when corrected for regression dilution bias were used in all calculations on the "usual" scale.

However, there will always be errors associated with generalizing from the data collected to the subregional level. From the perspective of uncertainty, subregions can be divided into three main categories:

1. subregions where most of the countries have nationally representative surveys;
2. subregions with a lower coverage of countries and/or countries for which well designed surveys exist but on sub-national populations; and
3. subregions with countries where few studies and little or no data existed.

A subregion in which a national study is available for most of the countries would be expected to have low uncertainty (e.g. AMR-A and WPR-A). The remaining 12 subregions can be placed into either category 2 or 3 , depending on the number of high-quality studies available. For these, subregional means and standard deviations were estimated from available data. Examining the heterogeneity observed between
different countries in these subregions provided a basis to quantify the uncertainty associated with data quality as well as extrapolation (see Figures 7.2 and 7.3). There may be a variety of causes underlying the heterogeneity, including sampling error and real sub-population differences. However, a subregion whose estimate is based on data from sub-national studies that suggest a wider range of mean cholesterol levels would have greater uncertainty. An example of this occurred in WPR-B, where, in the absence of a single national study for China, an estimate had to be based on all eligible studies even though there were significant differences between studies. Conversely, in WPR-A, heterogeneity is due in greater part to real population differences (i.e. Japan and Australia/New Zealand have substantially different cholesterol levels).

A simulation approach was taken to incorporate the uncertainty introduced in estimating mean cholesterol levels to reflect both sampling error as well as the variation of studies within countries. For each subregion separately, the simulation proceeded by reiterating the same weighted regression approach described earlier (i.e. weighted regression of mean cholesterol on mean age). Each iteration involved re-sampling of data points 10000 times by treating each study as a random effect (i.e. two components of variation: study sampling error plus variation of study within country). The regression analysis was then re-iterated to obtain uncertainty distributions.

For subregions where insufficient data were available to assess the second component of variation accurately between countries, data were utilized from the data-rich subregions. Specifically, the average intercountry variation observed in AMR-A, AMR-B, EUR-A, EMR-B, WPRA and WPR-B was applied to the remaining eight subregions.

Similar simulations were utilized to estimate the uncertainty intervals around the estimated standard deviations, the only difference being that the sampling distribution for the standard deviations was based on a chisquare in place of a normal distribution. Results from these simulations are provided in Tables 7.5 and 7.6.

### 2.4 Theoretical-minimum-risk exposure distribution

To make a judgment on the theoretical minimum cholesterol level, the evidence of the association between cholesterol and relative risk of cardiovascular end-points and data from "low cholesterol" populations were examined.

## LOWEST RELATIVE RISK OF END-POINTS

A variety of prospective studies have examined the association between cholesterol and cardiovascular end-points. There is strong evidence that increased cholesterol is associated with increased risk of IHD, and the relationship is approximately linear on a logarithmic scale (Law 1999; Law et al. 1994b).
Table 7.5 Values of $95 \% \mathrm{Cl}$ for mean cholesterol ( $\mathrm{mmol} / \mathrm{l}$ ) by subregion, sex and age

Figure 7.9 The association between cholesterol and IHD in the Shanghai Factory Workers Study

Source:
Reprinted, by permission of the publisher, from Chen et al. (1991). Serum cholesterol concentration and coronary heart disease in population with low cholesterol concentrations. British Medical Journal, 303:276-282.

In populations from industrialized countries (e.g. Europe and North America), this relationship has seldom been demonstrated below a cholesterol level of $4.5-5.0 \mathrm{mmol} / 1$ (Chen et al. 1991). However, in other populations such as China, data suggest that this relationship may continue, without a threshold, below cholesterol levels of about $4.0 \mathrm{mmol} / \mathrm{l}$ (Chen et al. 1991; Law and Wald 1994; Law et al. 1994b) (Figure 7.9). Based on this evidence it would be feasible to set a theoretical minimum of usual cholesterol of at least $3.8 \mathrm{mmol} / \mathrm{l}$.

Another source of data is clinical trials of cholesterol lowering from recent meta-analyses. Trials included in these overviews achieved substantial reduction in cholesterol with no adverse effects. The reductions are summarized in Table 7.7. These reductions of cholesterol also occurred in the lowest cholesterol group, i.e. those with baseline mean cholesterol of about $5.0 \mathrm{mmol} / \mathrm{l}$. The aggregated data from trials therefore indicate that a substantial reduction in cholesterol is possible, across different baseline cholesterol levels, without risk of substantial adverse effects.

Further, the recently completed large-scale Heart Protection study (Heart Protection Study Collaborative Group 2002a, 2002b) demonstrated that cholesterol lowering in those with average or below average

total cholesterol levels was still associated with reduced risk of cardiovascular disease. This trial included over 20000 participants and found no evidence of a threshold level below which lowering cholesterol did not produce a lower risk.

## LOW CHOLESTEROL POPULATIONS

An alternative source of data relevant to setting a theoretical minimum comes from examining mean cholesterol levels in studies of so-called "unacculturated" populations with little cardiovascular disease and low cholesterol levels (Poulter and Sever 1994). Unacculturated generally refers to those populations that are relatively isolated and have preserved their lifestyle over many generations.

An overview of typical cholesterol values in men aged 45-64 years in different populations noted that while mean cholesterol ranged from 5.5 to $7.0 \mathrm{mmol} / \mathrm{l}$ in many industrialized populations, it was much lower in hunter-gatherer societies where mean values were as low as 3.0$3.5 \mathrm{mmol} / \mathrm{l}$ (Law 1999; Law and Wald 1994). Data from individual studies around the world that have focused on these "low cholesterol" populations are summarized in Table 7.8. In the Shanghai study, there was a strongly positive and apparently independent relation between cholesterol concentration and death from IHD, even at these lower levels (Chen et al. 1991) (Figure 7.10).

Typically, the data show that there is a very low prevalence of cardiovascular disease in these populations, which exhibit an absence of obesity due to diets low in salt, cholesterol and fat (particularly animal fat), and a lifestyle requiring heavy physical labour (Barnes 1965; Carvalho et al. 1989; Connor et al. 1978; He et al. 1991a, 1991b; Page et al. 1974; Poulter and Sever 1994; Sever et al. 1980). There is also evidence of low blood pressure levels, and no age-related rise in either cholesterol or blood pressure levels. Data from these studies indicate that many of these populations have mean cholesterol levels of about

Table 7.8 Cholesterol levels in low cholesterol populations

| Country (reference) | Population | Mean cholesterol levels | Patterns with age |
| :--- | :--- | :--- | :--- |
| Africa |  |  |  |
| Tanganyika <br> et al. I964) | Masai tribe (mostly <br> males) with virtually no <br> cardiovascular disease. | $3.0-3.7 \mathrm{mmol} / \mathrm{l} ;$ <br> $>5.2 \mathrm{mmol} / \mathrm{I}$ rare | No evidence of <br> increasing <br> cholesterol with <br> advancing age |
| Americas |  |  |  |
| Mexico (Casdorph <br> I972; Connor et al. | Tarahumara Indians <br> who lived in the <br> mountains | $3.0-3.5 \mathrm{mmol} / \mathrm{I}$ | No age-related |
| I978) |  |  |  |

$3.8 \mathrm{mmol} / \mathrm{l}$ or lower. Therefore, setting a theoretical minimum at 3.8 $\mathrm{mmol} / \mathrm{l}$ is justified based on all of the data.

## Safety of low cholesterol levels

Concerns have been expressed over whether lowering cholesterol may be harmful, and therefore setting a theoretical minimum too low may have adverse consequences. Some data have suggested a negative association between cholesterol and haemorrhagic stroke (Iso et al. 1989); however, a recent analysis has suggested that this is in fact more likely to be a null association (Suh et al. 2001). It should also be noted that even if there were a small increase in risk of haemorrhagic stroke for people with very low cholesterol levels, this would be outweighed overall by the benefits resulting from lower risk of IHD (Bucher et al. 1998; Law et al. 1994a).

There is no strong consistent evidence that low or reduced cholesterol concentrations increase mortality from non-cardiovascular diseases such as cancer or infection (Law et al. 1994a). Overviews of trials have not
detected increases in causes of non-cardiovascular disease mortality (Hebert et al. 1997; LaRosa et al. 1999) despite achieving relatively large decreases in cholesterol. In many cases, the apparent association is actually due to disease causing low cholesterol rather than vice versa (Law et al. 1994a). A recent meta-analysis of trials found no convincing evidence that the risk of "non-illness"-related mortality (deaths from suicide, accident or trauma) was strongly associated with cholesterol lowering (Muldoon et al. 2001).

Finally, data relating to low cholesterol levels come from research on those with heterozygous familial hypobetalipoproteinaemia. These individuals have cholesterol levels as low as $2.0-3.0 \mathrm{mmol} / \mathrm{l}$ and a prolonged life expectancy, as coronary artery disease is avoided-but no recognized adverse effects from the low cholesterol (Law 1999).

## Standard deviation of the theoretical-minimum-Risk EXPOSURE DISTRIbUTION

The choice of standard deviation around the theoretical minimum was based on examining the relationship of the standard deviation and mean of cholesterol using all available data from our review of the literature (Figure 7.10). From this illustration, a distribution with a mean of $3.8 \mathrm{mmol} / 1$ would typically have a standard deviation of $0.9 \mathrm{mmol} / 1$ (baseline), which equates to $0.6 \mathrm{mmol} / 1$ (usual).

## 3. Cholesterol-Disease relationships

Data on the relationship between cholesterol and disease outcomes come from two main types of studies (MacMahon 1994). Prospective observational studies provide data from which the effects of prolonged cholesterol differences can be estimated (MacMahon et al. 1990), that is, hazard ratios. Trials provide data about the effects of short-term cholesterol reduction (Collins et al. 1990), or risk reversal. Results from prospective observational studies will be considered first.

### 3.1 Data sources for hazard ratios

Observational studies have been conducted in a variety of settings that examine the association between cholesterol and disease. However, the results of many of these individual studies are limited. Many observational studies have small sample sizes or an insufficient number of end-points, and therefore lack the power required to provide reliable estimates of associations for different population subgroups (e.g. sex and age groups) and/or specific diagnostic categories (MacMahon et al. 1990). Individual studies do not always provide information on the direction of the association at lower cholesterol levels, making it difficult to assess whether the observed association is continuous or has a threshold level. In addition, these studies frequently do not standardize the size of the association for bias and confounding-in particular,

Figure 7.10 Association between mean cholesterol and standard deviation for review data

Table 7.9 Characteristics of major cholesterol cohort study overviews

| Study characteristics | Law et al. (1994b) | Prospective Studies Collaboration (PSC 1995) | Eastern Collaborative Research Group (Anonymous 1998a) | Asia-Pacific Cohort Studies Collaboration (APCSC secretariat, personal communication, 2001) |

| BP Blood pressure. |  |  |  |  |

Of the four overviews, only two included analyses for the IHD end-point; Law et al. (1994b) and APCSC (APCSC secretariat, personal communication, 2001). The former will be used as the primary data source for relative risk estimates of IHD due to the greater sample size. Three overviews included data on cholesterol and stroke (Anonymous 1998a; APCSC secretariat, personal communication, 2001; PSC 1995). However, only APCSC analyses were based on individual participant data and provided age-specific analyses of total stroke and stroke subtypes. It will therefore be the primary data source for relative risk estimates of stroke.

### 3.2 Analysis issues

An important factor that must be accounted for with estimates of the association between cholesterol and cardiovascular end-points from observational data is regression dilution bias. This bias occurs because baseline or one-off measures of cholesterol are subject to random fluctuations, due partly to the measurement process, and partly to any real but temporary deviations at the baseline from the usual cholesterol level (MacMahon et al. 1990). Therefore, baseline cholesterol values have a wider distribution than the "usual" cholesterol values. With repeated measures there is a "regression to the mean" of values (MacMahon 1994), whereby an initially extreme observation tends to become less abnormal with replication (Strachan and Rose 1991).

This imprecision in measurement not only influences distribution, but also affects the association with disease outcomes (MacMahon et al. 1990). Figure 7.11 illustrates the effect of regression dilution

Figure 7.1I Effects of regression dilution bias on the association between blood pressure and relative risk of cardiovascular disease

Systolic blood pressure ( mmHg )
bias for blood pressure, but the same would be true for cholesterol. The baseline distribution has a shallower slope than usual cholesterol on the curve-relation of cholesterol to relative risk of disease. Analyses have suggested that correcting for regression dilution bias increases the slope of the association by as much as $61 \%$ (Law et al. 1994c). If this bias is not corrected, the strength of the association between cholesterol and disease incidence is underestimated ("regression dilution bias") (MacMahon 1994). This systematically dilutes the apparent importance of cholesterol and can result in systematic and substantial underestimation of risk of disease with usual cholesterol (MacMahon et al. 1990).

The size of the dilution is directly related to the extent to which cholesterol measurements are subject to regression to the mean. Several major meta-analyses conducted in recent years aimed to address these limitations with correction for regression dilution bias (Anonymous 1998a; APCSC 1999; PSC 1995). It is possible to use repeated measures on cholesterol to obtain an estimate of the attenuation factor in order to correct for this bias in the analysis. An attenuation factor of 1.82 was calculated from remeasurement data in the Prospective Studies Collaboration (PSC) (1995), and 1.90 in the Eastern study (Anonymous 1998a). In the APCSC, analyses of remeasurement data from cohorts estimated that the correction factor was 1.8. (APCSC secretariat, personal communication, 2001). Here, use of the term "usual cholesterol" indicates that the association between cholesterol and the disease end-point has been corrected for regression dilution bias.

The surrogate dilution effect is another factor that should be considered specifically in cholesterol studies. This effect arises because observational studies underestimate the effect of lower cholesterol relative to the trials (Law et al. 1994c). In a cohort study, a $1 \mathrm{mmol} / /$ lower cholesterol concentration is associated with about $0.67 \mathrm{mmol} / 1$ of LDL, but in cholesterol lowering trials, a $1 \mathrm{mmol} / /$ lower total cholesterol is usually comparable to $1 \mathrm{mmol} / /$ lower LDL. Law et al. (1994c) adjusted for both regression dilution bias and the surrogate dilution effect in their analyses, and the final correction factor was 1.61.

### 3.3 Estimates of cholesterol-disease relationships

A summary of the results of the four prospective study overviews is presented in Table 7.10, and each of these end-points will now be considered in detail.

## Cholesterol and IHD

Analyses from the APCSC overview (APCSC secretariat, personal communication, 2001) and that by Law et al. (1994b) demonstrated that the relative risk of IHD increased with increasing cholesterol level, and that the association was roughly linear when plotted on a log scale (Figure 7.12 and 7.13).

Figure 7.12 Usual cholesterol level and risk of IHD in the Asia-Pacific region

Source: APCSC data (APCSC secretariat, personal communication, 2001).

This means that the proportional difference in risk associated with a given absolute difference in usual cholesterol is similar at all levels of cholesterol, at least within the range studied. This continuous association showed no evidence of a threshold level of cholesterol, below which lower levels of cholesterol are no longer associated with lower relative risks of IHD (down to almost $4.0 \mathrm{mmol} / \mathrm{l}$ ). Further, there was no evidence of an upper threshold level above which the relative risk of IHD increased much more rapidly (Anonymous 1998a; APCSC secretariat, personal communication, 2001; Law et al. 1994c; PSC 1995).

Overall, the analyses in both the APCSC (APCSC secretariat, personal communication, 2001) and by Law et al. (1994b) suggested that a $0.6 \mathrm{mmol} / \mathrm{l}$ lower cholesterol was associated with $24-27 \%$ lower risk of IHD. There was no evidence of a difference in the size of the association between males and females or fatal and non-fatal IHD end-points.

Age has an important influence on the size of the cholesterol-endpoint relationship, as the associations are steeper for those in younger age groups. (This also largely accounts for the apparent heterogeneity between the cholesterol-IHD associations in the cohorts in Figure 7.13.) This limits the ability to compare directly the overall relative risk estimates across the overviews, as it is only appropriate to compare age-specific results. The gradient of the cholesterol-IHD association varies with age at baseline, the gradient being much steeper for younger
Table 7.10 Summary results of major cohort study overviews

Figure 7.13 Incidence of ischaemic heart disease and usual cholesterol level in 10 cohort studies

[^20]age groups. While the proportional change in IHD risk per unit change in cholesterol is less extreme in old age than in middle age, the relationship remains positive for all age groups (APCSC secretariat, personal communication, 2001; Law et al. 1994b). It is therefore necessary to use age-specific estimates for hazard ratios in all cholesterol analyses for CRA.

The results of both overviews are relatively consistent, but due to the larger number of participants and end-points in the review by Law et al. (1994b), these relative risk estimates, transformed for application to GBD age groups, were used in the analyses of this chapter. Table 7.11 presents relative risks from the overview by Law et al. (1994b) transformed into GBD age groups for a $1 \mathrm{mmol} / \mathrm{l}$ difference in usual cholesterol.

## Cholesterol and stroke

Few data are available on the association between cholesterol and stroke, and the relationship is more complex. Many individual cohorts and the PSC have found no association between cholesterol and risk of stroke death (PSC 1995). However, recent meta-analyses and other studies have reported that this apparent null association may be principally due to a quantitatively different association between cholesterol and the two major types of stroke-haemorrhagic and ischaemic. A variety of studies have attempted to clarify these associations. Table 7.12 summarizes some of the largest cohort studies undertaken, with several hundred recorded stroke events by subtype.

Several of these studies showed evidence of a positive association between cholesterol and risk of ischaemic stroke (Anonymous 1998a; Benfante et al. 1994; Iso et al. 1989; Jorgensen et al. 1995; Leppala et al. 1999; Neaton et al. 1992, 1993; Yano et al. 1994). Other individual studies failed to find an association between cholesterol and ischaemic stroke (Nakayama et al. 1997; Szatrowski et al. 1984; Tanaka et al. 1982), but the extent of misclassification of stroke subtype was uncertain in these studies. The association of cholesterol with haemorrhagic stroke is less clear, with some analyses suggesting either a negative (Anonymous 1998a; Iso et al. 1989; Leppala et al. 1999; Neaton et al. 1992, 1993; Yano et al. 1989, 1994) or null association (Iribarren et al. 1996; Suh et al. 2001).

Analyses from the APCSC show the different association of cholesterol with stroke subtypes (Figure 7.14); a positive association for ischaemic stroke and a negative/null association for haemorrhagic stroke. In the CRA analyses, data from the APCSC overview were used, given the size and availability on individual data.

The age-specific relative risks of haemorrhagic and ischaemic stroke with a $1 \mathrm{mmol} / 1$ difference in usual cholesterol are presented in Table 7.13.

Figure 7.14 Usual cholesterol level and risk of haemorrhagic and ischaemic stroke

Haemorrhagic

Ischaemic

Source: APCSC data (APCSC secretariat, personal communication, 2001).

Overall, APCSC data indicated that the association of cholesterol with stroke varies with age at baseline, the gradient being much steeper for younger age groups. As discussed in relation to IHD, this means that the proportional change in stroke risk per unit change in cholesterol is less extreme in old age than in middle age (APCSC secretariat, personal communication, 2001). It is therefore necessary to use age-specific estimates for hazard ratios in all cholesterol analyses for CRA. There was no evidence of differences in the association between males and females, so sex-specific estimates are not necessary.

Despite having data from the APCSC, it is difficult to incorporate the different cholesterol-stroke subtype associations into CRA analyses as the only GBD end-point for stroke relates to total stroke. It is not possible to conduct analyses for ischaemic and haemorrhage stroke independently, and it is not appropriate simply to apply the relative risk for total stroke events to all 14 subregions, since there is evidence that the relative proportions of haemorrhagic and ischaemic stroke vary among them (Anderson et al. 1993; Bamford et al. 1990; Chen et al. 1992; Giroud et al. 1991; Hung 1993; Jeng et al. 1998; Nakayama et al. 1997; Suzuki et al. 1987; Thrift et al. 2001; Wu et al. 1992). Analyses of total stroke must therefore be modified to reflect these differing proportions, and the different types of association between cholesterol and stroke
Table 7.12 Data from major cohort studies on the association between cholesterol and risk of stroke subtype

| Study | Participants | Ischaemic stroke | Haemorrhagic stroke |

Source: APCSC data (APCSC secretariat, personal communication, 2001).
subtype. It was therefore necessary to estimate subregion- and agespecific proportions of ischaemic and haemorrhagic fatal and non-fatal strokes so that weighted RR values could be applied. (An assumption was made that these are the same for males and females.)

Several steps were undertaken to estimate stroke subtype proportions, and these are outlined in Appendix B. They included using data from "gold-standard" studies of stroke incidence, and other observational data on stroke subtypes by subregion. Having estimated the relative percentage of stroke subtypes by age, sex and subregion, the APCSC values of RR for ischaemic stroke were smoothed and then weighted as per these percentages. (Smoothed RRs for the five age groups were 0.61 , $0.69,0.76,0.82$ and 0.90 .) No association was found between cholesterol and haemorrhagic stroke.

### 3.4 Risk Reversal

As already alluded to, prospective observational studies provide data on the association between cholesterol and stroke and IHD, but they do not provide data on the impact of cholesterol lowering on these outcomes over time (MacMahon et al. 1990). From prospective studies alone, it is not possible to tell whether outcomes are reversible, or whether the association reflects, to some extent, irreversible cumulative effects of cholesterol differences that have persisted for years (Collins and Peto 1994).

The results from randomized clinical trials do provide data on reversibility. They are relevant to assessing how rapidly, and to what extent, the epidemiologically expected reductions in stroke and IHD are produced by lowering cholesterol levels (Collins and Peto 1994; Collins et al. 1990). They therefore provide estimates of the proportion of the potential long-term benefit from a particular cholesterol difference that may be expected within a few years of cholesterol lowering.

## Data sources on risk reversal

A variety of trials have studied the impact of cholesterol lowering. However, as with blood pressure lowering trials, individual studies usually lacked sufficient power to reliably detect moderate changes in events (Collins and Peto 1994; Collins et al. 1990; He and Whelton 2000). To accurately detect small but potentially important differences in risk reduction of cardiovascular disease (e.g. 10-15\%), it is necessary for trials to record many hundreds of end-points. Since most have not achieved this, overviews are necessary to provide more accurate estimates of the impact of cholesterol lowering on stroke and IHD. Results from these overviews will contribute to estimates of "risk reversibility".

A number of cholesterol lowering trials as well as major metaanalyses of such trials have been undertaken (Atkins et al. 1993; Blauw et al. 1997; Bucher et al. 1998; Byington et al. 2001; Crouse et al. 1997, 1998; Hebert et al. 1995, 1997; Holme 1990; LaRosa et al. 1999; Law et al. 1994b; Pignone et al. 2000; Ross et al. 1999; M. Law, personal communication, 2001). Most of these trials assessed the impact of lowering cholesterol on IHD, but data are also available on stroke. Results of an updated meta-analysis of all trials included in these previous overviews are given in Tables 7.14-7.16.

## Estimates of Risk reversal

## Cholesterol and risk of IHD

Trials of cholesterol lowering may be broadly grouped into "dietary interventions", "non-statin drugs" (e.g. fibrates), and "statin drugs". Many individual trials and a number of meta-analyses (including the updated meta-analysis) have analysed the association between cholesterol lowering and IHD. Overall, the trials have demonstrated a significant reduction in risk of IHD for those treated.

The current and previous meta-analyses of the early trials demonstrated a risk reduction in those treated of about $10-15 \%$, with dietary interventions or non-statin drugs such as fibrates or resins (Atkins et al. 1993; Bucher et al. 1998; Holme 1990). Later trials with statins, that achieved larger reductions in cholesterol, produced risk reductions of up to 25-30\% (Table 7.14) (Bucher et al. 1998; LaRosa et al. 1999; Pignone et al. 2000; Ross et al. 1999). One recently published overview included diet, fibrates, resins and statins (Bucher et al. 1998), but most recent meta-analyses have limited their analyses to statins. The review suggested that the effects of statins on risk reduction could be greater than other agents, but cautioned that analyses were based on between-study treatment comparisons rather than within study comparisons. Therefore, any apparent differences in drug efficacy may have been due to other factors such as differences in study design or populations. For example, participants in statin trials tended to be older, with higher event rates than on other trials, which may partly be responsible for differences in trial

results (Bucher et al. 1998). Another review is more relevant in addressing this issue. It examined the proportional reduction in risk from each trial titrated to a cholesterol reduction of $0.6 \mathrm{mmol} / \mathrm{l}$ as a yardstick. There was a dose-response relationship with bigger reductions in risk in trials attaining bigger cholesterol reductions, and statins tended to achieve greater reduction in total cholesterol. It was clear however, that for each method of lowering cholesterol (different drugs, diet and surgery), the proportional reduction in risk was close to that expected from the cholesterol reduction, suggesting little difference in relative effect of agents (Law et al. 2003).

Evidence from meta-analyses suggested that there were similar benefits from cholesterol lowering for males and females, and fatal and nonfatal events, but there was no evidence of age attenuation (LaRosa et al. 1999; Law et al. 1994b). However, trials are often not powered for such age subgroup analysis and often include only a narrow age band. On the whole, no substantial evidence has been presented for a significant difference in risk reduction of IHD between trials among those individuals with or without a prior history of cardiovascular disease (Atkins et al. 1993; Crouse et al. 1997, 1998; Hebert et al. 1997; Holme 1990; LaRosa et al. 1999; Law et al. 1994b).

Further important results from meta-analyses of cholesterol reduction trials relate to the time frame of the achieved benefits. A major overview published by Law et al. (1994b) included 28 trials of diet and non-statin drugs, 45254 individuals and 4421 deaths from IHD. It demonstrated that most of the benefits were evident after 5 years of sustained cholesterol lowering. In the first two years, a $0.6 \mathrm{mmol} / \mathrm{l}$ reduction in cholesterol was associated with a $7 \%(95 \%$ CI $0-14 \%)$ lower risk of IHD, but after 5 years, it was $25 \%$ ( $15-35 \%$ ) (Law et al. 1994b). An updated overview which included more cholesterol lowering trials including statins has confirmed these patterns with a $1.0 \mathrm{mmol} / \mathrm{l}$ reduction in LDL cholesterol associated with a $11 \% ~(95 \%$ CI $4-18 \%)$ lower risk of IHD at year 1. At 2 years this increased to $24 \%(17-30 \%)$, at $3-5$ years it was $33 \%(28-37 \%)$, and after 5 years it was $36 \%$ ( $26-45 \%$ ). (Law et al. 2003).

Most other reviews have not reported events according to duration of treatment, and instead only give an "average" risk reduction for the entire period of follow-up. A risk reduction of $20 \%$ after 5 years of follow-up, for example, for a given age group is a combined risk reduction for $1,2,3,4$ and 5 years, rather than a true representation of the risk reduction for a cohort of people after 5 years of treatment, which would be greater than $20 \%$. These data are a vital component to interpreting the time frames and extent of reversibility. The majority of the benefit of cholesterol lowering was achieved after 5 years (Law et al. 1994b). At this time, virtually all of the risk predicted by the observational studies had been reversed. There is no evidence that the effects of
cholesterol lowering on risk of IHD differ between males and females (Byington et al. 2001; LaRosa et al. 1999; Law et al. 1994b).

## Cholesterol and risk of stroke

Early observational studies, trials and overviews did not find an association between cholesterol and stroke. Part of the reason for this was that the analyses involved total stroke, and "concealed" differences in the type of association between cholesterol and each stroke subtype (Crouse et al. 1998). Early trials also only achieved small reductions in cholesterol and included few, mostly fatal, stroke events, which made the influence of cholesterol lowering difficult to detect (Crouse et al. 1998; Law 1999). Trials also tended to be of short duration, so that the long-term reduction in stroke was "diluted" by the absence of an early effect (Law 1999).

Data from individual trials are presented in Tables 7.14-7.16. As with IHD end-points, there were similar risk reduction in males and females and no evidence of age attenuation (Byington et al. 2001). However, trials were often not powered for this subgroup analysis and included only a narrow age-band.

The larger, more recent trial overviews have found a positive association between cholesterol and total stroke, and the size of the risk reduction in more recent overviews was about 20-25\% (Blauw et al. 1997; Bucher et al. 1998; Crouse et al. 1997, 1998; Hebert et al. 1997; Ross et al. 1999). Overviews have also noted a stronger association with non-fatal strokes (which comprise a higher proportion of ischaemic strokes) than fatal strokes (which comprise a greater proportion of haemorrhagic strokes) (Atkins et al. 1993; Blauw et al. 1997; Byington et al. 2001; Ross et al. 1999). One of the most recent overviews performed subgroup analysis and suggested different associations between cholesterol and haemorrhagic and ischaemic strokes (Byington et al. 2001), as predicted by the observational data.

In summary, the data from clinical trials of cholesterol lowering indicated that after 5 years, a reduction of approximately $0.6 \mathrm{mmol} / \mathrm{l}$ of cholesterol resulted in reversal of most or all of the epidemiologically expected risk for IHD (about 27\%). Interpretation is more difficult for stroke as many studies have combined ischaemic and haemorrhagic strokes into one category, when the association of cholesterol with ischaemic stroke differs from that of haemorrhagic stroke. Even when stroke subtype is specified, there will likely be differing rates of misclassification of stroke subtype between studies. However, more recent trial overviews appear to concur with the epidemiological data and suggest that total stroke risk can be reversed, but associations differ by stroke subtype. Unfortunately, analyses have not specifically analysed results by duration, so similar time frames for the cholesterol-IHD association will have to be used. These time frames for reversibility from trials will be
used in CRA analyses, but the relative risk estimates from cohort studies will be used in preference to those from trials for both stroke and IHD. Cohort studies are much larger than the trials, their statistical power is greater, and they are also better able to examine associations across a wide range of cholesterol values (Law 1999). Furthermore, age-specific estimates are more readily available.

## 4. Results

### 4.1 Attributable fraction

The "attributable fraction" refers to the proportion of disease burden that would theoretically not have occurred if the population distribution of cholesterol had been equal to that of the theoretical minimum (mean cholesterol $=3.8 \mathrm{mmol} / \mathrm{l}$ ).

## Stroke

Globally, $32 \%$ of ischaemic stroke was attributable to a total cholesterol level $>3.8 \mathrm{mmol} / \mathrm{l}$ (range of $25-45 \%$ by subregion). Subregions with the lowest attributable fractions included AFR-D, AFR-E and WPRB. In contrast, EUR-C and EUR-A had the highest values. In most subregions, the attributable fractions were slightly lower for males than females.

## ISCHAEMIC HEART DISEASE

Globally, $56 \%$ of IHD was attributable to a total cholesterol level $>3.8 \mathrm{mmol} / \mathrm{l}$ (range of $44-68 \%$ by subregion). Subregions with the lowest attributable fractions included AFR-D, SEAR-B and WPR-B. In contrast, EUR-C and EUR-A had the highest values.

### 4.2 Attributable disease burden

For the year 2000, the World Health Organization (WHO) estimated that there were 55.9 million deaths and 1455 million DALYs worldwide; approximately $22 \%$ of these deaths and $7 \%$ of these DALYs were due to ischaemic heart disease and stroke. The burden of disease was distributed across the developed and developing world (e.g. about one quarter of all stroke deaths and one third of IHD deaths occurred in the least developed regions), and predominantly affected those aged $>60$ years.

The "attributable burden" refers to the number of deaths or DALYs that would theoretically not have occurred if the population distribution of cholesterol had been equal to that of the theoretical minimum (mean cholesterol $=3.8 \mathrm{mmol} / \mathrm{I})$. In total, the attributable burden equated to 805000 stroke deaths, and about 3.6 million IHD deaths. For DALYs, these figures were 8.3 million stroke DALYs, and 32.1 million IHD DALYs (Table 7.17).

Table 7.I7 Attributable deaths and DALYs for cholesterol $>3.8 \mathrm{mmol} / \mathrm{l}$ by subregion and cardiovascular end-point

| Subregion | Stroke | IHD | Stroke | IHD |
| :---: | :---: | :---: | :---: | :---: |
|  | Deaths (000s) |  | DALYs (000s) |  |
| AFR-D | 18 | 68 | 219 | 738 |
| AFR-E | 21 | 68 | 267 | 767 |
| AMR-A | 33 | 317 | 377 | 2086 |
| AMR-B | 31 | 136 | 448 | 1425 |
| AMR-D | 3 | 15 | 47 | 150 |
| EMR-B | 7 | 75 | 89 | 836 |
| EMR-D | 26 | 188 | 287 | 2037 |
| EUR-A | 96 | 451 | 779 | 2600 |
| EUR-B | 45 | 235 | 474 | 1984 |
| EUR-C | 176 | 729 | 1637 | 5683 |
| SEAR-B | 18 | 94 | 224 | 1016 |
| SEAR-D | 145 | 851 | 1542 | 9548 |
| WPR-A | 20 | 58 | 219 | 389 |
| WPR-B | 165 | 322 | 1724 | 2847 |
| World | 805 | 3609 | 8332 | 32105 |

Worldwide this means that 4.4 million deaths (about $7.9 \%$ of the total) and 40.4 million DALYs $(2.8 \%$ of the total) were estimated to be due to non-optimal cholesterol. The proportion of DALYs was lower than the proportion of deaths, as most cholesterol-related cardiovascular disease events occurred in middle or old age, so the years of life lost due to premature mortality and years of life lost due to disability is a smaller percentage of the total DALYs than of the total deaths.

The age group with the greatest attributable deaths for both males and females was $70-79$ years. The number of attributable deaths then declined, reflecting the smaller denominator population, and the smaller total number of events in the oldest age group. For DALYs, this decline occurred sooner, as there are less years of life lost and years of life lived with disability with advancing age.

For each end-point, the attributable deaths were higher for males than females for the age groups 30-44 and 45-59 years. In contrast, attributable deaths were higher for females in the oldest age groups, $70-79$ and $\geq 80$ years. There was a similar trend for attributable DALYs. This was due to older females having higher mean cholesterol (and therefore greater attributable fraction) than males, and there are also a larger
number of cardiovascular deaths occurring in older females compared to older males.

## Stroke

The subregions with the highest attributable ischaemic stroke burden were EUR-C ( 176000 deaths, 1.6 million DALYs), WPR-B ( 165000 deaths, 1.7 million DALYs) and SEAR-D ( 145000 deaths, 1.5 million DALYs).

ISCHAEMIC HEART DISEASE
The subregions with the highest attributable IHD burden were SEAR-D ( 851000 deaths, 9.6 million DALYs) and EUR-C ( 729000 deaths, 5.7 million DALYs).

Overall, approximately $40 \%$ of attributable DALYs occurred in the most developed subregions ( 16.2 million), $40 \%$ ( 15.6 million) in high mortality developing subregions, and $20 \%$ ( 8.6 million) in low mortality developing subregions. A higher proportion of these deaths and DALYs were from IHD than stroke in all subregions.

These results indicate where most of the worldwide attributable cardiovascular disease burden occurred, and provide any given subregion with an indication of absolute size of the attributable burden. However, the age structure, population size, and the number of estimated events occurring in a subregion, influences the ranking of subregions by absolute number of attributable deaths and DALYs. The relative impact of the attributable DALYs indicates that between about $2-25 \%$ of all deaths and $0.5-12 \%$ of all DALYs across the subregions were attributable to non-optimal cholesterol. Approximately $16 \%$ of all deaths and $8 \%$ of all DALYs were attributable to excess cardiovascular disease in developed subregions, and about $5 \%$ and $2 \%$ in high and low mortality developing subregions, respectively.

## 5. Discussion

### 5.1 Attributable deaths and disease burden

The analyses in this chapter suggest that globally, a substantial proportion of cardiovascular disease is attributable to non-optimal cholesterol, defined as mean cholesterol $>3.8 \mathrm{mmol} / \mathrm{l}$. Overall, about one third of ischaemic stroke and over half of IHD was attributable to non-optimal cholesterol. The attributable fractions were higher in the more developed parts of the world than the least developed regions, as would be expected given the higher cholesterol levels.

Worldwide, 4.4 million deaths (about $7.9 \%$ of the total) and 40.4 million DALYs ( $2.8 \%$ of the total) were estimated to be due to nonoptimal cholesterol. Overall, the results suggest that a considerable proportion of cardiovascular disease is related to non-optimal cholesterol
and this translates into an important portion of deaths and years of life lost to deaths and disability worldwide.

### 5.2 Attributable deaths and disease burden by subregion

In absolute terms, most of the excess burden of cardiovascular disease occurred in subregions WPR-B, SEAR-D and EUR-C; approximately $10-20 \%$ of worldwide attributable deaths and DALYs occurred in these subregions. The relative impact that attributable deaths and DALYs have in different subregions may also be calculated as the proportion of all deaths and DALYs attributable to non-optimal cholesterol (i.e. mean $>3.8 \mathrm{mmol} / \mathrm{l}$ ) within each specific subregion. Overall, between $2 \%$ and $25 \%$ of all deaths and 0.5 and $12 \%$ of all DALYs across subregions were attributable to non-optimal cholesterol. This excess burden was highest in European subregions where mean cholesterol levels were highest.

## 6. Trends in mean cholesterol levels over time by age, sex and Subregion

The CRA project includes estimates of avoidable burden, that is, the reduction in future burden that would be observed if current levels of exposure to a risk factor were reduced to those specified by a counterfactual distribution of exposure. To perform these calculations an estimate must be made of cholesterol distributions in the future under a "business-as-usual" scenario. This requires estimates of changes in current cholesterol levels 10,20 and 30 years into the future by age, sex and subregion.

Several basic steps were necessary to produce these estimates and each one to some extent dictated the next. First, the literature was reviewed to assess what we already know about trends in cholesterol in different populations. Second, subregions were categorized into broad groupings based on likely direction of changes in cholesterol levels over time. Third, the future trends in cholesterol distribution were estimated.

### 6.1 Literature review of cholesterol trends over time

There is evidence in the literature that risk factors such as cholesterol change over time, and a variety of studies from different world regions and populations have demonstrated increases and decreases in cholesterol levels (Capewell et al. 2000; Dobson et al. 1999; Evans et al. 2001; Law and Wald 1994; McGovern et al. 1996; Sakata and Labarthe 1996; Sigfusson et al. 1991; Suh 2001; Tuomilehto et al. 1991; Vartiainen et al. 1994, 2000). These data were reviewed by subregion. In addition, data on fat intake from the Food and Agriculture Organization of the United Nations (FAO) were reviewed as fat intake correlates with mean cholesterol levels. Changes in mean cholesterol levels in recent literature relate predominantly to AMR-A, EUR-A and WPR-A.

Figure 7.15 Percentage of total calories from fat per capita per day

The best available FAO data (www.fao.org) cover the whole world, but the country groupings differ from those of WHO. FAO data may be presented as the total number of calories supplied as fat per day, or percentage of daily calories supplied as fat (Figure 7.15). (These data only relate to total fat, and have not been subdivided further, e.g. into saturated or animal fat vs unsaturated fat.)

## AMR-A AND EUR-A

Studies in the United Kingdom of Great Britain and Northern Ireland (Capewell et al. 1999; Law and Wald 1994), the United States (Law and Wald 1994; McGovern et al. 1996), Finland (Tuomilehto et al. 1991; Vartiainen et al. 1994, 2000), Iceland (Sigfusson et al. 1991) and other parts of Europe (Law and Wald 1994) have documented reductions in mean cholesterol levels. In the more recent studies from the 1980s onwards, these decreases have been approximately $0.02-0.03 \mathrm{mmol} / \mathrm{l}$ of cholesterol per year in males and females (Capewell et al. 2000; Dobson et al. 1999; Evans et al. 2001; McGovern et al. 1996; Vartiainen et al. 2000). FAO data also show a levelling or decline of mean cholesterol levels recently in North America (AMR-A) and Europe (EUR-A). The direction of these trends correlates with those demonstrated for blood pressure in the same studies.

WPR-A
Reduction in mean cholesterol levels has been documented in New Zealand and Australia (Capewell et al. 2000; Dobson et al. 1999; Law
and Wald 1994). In contrast, there appears to have been an increase in mean cholesterol levels in Japan since the 1980s (Law and Wald 1994; Okayama et al. 1993; Sakata and Labarthe 1996) in the order of about $0.03-0.04 \mathrm{mmol} / \mathrm{l}$ per year (Sakata and Labarthe 1996). This would result in an overall increase in cholesterol levels in WPR-A, owing to the larger population size of Japan. WPR-A covers countries that would be included by FAO in Asia (Japan) and Oceania (Australia, New Zealand and the Pacific), where trends in fat consumption indicate that cholesterol levels are increasing.

## EUR-B AND EUR-C

Some decreases in cholesterol have been recorded recently in parts of eastern Europe (Bobak et al. 1997), but the data are limited. The FAO region that covers the former Soviet Union and the Russian Federation most closely maps to EUR-B and C, and also suggests a levelling off and possible decline in fat consumption.

WPR-B
Mean cholesterol levels appear to be increasing in China and in the Republic of Korea (Evans et al. 2001; Suh 2001), which correlates with increases in fat consumption in China.

## Other subregions

Very few data were available on several developing subregions (AFR-D, E, AMR-B, D, EMR-B, D, SEAR-B and D); however, certain data demonstrated that as regions become more industrialized or "acculturated", risk factor profiles such as blood pressure and cholesterol change. This is particularly evident in migration studies conducted in a variety of settings (Poulter and Sever 1994), such as Africa (Poulter et al. 1988, 1990), China (He et al. 1991a, 1991b), and the Pacific (Joseph et al. 1983; Salmond et al. 1985, 1989), which suggest that blood pressure and cholesterol levels rise after people migrate to more urbanized "acculturated" settings. The trends are as follows.

AMR-B and D: FAO data from Central and South America suggest that overall, fat consumption is increasing.

EMR-B and D; SEAR-B and D: These subregions are all included in the FAO grouping of Asia where levels of fat consumption are increasing.

AFR-D and E: FAO data suggest small increases in fat consumption.

### 6.2 Potential categories of cholesterol change

Data presented above indicate that mean cholesterol levels appear to be decreasing in many of the most developed subregions, while they are increasing or plateauing in less developed subregions. However, estimating how long the current trends will continue and quantifying the changes is difficult.

A published meta-analysis assessed the quantitative importance of dietary fat to blood concentrations of total cholesterol (Clarke et al. 1997). However, these results are difficult to extrapolate to FAO data as they relate to isocaloric replacement of fats by carbohydrates. The FAO data demonstrated not only increasing caloric fat intake, but also increasing caloric intake from other sources and overall. Therefore, the same associations do not apply. The following potential scenario was therefore based on current evidence of time trends, and previously documented changes in mean cholesterol levels.

Owing to the limited data available, these estimates are susceptible to a high degree of uncertainty. A wide range of factors could influence future risk factor levels, and it is difficult to capture these factors even with sophisticated modelling. A decision was thus made to use a relatively simple, but transparent method for the purposes of these analyses.

## Estimates of mean cholesterol levels over time

Table 7.18 presents an overview of the cholesterol trends over time, by subregion. The following estimates summarize mean cholesterol levels by subregion, sex and age, currently and in 2010, 2020 and 2030 (Tables 7.19-7.22).

Table 7.18 Scenario for changes in mean cholesterol levels (mmol/l) by subregion over the next 10,20 and 30 years $^{2}$

| Subregion | 2000 to 2010 | 2010 to 2020 | 2020 to 2030 | Comment |
| :---: | :---: | :---: | :---: | :---: |
| AMR-A | $\downarrow 0.3 \mathrm{mmol} / \mathrm{l}$ | $\downarrow 0.3 \mathrm{mmol} / \mathrm{l}$ | $\downarrow 0.2 \mathrm{~mol} / \mathrm{l}$ | $\downarrow$ attenuating over time |
| EUR-A | $\downarrow 0.3 \mathrm{mmol} / \mathrm{l}$ | $\downarrow 0.3 \mathrm{mmol} / \mathrm{l}$ | $\downarrow 0.2 \mathrm{~mol} / \mathrm{l}$ | $\downarrow$ attenuating over time |
| WPR-A | $\uparrow 0.2 \mathrm{mmol} / \mathrm{l}$ | $\rightarrow$ plateau | $\downarrow 0.1 \mathrm{~mol} / \mathrm{l}$ | $\uparrow$ due to influence of Japan over next 10 years, then plateau and start to decrease |
| AMR-B, D | $\uparrow 0.2 \mathrm{mmol} / \mathrm{l}$ | $\uparrow 0.1 \mathrm{mmol} / \mathrm{l}$ | $\rightarrow$ plateau | $\uparrow$ attenuating over time, then plateau |
| EUR-B, C | $\rightarrow$ plateau | $\downarrow 0.1 \mathrm{~mol} / \mathrm{l}$ | $\downarrow 0.1 \mathrm{~mol} / \mathrm{l}$ | $\rightarrow$ plateau initially then start to decrease as some evidence on this already happening in some regions |
| WPR-B | $\uparrow 0.3 \mathrm{mmol} / \mathrm{l}$ | $\uparrow 0.2 \mathrm{mmol} / \mathrm{l}$ | $\uparrow 0.1 \mathrm{mmol} / \mathrm{l}$ | $\uparrow$ attenuating over time |
| SEAR | $\uparrow 0.2 \mathrm{mmol} / \mathrm{l}$ | $\uparrow 0.1 \mathrm{mmol} / \mathrm{l}$ | $\rightarrow$ plateau | $\uparrow$ attenuating over time, then plateau |
| EMR | $\uparrow 0.2 \mathrm{mmol} / \mathrm{l}$ | $\uparrow 0.1 \mathrm{mmol} / \mathrm{l}$ | $\rightarrow$ plateau | $\uparrow$ attenuating over time, then plateau |
| AFR | $\uparrow 0.2 \mathrm{mmol} / \mathrm{l}$ | $\uparrow 0.1 \mathrm{mmol} / \mathrm{l}$ | $\rightarrow$ plateau | $\uparrow$ attenuating over time, then plateau |

## Acknowledgements

Particular thanks are due to the Asia-Pacific Cohort Studies Collaboration secretariat, and all study collaborators for allowing us to access and analyse their data for estimates of relative risk. The Prospective Studies Collaboration assisted with analyses and provided unpublished data on relative risk estimates that could be compared with those presented here.

The authors are grateful to Varsha Parag and Derrick Bennett for biostatistical support. Angela Hurley provided valuable research assistance and Clarissa Gould-Thorpe provided secretarial support.

## Note

1 See preface for an explanation of this term.

Appendix B: Methodology for estimating stroke subtypes by age, sex, subregion and fatal and non-fatal events
Subregional- and age-specific proportions of ischaemic and haemorrhagic fatal and non-fatal strokes were estimated so that weighted RRs could be applied. Based on published data, an assumption was made that these are the same for males and females. Several steps were undertaken to estimate stroke subtype proportions, and these are outlined below.

## Step 1. Assess age patterns of haEmorrhagic and <br> ISCHAEMIC STROKE

The most reliable data on age patterns of stroke subtypes are available from a small selection of "gold standard" incidence studies, most of which were included in a review (Sudlow and Warlow 1997). These studies include the Melbourne stroke study (Thrift et al. 2001), Oxfordshire stroke project (Bamford et al. 1990), Perth community stroke study (Anderson et al. 1993) and the Dijon study (Giroud et al. 1991). Broadly, similar age patterns have also been seen in other studies.

Utilizing the combined age-specific data from these four studies, the percentage of ischaemic strokes in 10-year age categories is presented in Figure B.1. (The number of strokes in the youngest age group is small compared to the other age groups and is therefore less reliable.)

Figure B.I Percentage of ischaemic strokes by age using data from four "gold standard" studies with linear regression line

Table B.I Estimates of the proportion of stroke subtypes by age

|  | Age group (years) |  |  |  |  |
| :--- | :---: | :---: | :---: | :---: | :---: |
| Stroke subtypes | $30-44$ | $45-59$ | $60-69$ | $70-79$ | $\geq 80$ |
| $\%$ ischaemic | 77 | 81 | 84 | 87 | 89 |
| $\%$ haemorrhagic | 23 | 19 | 16 | 13 | 11 |

The linear regression was then used to estimate the proportions of ischaemic stroke by GBD age groups using the midpoint in each GBD age category. The remaining strokes were classified as haemorrhagic (Table B.1).

## Step 2. Estimate the age-specific subtype proportions for fatal and NON-FATAL EVENTS

Table B. 1 relates to total strokes, but these proportions will differ for fatal and non-fatal strokes as the case fatality rates for the ischaemic and haemorrhagic strokes are different. The "gold standard" incidence studies (Sudlow and Warlow 1997) suggest that the one-month case fatality rates range from $10 \%$ to $23 \%$ (crude average $=14 \%$ ) for ischaemic stroke, and $35 \%$ to $54 \%$ (crude average $=45 \%$ ) for haemorrhagic stroke. If it is assumed that these case fatality rates apply for all age groups, these crude percentages can be applied to each age group to provide estimates of the overall proportion of stroke subtypes for fatal and non-fatal events (Table B.2).

These percentages may then be converted in proportions of ischaemic and haemorrhagic stroke within the fatal and non-fatal categories for each age group (Table B.3).

Table B. 2 Estimates of subtype proportions for fatal and non-fatal events by age

| Age group (years) | Total stroke (\%) |  | Fatal stroke (\%) |  | Non-fatal stroke (\%) |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | Ischaemic | Haemorrhagic | Ischaemic | Haemorrhagic | Ischaemic | Haemorrhagic |
| 30-44 | 77 | 23 | 11 | 10 | 66 | 13 |
| 45-59 | 81 | 19 | 11 | 9 | 70 | 10 |
| 60-69 | 84 | 16 | 12 | 7 | 72 | 9 |
| 70-79 | 87 | 13 | 12 | 6 | 75 | 7 |
| $\geq 80$ | 89 | 11 | 12 | 5 | 77 | 6 |

Table B. 3 Percentage of stroke subtypes within fatal and non-fatal categories

|  | Fatal stroke (\%) |  |  | Non-fatal stroke (\%) |  |
| :--- | :---: | :---: | :---: | :---: | :---: |
| Age group (years) | Ischaemic | Haemorrhagic |  | Ischaemic | Haemorrhagic |
| $30-44$ | 51 | 49 |  | 84 | 16 |
| $45-59$ | 57 | 43 |  | 87 | 13 |
| $60-69$ | 62 | 38 | 89 | 11 |  |
| $70-79$ | 68 | 32 | 91 | 9 |  |
| $\geq 80$ | 72 | 28 | 93 | 7 |  |

Step 3. Estimate how these age-specific subtype proportions can be APPLIED TO DIFFERENT REGIONS
The age-specific subtype proportions in Table B. 3 would only apply to subregions such as AMR-A and EUR-A, from where the data on which the estimates were based came. Estimates were also required for other subregions. The literature suggests that haemorrhagic stroke is relatively more common (about 30-40\% of all strokes) in Japan (Nakayama et al. 1997; Suzuki et al. 1987), China (Chen et al. 1992; Wu et al. 1992) and Taiwan, China (Hung 1993; Jeng et al. 1998) and lower in countries in North America and Europe (about 10-15\% of all strokes) (Sudlow and Warlow 1997). Unfortunately, reliable data on the remainder of the world are extremely limited or non-existent, and there are no internally consistent WHO estimates available.

The level of cholesterol is important in determining the overall ratio of ischaemic to haemorrhagic strokes in any world region (APCSC 1999). Subregions may therefore be crudely ranked based on their mean cholesterol levels, grouped into three basic subregional categories, and average percentages of haemorrhagic stroke applied. An example is given in Table B.4.

Table B. 4 Subregional grouping by mean cholesterol and percentage haemorrhagic stroke ${ }^{\text {a }}$

| Subregional grouping | Cholesterol level | Overall \% haemorrhagic stroke |
| :--- | :--- | :---: |
| AMR-A, EUR-A, EUR-C | $\geq 5.8 \mathrm{mmol} / \mathrm{l}$ | 15 |
| AFR-D, AFR-E, AMR-B, AMR-D, | $5.1-5.7 \mathrm{mmol} / \mathrm{I}$ | 20 |
| EMR-B, EMR-D, EUR-B, SEAR-D, WPR-A |  |  |
| SEAR-B, WPR-B | $\leq 5.0 \mathrm{mmol} / \mathrm{l}$ | 30 |

[^26]The case fatality rates used previously ( $14 \%$ ischaemic, $45 \%$ haemorrhagic) are applicable to WPR-A, AMR-A and EUR-A, but case fatality would be higher in other subregions. Limited data are available, but when case fatality rates of $20 \%$ for ischaemic stroke and $60 \%$ for haemorrhagic stroke (Chen et al. 1992; Li et al. 1985) are applied to other subregions, five potential scenarios result (Table B.5).

These proportions may then be translated into age-specific proportions for fatal and non-fatal ischaemic and haemorrhagic strokes (Table B.6).

Table B. 5 Subregional grouping by mean cholesterol and percentage haemorrhagic stroke

| Subregional grouping | \% haemorrhagic <br> stroke | Ischaemic stroke <br> case fatality (\%) | Haemorrhagic <br> case fatality (\%) |
| :--- | :---: | :---: | :---: |
| EUR-A, AMR-A | 15 | 14 | 45 |
| EUR-C | 15 | 20 | 60 |
| WPR-A | 20 | 14 | 45 |
| EMR-B, EMR-D, EUR-B, AFR-D, | 20 | 20 | 60 |
| AFR-E, AMR-B, AMR-D, SEAR-D | 30 | 20 | 60 |
| SEAR-B, WPR-B |  |  |  |

Table B. 6 Proportion of fatal and non-fatal stroke subtypes by age and subregion

| Age group (years) | Fatal stroke (\%) |  | Non-fatal stroke (\%) |  |
| :---: | :---: | :---: | :---: | :---: |
|  | Ischaemic | Haemorrhagic | Ischaemic | Haemorrhagic |
| EUR-A, AMR-A |  |  |  |  |
| 30-44 | 51 | 49 | 84 | 16 |
| 45-59 | 57 | 43 | 87 | 13 |
| 60-69 | 62 | 38 | 89 | 11 |
| 70-79 | 68 | 32 | 91 | 9 |
| $\geq 80$ | 72 | 28 | 93 | 7 |
| EUR-C |  |  |  |  |
| 30-44 | 53 | 47 | 87 | 13 |
| 45-59 | 59 | 41 | 90 | 10 |
| 60-69 | 64 | 36 | 91 | 9 |
| 70-79 | 69 | 31 | 93 | 7 |
| $\geq 80$ | 73 | 27 | 94 | 6 |

Table B. 6 Proportion of fatal and non-fatal stroke subtypes by age and subregion (continued)

| Age group (years) | Fatal stroke (\%) |  | Non-fatal stroke (\%) |  |
| :---: | :---: | :---: | :---: | :---: |
|  | Ischaemic | Haemorrhagic | Ischaemic | Haemorrhagic |
| WPR-A |  |  |  |  |
| 30-44 | 41 | 59 | 78 | 22 |
| 45-59 | 48 | 52 | 82 | 18 |
| 60-69 | 53 | 47 | 85 | 15 |
| 70-79 | 60 | 40 | 88 | 12 |
| $\geq 80$ | 64 | 36 | 90 | 10 |
| EMR-B, EMR-D, EUR-B, AFR-D, AFR-E, AMR-B, AMR-D, SEAR-D |  |  |  |  |
| 30-44 | 43 | 57 | 82 | 18 |
| 45-59 | 50 | 50 | 85 | 15 |
| 60-69 | 55 | 45 | 88 | 12 |
| 70-79 | 61 | 39 | 91 | 9 |
| $\geq 80$ | 66 | 34 | 92 | 8 |
| SEAR-B, WPR-B |  |  |  |  |
| 30-44 | 28 | 72 | 70 | 30 |
| 45-59 | 35 | 65 | 77 | 23 |
| 60-69 | 41 | 59 | 81 | 19 |
| 70-79 | 49 | 51 | 85 | 15 |
| $\geq 80$ | 54 | 46 | 88 | 12 |

## Chapter 8

# Overweight and obesity (High body mass index) 

W. Philip T. James, Rachel Jackson-Leach, Cliona Ni Mhurchu, Eleni Kalamara, Maryam Shayeghi, Neville J. Rigby, Chizuru Nishida and Anthony Rodgers

## Summary

It is widely acknowledged that being overweight is associated with an amplified risk of disease, particularly if body fat is deposited within the abdomen, as suggested by a high waist-circumference measurement. This chapter aims to estimate the burden of disease attributable to overweight and obesity as indicated by a high body mass index (BMI), by age, sex and subregion. ${ }^{1}$

BMI, which is calculated as weight ( kg ) divided by height squared $\left(\mathrm{m}^{2}\right)$, was chosen as a simple measurement of body weight in relation to height. While increases in both body fat and lean tissue cause increments in BMI, relationships between body weight and health are conventionally expressed in terms of BMI rather than body fat. Data on population weight and height, often collected as part of general medical or economic surveys, were obtained, typically from specially-commissioned analyses from ministries of health. Where these data sets or published representative information were lacking, earlier data published for each country were used. All information based on studies of select groups within a population were excluded. In addition, only data obtained by actual measurement of heights and weights by trained observers were included. As data were not available for some countries, it was necessary to extrapolate from data for other countries or subregions when deriving estimates of BMIs for the different age groups in each subregion.

Analyses of the relationship between BMI and both mortality and morbidity suggested that the theoretical optimum mean population BMI was approximately $21 \mathrm{~kg} / \mathrm{m}^{2}$. This value is far removed from those now found in many parts of the world. The analyses based on this continuous relationship therefore replaced the usual categorical analyses based on rates of overweight and obesity in the different subregions.

The disease outcomes assessed in relation to excess weight were type II diabetes (diabetes mellitus), ischaemic heart disease, stroke, hypertensive heart disease, osteoarthritis, and cancers of the postmenopausal breast, colon, endometrium and kidney. As it was evident that adult BMIs of $>21 \mathrm{~kg} / \mathrm{m}^{2}$ were associated with the development of disease, the burden of disease attributable to high BMI was calculated from this baseline. New analyses based on 33 cohort studies carried out within the Asia-Pacific region were used to estimate the incremental risk of cardiovascular disease associated with each unit increase in BMI above 21 $\mathrm{kg} / \mathrm{m}^{2}$. The relationship between BMI and the risk of type II diabetes was derived from both unpublished and published data comprising measured anthropometry and fasting blood sugar measurements, extracted from nationally representative studies. Equivalent increments in the risks of co-morbidities associated with body-weight gain were assumed for all parts of the world.

High mean BMIs and elevated rates of overweight and obesity were found in the Americas, Europe, the Middle East and in the Western Pacific. It is estimated that rates of obesity vary geographically from $2-3 \%$ in some Asian countries to $75 \%$ in several Pacific Island nations. Currently, there are more than 300 million obese and more than 750 million overweight individuals in the world.

The proportions of the global burden of disease attributable to increases in BMI were $58 \%$ for type II diabetes, $21 \%$ for ischaemic heart disease, $39 \%$ for hypertensive disease, $23 \%$ for ischaemic stroke, $12 \%$ for colon cancer, $8 \%$ for postmenopausal breast cancer and $32 \%$ for endometrial cancer in women, and $13 \%$ for osteoarthritis. This means that the global burden of disease attributable to excess BMI in adults amounted to more than 30 million disability-adjusted life years (DALYs) in 2000, mostly incurred from ischaemic heart disease and type II diabetes. There were two and a half million deaths associated with this exposure. These are average global figures and there are remarkable variations by subregion and by disease. Thus EUR-C has the greatest burden of DALYs, this being dominated by the impact of high BMI on ischaemic heart disease, whereas the two African subregions have the lowest burden of DALYs. The burden of diabetes attributable to high BMI is greatest in WPR-B and AMR-B, with AMR-A also having a substantial burden. DALYs attributable to stroke were also dominated by the impact of high BMIs in both EUR-C and WPR-B, while the burden of DALYs caused by cancer was substantial in the European subregions, AMR-A, AMR-B and WPR-B.

Current trends were used to predict the increases in BMI and disease burden that are likely to occur by 2030, assuming that no new measures are taken to counteract the rapid recent increases in body weight in all parts of the world. On this basis, it is predicted that the burden of disease will increase substantially in most parts of the world, but there will probably be remarkable variations by subregion.

## 1. Introduction

Although the measurement and analysis of body weights and heights have been recognized as general indices of health for many years, it is only comparatively recently that the World Health Organization (WHO) has set out criteria for assessing underweight and overweight in both children and adults (WHO 1995). These new analyses of the impact of excess body weight came from insurance data generated in the first half of the 20th century which were used to identify optimum weights-forheight above which life expectancy was reduced, for both men and women. In the second half of the 20th century, it became clear that abnormalities in blood lipids relating to the risks of ischaemic heart disease were amplified by excessive body-weight gain, as was the risk of high blood pressure, type II diabetes, gallbladder disease and some cancers. It also became clear that the mechanical impact of excess body weight induced breathlessness and promoted arthritis in the weightbearing joints. In developed countries, overweight women were stigmatized, with marked consequences on their sense of well-being, social interactions and even their employment and marriage prospects.

The traditional concerns of governments and policy-makers have focused on undernutrition, with greater emphasis being placed on the continuing problem of childhood protein-energy malnutrition, which is found especially in children aged $0-4$ years. This condition is still prevalent in many countries despite economic progress (James et al. 2000), as described in chapter 2. Many nations now have reasonable systems for monitoring children's growth and can provide estimates of the prevalence of stunting, wasting and overweight in children aged $<5$ years (de Onis and Blössner 2000). Unfortunately, the value of monitoring the weights and heights of older children and adults has not been appreciated until fairly recently. Since the 1997 WHO Expert Consultation on Obesity (WHO 2000), there has been a substantial increase in the number of publications presenting newly-analysed data from past studies in different parts of the world. Thus, the regular national NHANES surveys in the United States of America (Stevens et al. 1999) allowed the magnitude of the problem of overweight to be recognized, and many cardiovascular surveys, for example the WHO MONICA surveys (Dobson et al. 1998), also documented high prevalences of overweight and obesity in Europe and Australasia. Other surveys such as the INTERSALT study (Dyer and Elliott 1999) revealed high prevalences of excess weight in some developing countries, including Brazil (James and Francois 1988). The data presented by many of these studies are not representative and do not include validation of the measurements of height and body weight. Nevertheless, it is apparent that many new national surveys are now being undertaken and a much more extensive database is expected to become available within the next few years.

This chapter was based on an extensive search of the literature to identify appropriate data sets and also specifically-commissioned analyses provided by a number of individuals, organizations and governments.

## 2. Choice of exposure variable

### 2.1 Definitions of body weight and of risk factors

## The use of the BMI

The present analysis is based exclusively on the use of the BMI, which is calculated as weight $(\mathrm{kg})$ divided by height squared $\left(\mathrm{m}^{2}\right)$. The height and weight of both children and adults are crude indices of the impact of many environmental factors, (including diet and infections) on the genetic growth potential of the individual over short and long periods of time, and affect many health outcomes.

BMI is the most appropriate simple indicator by which weight-forheight can be related to health outcome. WHO (1995) therefore proposed the use of BMI to monitor both undernutrition and overweight. The power of height is taken as 2.0 although it has been shown in many analyses that 1.5 might be more appropriate for women on the basis that this index in population studies proves to be approximately heightindependent (Micozzi et al. 1986). Nevertheless, international convention, as represented by two major WHO Technical Consultations (WHO 1995,2000 ), endorsed the use of a common BMI scheme for adults irrespective of sex or age.

Preliminary analyses of the global burden of disease associated with higher BMI, based on the current data sets, suggested that the population distribution of BMI values for men and women in each age group provided more valuable information than simply the proportions of the population who are classified as overweight and obese. These categories of overweight and obesity are used extensively by clinicians for patient management decisions, by the public and by policy-makers. Therefore, the proportions of overweight and obese people in the population are included in this chapter despite the fact that this information was not used in the calculation of the contribution of different values of BMI to the disease burden.

In these subsidiary analyses, the standard WHO BMI categories were used, except that the term "overweight" was taken as referring to BMI values of $25.0-29.9 \mathrm{~kg} / \mathrm{m}^{2}$ only and did not include the "obese" category, i.e. BMI of $\geq 30 \mathrm{~kg} / \mathrm{m}^{2}$, since these two groups, overweight and obesity, are often referred to independently. More extreme categories of obesity have been specified (WHO 2000), but were not included in the current global analyses.

Recently, it has been proposed that a lower BMI range of "healthy", "normal" or "acceptable" weights should be applied to groups of Asian
people (see below), but in the current analysis an assessment was made of the impact of increments in BMI on disease risk in different parts of the world, which was therefore not dependent on different schemes for categorizing overweight and obesity.

## BODY WEIGHT IN CHILDREN

It has become increasingly common for epidemiologists to express heights and weights of children in terms of the same BMI as used in adults, despite detailed analyses showing that BMI varies by age and sex during growth. Criteria have therefore now been developed for specifying the normal weight-for-height of children in terms of BMI for each age group, by sex, until adult height is achieved at approximately 18 years of age. There are three approaches to the categorical analysis of BMI in children: the traditional approach whereby an "abnormal" group is taken to be more than two standard deviations from the mean, the new International Obesity Task Force (IOTF) approach that relates BMI categories in childhood to the accepted classification in adults (Cole et al. 2000), and a new Centers for Disease Control and Prevention (CDC) set of standards whereby obesity is specified as $>95$ th BMI percentile of carefully selected representative data from the United States (Ogden et al. 2002).

It is recognized that children of similar body proportions but of different heights at the same age will have different BMI values and that to obtain height-independent indices would require a sequential adjustment in the power value of height from about age 5 years upwards (Franklin 1999). Nevertheless, given that population comparisons are being made here, rather than the monitoring of the growth of individuals, weights and heights for children have been expressed in terms of BMI and these calculations have been applied only to children aged 5-18 years. The large body of nationally representative data for children aged $<5$ years collated by WHO and presented in chapter 2 provides the relevant information for this age group. However, the burden of disease estimates presented here are only for adults aged $\geq 30$ years. This age limit was chosen because there are as yet insufficient prospective studies of an appropriate magnitude in children and young adults to allow quantitative analyses of the impact of excess weight gain on the incidence of noncommunicable diseases in individuals aged $<30$ years.

### 2.2 Other exposure determinants

## Body fat

It is often assumed that health-related data would ideally be related to good measures of body fatness, and that the combination of weight and height in the form of BMI provides a crude index of body fatness. In practice, however, too few studies have measured body fatness and health outcomes at different ages and in different societies to allow an analysis
of whether a more specific measure of body fat than BMI would give greater predictive power for health outcomes. Given the many prospective studies that use BMI, the current convention has been maintained while recognizing that recent data show that different ethnic groups have substantially different proportions of body fat at the same value of BMI. For example, the ratio of fat: lean tissue is highest in Indian people, while values for Chinese people are intermediate between those for Indians and Caucasian peoples (Deurenberg et al. 2002), and Polynesians are increasingly recognized as having a relatively high proportion of lean tissue (Swinburn et al. 1999). On this basis, Deurenberg and colleagues have suggested that different BMI values should be chosen if the intention is to standardize international comparisons on the basis of body fat (Deurenberg et al. 1998, 2002). There are, however, no international studies as yet which would allow all population groups to be set a particular BMI value based on their fat:lean tissue ratios and the relationship of these indices to health outcomes.

Therefore, this chapter maintains the current convention of using BMI as an indicator of body fatness in adults. It is recognized that not only do women have substantially more fat tissue than men at equivalent BMIs (Shetty and James 1994), but also that both men and women lose lean tissue during the course of their adult lives such that, at an equivalent BMI, a 75 -year-old man or woman has substantially greater proportion of fat than a 25 year old (James et al. 1988). This is not a cohort effect since the same changes have been shown, at least in men, in the Baltimore study of ageing, which evaluated the changing body composition of the same men over a 50-year period (James et al. 1989).

## CORrECTIONS FOR UNUSUAL BODY PROPORTIONS

The proportions of the major body parts which contribute to height may be different in different ethnic groups. For example, some African tribes are considered to have exceptionally long legs, whereas the indigenous populations of Central America are often cited as being small with very short legs (Norgan 1994a). It can readily be shown that even if the proportions of both the trunk and legs are equal in very short and tall peoples, the actual BMIs of these peoples will be very different. This has led Norgan (1994b) to develop a simple correction for BMI measurement based on the ratio of sitting height to total height. Although this is well-recognized (WHO 1995) and is valuable when looking at particular groups, the limited availability of good data on sitting height meant that it was not possible to incorporate this correction for BMI into the current analyses.

## WAIST CIRCUMFERENCE

Originally it was hoped that sufficient data would become available on waist circumference to allow an assessment of the usefulness of this measure in predicting the health of different communities. There are
many analyses that demonstrate that waist circumference provides a reasonable indicator of the quantity of abdominal fat, which correlates with the amount of intra-abdominal or visceral fat (Despres et al. 2001). This fat is considered to be metabolically rather different from subcutaneous fat in its responsiveness to dietary change and in its array of metabolite and hormonal outputs. An excess of abdominal fat has been associated with a range of metabolic abnormalities and diseases (Despres et al. 2001). The measurement of waist circumference is often found to be more valuable than BMI itself, for example, in predicting the likelihood of ischaemic heart disease (Lapidus et al. 1984; Larsson et al. 1984) or diabetes (Chan et al. 1994). The National Institutes of Health (NIH) report from the United States (NIH 1998) used waist circumference measurements as a suitable indicator of additional risk within a given range of BMI. In some studies, there seems to be additional predictive power when the waist:hip ratio rather than just waist circumference is used. The hip measurement indicates the degree of fat accumulation around the hips and this deposition may help in some way to limit the health impact of abdominal fat accumulation (Seidell et al. 2001b). Nevertheless, there seems to be increasing acceptance that, for general use, a single measure of waist circumference provides a simple index of fat distribution and additional risk (Seidell et al. 2001a).

Proposals have been also made for lower cut-off points for measurements of waist circumference for use in Asian communities (WHO/IASO/IOTF 2000) and new Chinese analyses have also proposed different values (Zhou 2002). There is also now increasing evidence that many communities, e.g. African and Hispanic Americans in the United States, Indians in India and elsewhere, the Chinese and Latin Americans have a greater propensity as adults to accumulate excess adipose tissue in the abdominal area than Caucasians in Europe or the United States (Ford et al. 2002; Sánchez-Castillo et al. 2003; Sargeant et al. 2002; Singh et al. 1995; Zhou et al. 2002). Although the selective accumulation of abdominal fat is indicative of a much greater risk of diabetes, hypertension, ischaemic heart disease, strokes and gall bladder disease, cross-sectional studies of the African diaspora in West Africa, the Caribbean and the United States show that the relationship of waist circumference to disease seemed to vary by region, perhaps because of concomitant regional dietary differences (Okosun et al. 1998, 2000). Nationally representative data and long-term cohort studies of the health impact of different indices of abdominal obesity in different communities are also currently insufficient to allow the use of some measures of waist circumference to estimate the BMI-disease relationship in different parts of the world.

The propensity to abdominal obesity within a community seems to be markedly influenced by stunting or a small size in childhood (Schroeder et al. 1999) and also by size at birth (Barker 1998). Changes in the hypo-thalamic-pituitary-adrenal axis controlling pituitary hormone and
corticosteroid metabolism in response to fetal nutritional deprivation and early postnatal events are also evident experimentally (Seckl et al. 2001) and abdominal obesity is associated with abnormal control of corticosteroid metabolism (Björntorp and Rosmond 1999). Evidence from India shows that children aged 4 and 8 years who were born small and later showed accelerated growth had a propensity to abdominal obesity with greater insulin resistance and higher blood pressure (Yajnik 2000). The current data available on a global basis do not, however, allow a systematic adjustment of health risk based on birth weights in different parts of the world, or the prediction of childhood BMIs from infant birth weights. A substantial proportion of the world's population that has been existing on marginal diets for centuries may have been sensitized to excess body-weight gain, this being reflected in the greater propensity to accumulate abdominal fat and in the higher prevalence of the metabolic syndrome of multiple risk factors for chronic diseases of adults such as diabetes, hypertension and ischaemic heart disease in Hispanic and non-Caucasian ethnic groups (Ford et al. 2002).

## 3. Methods of identifying sources AND STUDIES

### 3.1 Studies of interest

Studies of interest were identified using the following methods:

- Searches of the Medline and Embase databases were conducted systematically for all 191 countries of the world. Medline searches were performed with the keywords "BMI" and "obesity", each paired with "cardiovascular disease", "hyperlipidaemia", "cholesterol", "stroke", "ischaemic heart disease", "osteoarthritis", "diabetes mellitus type II", "cerebrovascular disease", and in combination with each country name, i.e. $2 \times 8 \times 191$ searches. Example: BMI AND cardiovascular disease AND country X. Both United Kingdom and American English spellings were used in the searches. Embase searches were performed with the keywords "BMI", "obesity", "body mass", "body height", "weight", "children", and "adults". Countries were not specified in these searches.
- IOTF contacted each WHO Regional Nutrition Officer to request help with the analyses. The precise format for these was specified and each region was asked to help identify appropriate contacts from whom reliable national data on both BMI and diet could be obtained.
- Numerous direct contacts were made with governments and individuals to determine whether unpublished data were available. It is significant that with obesity now becoming a high profile issue throughout the world, many investigators, on learning of this
project, stated that they now wished to publish in their own right information on prevalence rates that had remained unpublished for several years.
- Relevant data sets were retrieved from online databases, or purchased and re-analysed. These included a United States Agency for International Development (USAID)-sponsored series of Demographic and Health Surveys (DHS) conducted by Macro International, the United States National Health and Nutrition Examination Survey (NHANES) III, and the 1998 Health Survey for England.
- Analyses of 33 cardiovascular cohort studies being conducted in the Asia-Pacific region and participating in the Asia-Pacific Cohort Studies Collaboration (APCSC) were also used to derive the relative risks of cardiovascular disease associated with increases in BMI.

For data from the identified studies, the following inclusion criteria were used.

- Nationally representative data were preferred.
- Clinical data were excluded whenever possible because they reflect a subgroup of the population with particular medical problems and could not be considered nationally representative.
- Only measured anthropometric data were used to assess the national information on BMI. A good correlation between measured and reported weights and heights can be found (Flegal and Troiano 2000), but many international analyses of reported vs measured heights and weights, including those from the United States, reveal discrepancies which underestimate weight and overestimate height, these discrepancies being particularly apparent in the groups of overweight people (see Niedhammer et al. 2000). Australian analyses have also shown that there can be very substantial differences in the prevalences of overweight and obesity as judged by the two approaches (Anonymous 1999). Nevertheless, for prospective analyses, the overall associations between reported weights and heights and health outcomes are unlikely to be seriously affected, even if the magnitude of the association becomes more uncertain. Therefore, some results of major studies employing self-reported weights and heights were used to illustrate disease relationships (although the quantitative associations used in estimates of impact on the health of the population are all derived from studies employing actual measurement of BMI). Given the levels of inaccuracy and bias associated with self-reported BMI, the use of such data was considered inappropriate for the purpose of estimating exposure. A small bias could have a substantial impact on the estimated prevalences of overweight and obesity in the tail of the BMI distribution. This criterion excludes many high profile publications that rely on self-reported weights and heights, particularly from

European Union surveys, and a large number of studies from the United States.

- A sufficiently large sample size was required, with preference being given to studies investigating $\geq 1000$ individuals. For countries with no data, studies with smaller samples were not excluded.
- The earliest cut-off date for data collection was 1990 , whenever possible. Where no suitable studies were available, studies dating from 1980 onwards were considered.
- For diabetes, only representative population measures of fasting plasma glucose were used. Ideally, representative data from children and adults tested with a standard glucose load are desirable for a full assessment of the prevalence of diabetes in relation to BMI, but there are very few studies with nationally representative data available from developing countries. No studies which involved the self-reporting of the presence of diabetes were considered appropriate for estimating national prevalences of diabetes, since surveys have repeatedly shown that representative assessments of population groups find a substantial proportion of unrecognized cases of diabetes within the community. In general, as age and BMI increase, the number of individuals with unrecognized diabetes also increases and there can therefore be substantial systematic biases. On this basis, only nationally representative data on fasting blood glucose levels, in combination with measured weights and heights, were used to assess the risk of diabetes associated with body-weight gain. The reason for relying on prevalence rather than incidence data for diabetes to estimate risk in relation to excess body weight is set out in a later section.

### 3.2 Measurements in children

The quantitative assessments of the disease burden caused by high BMI reported here only apply to adults aged $\geq 30$ years. However estimates were also made of BMI values among children, by age, sex and subregion. This was for two reasons. First, these estimates are relevant to estimates of avoidable burden, since BMI levels track over time and so they will guide projections of the distribution of adult BMI in the next few decades. Second, high BMI is responsible for a disease burden in children and there is increasing evidence that high BMI in childhood markedly enhance the risks of disease once these children become adults; these relationships need to be included in hazard size estimates in the future. Therefore, these analyses attempted to estimate the distribution of BMIs for each 1 -year age group for ages $5-18$ years (i.e. until the typical end of child and adolescent normal growth [see the WHO Expert Technical Consultation on Anthropometry, WHO 1995]) and for ages 18-29 years combined.

In analysing the basis of overweight in children (Dietz and Bellizzi 1999), a concept was developed by IOTF which allowed a coherent set of nationally representative data on BMI percentiles at age 18 years to be obtained from both developed countries (prior to the recent emergence of many children with clear clinical obesity) and developing countries. The percentile values corresponding to BMIs of 25 and $30 \mathrm{~kg} / \mathrm{m}^{2}$ at age 18 years were used to derive sex- and age-specific cut-off points for the categorical analysis of overweight (see Cole et al. 2000). In the United States, CDC have also produced reference curves, but these are based arbitrarily on the 85 th and 95 th percentiles of carefully selected nationally representative data (Ogden et al. 2002). The data for this chapter are presented according to the IOTF system, Roberts and Dallal (2001) having concluded that the IOTF reference levels were more suitable for international comparisons.

## 4. Estimating mean BMI And prevalences of OVERWEIGHT AND OBESITY

Given that representative data were not available for all 191 countries, it proved necessary to undertake a number of extrapolations. Some of the principal approaches are set out below.

### 4.1 Description of subregional availability of data

AFR-D
Childhood mean BMI data were from Mali and Senegal. In adults, subregional estimates were based on data from Cameroon, the Gambia, Ghana, Nigeria, Mali and Senegal. Data were also obtained for the Seychelles but were not included in the estimate. Mean BMI data are outlined in Table 8.1.

## AFR-E

In children, subregional mean BMI data were from Ethiopia, South Africa and Zimbabwe. In adults, estimates were based on data from Ethiopia, Kenya, Malawi, South Africa, the United Republic of Tanzania and Zimbabwe. Data available from Kenya and the United Republic of Tanzania were limited to females only. Mean BMI data are outlined in Table 8.2.

## AMR-A

For children, subregional mean BMI data were derived from both Canada and the United States. Although the Canadian data were not nationally representative, it was felt that these data should be used until nationally representative data become available in the required format. In adults, data were available from all countries in the subregion. Data from Cuba were provided in different age categories and were adjusted

- No data.
a Data provided for Cameroon were estimated from graphs as actual figures were not available.
according to the methodology outlined in section 4.4. Mean BMI data are outlined in Table 8.3.

AMR-B
Data on mean BMI in childhood were derived using findings from Argentina, Brazil and Mexico. The standard deviation for mean BMI in children was not available. To estimate standard deviation, the methodology outlined in section 4.6 was applied to data from EMR-B. For adults, subregional data were taken from Argentina, Barbados, Brazil, Mexico and Paraguay. Data were also obtained for Saint Lucia but were not included in the subregional analysis. Mean BMI data are outlined in Table 8.4.

AMR-D
Limited data were available for this subregion and neither population sample presented for children was considered to be nationally representative. However, it was considered inappropriate to exclude these data and to extrapolate from other subregions. For Guatemala, only data from children living in high altitude areas were considered in the calculations. Data for adults were only available for females. Subregional estimates for females were used to derive estimates for males, using

the Islamic Republic of Iran, Jordan, Kuwait, Lebanon, Saudi Arabia and the United Arab Emirates. Only data for Lebanon were provided in the appropriate age categories; all other data were subject to the methodology outlined in section 4.4. Mean BMI data are outlined in Table 8.6.

## EMR-D

Childhood data were not available in this subregion in the required format. Using the methodology outlined in section 4.5 , it was concluded that it would be most appropriate to use data from the AFR-E subregion in order to determine the estimates for children. Mean BMI data for adults were limited to Pakistan and Egypt (females only). No data were available for the $\geq 80$ years age category, therefore the methodology outlined in section 4.4 was applied. Mean BMI data are outlined in Table 8.7.

## EUR-A

Availability of mean BMI data is described in Table 8.8.

Table 8.7 Mean BMI for adults in EMR-D

|  |  | Mean BMI (kg/m²) <br> Age group (years) |  |  |  |  |  |  |

| No data. |  |  |  |  |  |  |  |  |

EUR-B
In children, data on mean BMI were available from Bulgaria, Poland, Slovakia and Turkey. In adults, data on mean BMI were available from Romania, Slovakia, Tajikistan, Turkey and Uzbekistan, and are outlined in Table 8.9.

EUR-C
Limited data were available for children in EUR-C, from the Russian Federation only. In adults, data were available for Hungary, Latvia, Lithuania and the Russian Federation and are outlined in Table 8.10.

SEAR-B
There were no data available for children in this subregion, thus data from AFR-E were used, as specified in section 4.5. As no data for adults were available for Indonesia or Sri Lanka, subregional figures were based on data from Thailand, as outlined in Table 8.11. Normally these data would have been excluded as they came from attendees at a dental clinic. However, as no other data were available in the required format at the time, it was decided that they should be included in the absence of any more appropriate data.

SEAR-D
Data for children were available from Nepal. Data for adults were available for Bangladesh, India (females only) and Nepal. Mean BMI values available are shown in Table 8.12.

WPR-A
Data were available for both children and adults for Australia and Japan, as outlined in Table 8.13.

WPR-B
As no data were available for children in WPR-B, data from AFR-E were used as specified in section 4.5. Data for adults were available for China,

### 4.2 Obtaining subregional estimates from COUNTRY-SPECIFIC ESTIMATES

In order to obtain subregional estimates of mean BMI, prevalences of overweight and obesity and their associated standard errors for sex- and age-specific categories, a meta-analysis was initially considered. In this approach, estimates from different studies would be combined into a single weighted estimate, using the variance of the estimate as the weight. The combined estimate of the variances would then be the inverse of the sum of the study-specific variances. There were two major drawbacks which made this approach unsuitable.

- Countries with unknown variances would be excluded from the subregional analysis for the estimate of mean BMI or prevalences of overweight and obesity.
- The method of weighting by the variance of the study (which is highly dependent on the sample size and the design of the study, with "better", larger studies having the smallest variances) assumes an equal population for each sample. The approach does not take into account differences in population sizes.

A second approach was to obtain a single estimate of mean BMI and the prevalences of overweight and obesity by using a populationweighted average. Standard deviations were estimated using standard statistical relationships. ${ }^{2}$

For simplicity, a simple average of the standard errors of the prevalences of overweight or obesity was used to obtain subregional estimates. In cases where no country data were available and the prevalences of overweight or obesity were based on predictions, the subregional standard error was that of the prediction.

### 4.3 CONVERTING MEAN BMI TO PROPORTIONS OF OVERWEIGHT and obesity and vice versa

BMI distributions are skewed in almost all age and sex categories throughout the world. Thus mean BMI with standard deviation does not accurately describe the whole BMI distribution and usually no further details of the distribution are available. However, Rose and Shipley (1990) showed that the prevalence of obesity ( $\mathrm{BMI} \geq 30 \mathrm{~kg} / \mathrm{m}^{2}$ ) was highly correlated with mean BMI in the selected group of adults, the prevalence of obesity increasing by $4.22 \%$ per unit $\left(1 \mathrm{~kg} / \mathrm{m}^{2}\right)$ increase in mean BMI. This approach was repeated in the present analysis, which was based on adult data (all ages $\geq 18$ years combined) from 36 countries with continuous and categorical data for females and 26 countries with continuous and categorical data for males (Table 8.15). The mean BMI values for countries used in this estimation varied widely from $18.1 \mathrm{~kg} / \mathrm{m}^{2}$ to $29.2 \mathrm{~kg} / \mathrm{m}^{2}$. Mali was excluded from the current analyses in males because it was an outlier. Mean sex-specific BMI vs percentages of overweight and obesity are shown in Figures 8.1 and 8.2.

There is a clear positive linear association for both sexes. The regression equations that describe the graphs are:

[^29]Figure 8.2 Mean BMI and percentage of the adult population that is obese

Note: The predicted relationship is shown, together with the $95 \%$ confidence intervals of the prediction. The quadratic equations are given below.

Males $(\%$ overweight $)=-110.4+5.7 \times($ mean BMI)
Females $(\%$ overweight $)=-74.2+3.97 \mathrm{x}($ mean BMI)
In both cases, the $\beta$ coefficient was highly statistically significant and the models accounted for $>90 \%$ of the total variation. There was also a strong correlation between mean BMI and percentages of obese adults in the population, as seen in Figure 8.2.

Males $(\%$ obese $)=205.1-20.4 \times($ mean BMI $)+0.5 \times(\text { mean BMI })^{2}$
Females $(\%$ obese $)=168.5-17.4 \times($ mean BMI $)+0.4 \times(\text { mean BMI })^{2}$
The following conditions applied:

- the predictions had to be positive (since they are percentages);
- the predictions must be $<100$; and
- the sum of the predicted percentages of people in the overweight and obese categories must be $\leq 100$ (the sum is equal to 100 in the extreme case whereby no individuals belong to the underweight or normal BMI categories).

These conditions hold simultaneously for mean BMIs of $21.3-29.7 \mathrm{~kg} / \mathrm{m}^{2}$ for males and $20.1-33.9 \mathrm{~kg} / \mathrm{m}^{2}$ for females. Predictions which fell outside these ranges were therefore not considered. These four models (Equations 1-4) for predicting the prevalences of overweight and obesity from mean BMIs were then applied to other populations when necessary.

Finally, the assumption was made that the equations held true for each age group and every country, so that the estimates could be
derived uniformly. This assumption seemed justified because wherever data were available the patterns of mean BMI and percentages of overweight and obesity were similar across age groups in most of the countries assessed.

### 4.4 Age and sex extrapolation

## Obtaining estimates for the required age groups

Apart from data personally donated to or re-analysed by IOTF, all other data were reported in different age categories from those required for this work. To obtain data in these age categories, it was assumed that:

- the numbers of persons in each year within an age group were the same and equal to the total number of people in the age group divided by the number of years in the age group.
- the mean BMI and the standard deviation for each year within an age group were the same and equal to the mean BMI and standard deviation in the age group as a whole.
Single years or convenient groups of years were treated as different strata which were then combined to obtain the desired estimates in any age categorization.

## EXtrapolation to adult age groups for which no data WERE AVAILABLE

It was not always possible to obtain data for all age groups, particularly for the oldest (70-79 and $\geq 80$ years) at a subregional level. WPR-B, where this problem was initially encountered for both sexes in people aged $>70$ years, is used as an example, although data subsequently became available for this subregion.

In the majority of the available data worldwide, the mean BMI increased with age and then started falling with rising age. Figure 8.3 shows the relationship between mean BMI and age in WPR-B. It was assumed that the mean BMI remained constant within each age group and changed only when moving from one age group to another.

The following regression equations describe the graphs:

$$
\begin{aligned}
& \text { Females }(\text { Mean BMI })=16.71+0.27 \times(\text { age })-0.0024 \times\left(\text { age }^{2}\right) \\
& \text { Males }(\text { Mean } B M I)=16.62+0.14 \times(\text { age })-0.0011 \times\left(\text { age }^{2}\right)
\end{aligned}
$$

Using these equations, the sex-specific mean BMI for each single year from age 70 years and above could be predicted. The overall mean BMI in the age group 70-79 years was set equal to the average of the mean BMIs for the individual years. The same procedure was used to estimate the mean BMI in the age group $\geq 80$ years. The results are shown in Table 8.16. The illustrated approach was used for EMR-B.

Table 8.16 Predicted mean BMI values in the oldest age groups in WPR-B

|  | Mean BMI $\left(\mathrm{kg} / \mathrm{m}^{2}\right)$ |  |
| :--- | :---: | :---: |
| Age group (years) | Females | Males |
| $70-79$ | 23.9 | 24.2 |
| $\geq 80$ | 22.8 | 23.8 |

Figure 8.3 The relationship between mean BMI and age in WPR-B

## Extrapolating data from one sex to the other

Many countries reported results either for both sexes combined or for one sex only. For example, on a subregional basis, no suitable data were available for males in AMR-D. The crude mean BMI for females in all subregions (calculated as the mean of the subregion-specific estimates for all ages combined) was $23.7 \mathrm{~kg} / \mathrm{m}^{2}$ and was 0.4 units greater than the crude mean BMI for men in all subregions ( $P=0.7$ ). To determine whether this was the case in each age group, the age-specific differences in mean BMI between females and males were estimated for all subregions. For all age groups apart from the oldest (i.e. $\geq 80$ years), the mean BMI for females was greater than that for males, as shown in Table 8.17.

These values served as correction factors when using data from males to estimate mean BMI for females and vice versa (without considering whether the differences between mean BMI for males and for females were significant). Thus, for each age group the respective correction factor was subtracted from mean BMI values for females to obtain the values for males. In most studies, it is found that women tend to have

# Table 8.17 Age-dependent differences between mean BMI for females and for males 

|  | Age group (years) |  |  |  |  |  |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: |
|  | $18-29$ | $30-44$ | $45-59$ | $60-69$ | $70-79$ | $\geq 80$ |
| Differences in mean BMI <br> (females-males) | 0.3 | 0.5 | 0.7 | 0.8 | 0.3 | -0.1 |

higher BMIs than men and this seems to be related to the deposition of fat rather than metabolically active lean tissue with body-weight gain. Women lay down a lower proportion of lean tissue and thus have to put on more weight before the slower increase in the mass of lean tissue raises the basal metabolic rate sufficiently to add to the exercise costs of their greater weight and achieve an energy output which finally matches their energy intake (James and Reeds 1997).

### 4.5 Estimating Childhood data

When no data were available for children for any of the countries within a subregion, an estimate was made of the distribution of BMI in children for that subregion by extrapolating from subregions with data and having equivalent economies, as judged by their gross national products (GNP). In the absence of any other data, WPR-A was extrapolated for AMR-A.

In general, plotting the mean age-standardized BMI for adults for each subregion (calculated as a simple average of population-weighted means for both sexes and for all ages $\geq 18$ years) vs GNP (on a subregional basis) shows a broad relationship between increasing GNP and mean BMI in subregions with GNPs of $<$ US $\$ 10000$ per year (Figure 8.4). For countries with the lowest GNPs, the assumption was made that BMIs for children would be similar in subregions with low GNP and low mean BMI for adults. This is subject to large uncertainty, given the complex underlying factors that determine body weight and height.

At the time of writing, no data were available for children in EMRD and WPR-B. The GNPs of countries in EMR-D were similar to those in AFR-E; the average GNP in EMR-D was US\$ 652 (with a range of US $\$ 110-1290$ ), whereas the average GNP in AFR-E was US $\$ 647$, (with a range of US\$80-3520). Mean BMI values were also similar in both populations, with values being slightly higher in EMR-D. The distribution of BMIs in children in AFR-E was therefore applied to EMR-D. The distributions of GNP and BMI for adults in SEAR-B and WPR-B were also similar, but there were no data for children, so the AFR-E values were used for these subregions, AFR-E being the closest to these subregions economically and also in terms of BMI.

Further problems arose when the mean BMIs for children were available, but not the standard deviations, as in AMR-B. The standard

Figure 8.4 The relationship between mean BMI for adults and GNP in nine subregions

deviations of BMIs for children in AMR-B were therefore also assumed to have the same variability as in EMR-B.

Very little in the way of categorical data was available for children and it was therefore necessary to extrapolate extensively, pending appropriate data becoming available.

### 4.6 The estimated mean BMI and standard deviation for EACH SUBREGION, BY AGE AND SEX

These data are presented in the standard format proposed for the CRA project. The mean BMIs for each year for ages 5-17 years inclusive for males and females separately were obtained and are given in Tables 8.18 and 8.19.

The initial BMI analyses were made as previously, considering children in 1-year age groups, firstly for the countries with data. From these values, the mean BMIs of the 1-year age groups within the subregion were estimated. Assuming equivalent numbers of people in each year of each specified age group, it was possible to provide mean BMIs, standard deviations and confidence intervals for the age groups 514 years and 15-29 years used in the CRA analyses. It was recognized that these values could not be used in the usual way to predict different categories of excess weight because of the normal changes in body weight
Table 8.18 The mean BMIs for children and adults in all subregions, by sex and age ${ }^{\text {a }}$

Note: Figures in shaded cells were estimated as outlined in the methodology section.
and BMI during childhood development. The data on mean BMIs are presented in Table 8.20. Table 8.21 contains the standard deviations for these estimates, while Table 8.22 lists the number of subjects measured and used in this analysis, in order to provide a preliminary perspective on the validity of these estimates.

### 4.7 Final estimates of the prevalence of overweight and obesity, by age, sex and subregion

Table 8.23 shows the subregional prevalences of overweight, as defined by a BMI of between 25.0 and $29.9 \mathrm{~kg} / \mathrm{m}^{2}$. For the age groups $5-14$ years

Table 8.2I The standard deviations of the mean BMI estimates by subregion, sex and age

| Subregion | Sex | Age group (years) |  |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |

Note: Figures in shaded cells were estimated as outlined in the methodology section.
and 15-29 years, these prevalence figures can be used in their condensed form because allowances have already been made for the age- and sexspecific cut-off points in the BMI percentiles corresponding to a BMI of $25.0 \mathrm{~kg} / \mathrm{m}^{2}$ at age 18 years. The rather crude nature of the calculation of BMI does not take into account the different ages at which pubertal changes occur in different subregions of the world; but the figures for prevalence are more robust and usable than the data on mean BMI described earlier, given the implications of definitions and cut-offs for overweight and obesity among adolescents.

Table 8.22 The number of subjects used when estimating the mean and standard deviation in each age category for Tables 8.20 and 8.21

- No data.

The prevalences of obesity corresponding to the subregional groupings by sex and age are listed in Table 8.24. Again, the accepted WHO criterion is taken, i.e. $\mathrm{BMI} \geq 30 \mathrm{~kg} / \mathrm{m}^{2}$, and children have been assessed in relation to the cut-off percentile for BMI proposed by IOTF. This percentile varies by age and sex during childhood as growth and pubertal changes occur, but these collated values provide an overall estimate of the prevalences of substantial excess weight in both children and adults.

The estimated standard errors for the prevalences of overweight and obesity are given in Tables 8.25 and 8.26 .

## 5. RISK FACTOR-DISEASE RELATIONSHIPS

This section reviews evidence for causality relating BMI to different disease and injury outcomes; provides a rationale for choosing $21.0 \pm 1.0$ $\mathrm{kg} / \mathrm{m}^{2}$ (mean $\pm \mathrm{SD}$ ) as the BMI value of theoretical population minimumrisk of adverse health effects; and summarizes the sources of data for the hazard estimates required for estimates of the attributable fraction for the population. To date, there have been no systematic reviews of cohort studies that present age- and sex-specific associations of adverse health outcomes with BMI as a continuous variable (rather than for

The obesity rates in children were particularly variable in some subregions, e.g. EUR-B, because they were based on relatively small samples and the obesity cut-off point reflects an extreme percentile distribution of BMIs.
cut-off points, so that the full impact can be captured), and all affected outcomes and for different subregions. Therefore some trade-offs had to be made to obtain the best estimates of hazard size for this project. The following analysis is based on a series of systematic reviews, the two principal ones being of BMI and vascular disease, and BMI and cancer.

### 5.1 Evidence for causality

Traditionally, excess body weight and obesity have been considered as risk factors in epidemiological terms, despite the fact that the International Statistical Classification of Diseases (ICD) has specified obesity as a disease in its own right since 1948. The effects of excess weight as a risk factor are at least partly mediated through changes in other risk

factors, such as blood pressure and abnormal blood lipids. More recently, it has become clear that excess weight is not only of value in predicting the risk of suffering from particular diseases, but that intentional weight loss reduces these intermediate risk factors (such as high blood pressure); and experimental evidence is also emerging for reduced disease outcomes (Sjöström et al. 1999). This experimental evidence provides the strongest evidence of causality and is summarized in the following sections. The observational evidence from cohort studies linking

BMI to adverse health outcomes is also described in more detail in the subsequent sections, as these studies provided estimates of exposuredisease hazard size. Together, these sources of data show that the associations found between BMI and many disease outcomes satisfy the widely-accepted criteria for causal relationships: they are strong, consistent, have a dose-response relationship and are biologically plausible (Hill 1965).

### 5.2 Health outcomes caused by excess body weight

The health outcomes that were considered are presented in Table 8.27; the causal relationship between excess body weight and these conditions is dealt with later.

### 5.3 The optimum population BMI (THEORETICAL-MINIMUM-RISK)

The theoretical-minimum-risk distribution of BMI in the population is that which is associated with the lowest health risks related to BMI. This choice of the theoretical minimum needs to take into account the fact that there are hazards associated with low as well as high BMIs (Shetty
and James 1994). The optimum trade-off is based on a balance between the level down to which the risk of developing diseases associated with high BMI persists (described in subsequent sections, but generally $20 \mathrm{~kg} / \mathrm{m}^{2}$, once the confounding effects of smoking and co-morbid prevalent diseases are accounted for) and the health hazards and reduced physical capacity found at lower BMIs. The handicaps related to underweight stem from a chronic dietary energy deficit and other phenomena related to undernutrition. These are summarized in Figures 8.5 and 8.6.

Analyses have been made (James and Francois 1994) of the relationship between the proportion of adults in the population who are underweight (i.e. BMI of $<18.5 \mathrm{~kg} / \mathrm{m}^{2}$ ) and the median BMI of the population. This definition of underweight was accepted by WHO in both the 1995

Figure 8.6 Median or mean BMI and the prevalence of (a) underweight and (b) overweight in different populations

Source: (a) James and Francois (1994); (b) Regression lines taken from Figure 8.I.
report on the uses of anthropometry (WHO 1995) and in the more recent report on obesity (WHO 2000). Figure 8.6(a) presents unpublished representative data obtained from 27 large national surveys of developing countries. By specifying underweight adults as those with a BMI of $<18.5$ $\mathrm{kg} / \mathrm{m}^{2}$ it becomes clear that an optimum median BMI needs to be about 22.0 or more to ensure that fewer than about $10 \%$ of women are underweight (see below).

In order to compare the proportions of people with low and high BMIs in the population at different mean BMIs, data relating underweight (i.e. BMIs of $<18.5 \mathrm{~kg} / \mathrm{m}^{2}$ ), to overweight, (i.e. BMIs of $\geq 25.0 \mathrm{~kg} / \mathrm{m}^{2}$ ), are required. To simplify this comparison, the two figures are presented side by side in Figure 8.6, but it should be noted that they are drawn from different data sets and that the data relating to underweight are presented in relation to the median rather than the mean BMI. However, at lower BMIs the mean and median values are very similar. It can be seen that when Figures 8.6(a) and (b) are compared, a BMI of $21.0-22.0 \mathrm{~kg} / \mathrm{m}^{2}$ emerges as an optimum BMI at which the chances of there being substantial proportions of either underweight or overweight people in the population are minimized. At a BMI of about $21 \mathrm{~kg} / \mathrm{m}^{2}$, the minimum proportion of underweight and overweight people in the population is about $10 \%$ for males, according to Figure 8.6(a), and for both sexes, according to Figure $8.6(\mathrm{~b})$. To achieve a proportion of only $10 \%$ of women being underweight requires that the mean BMI of the population be about $22.5 \mathrm{~kg} / \mathrm{m}^{2}$. However, at this mean BMI already
about $15 \%$ of the female population is overweight, according to Figure 8.6(a). Given the clear evidence for health hazards in women, even at BMIs of $23 \mathrm{~kg} / \mathrm{m}^{2}$ and above (Willett et al. 1995), and the modest handicaps currently evident for women within the first grade of underweight, i.e. BMIs of $17.0-18.4 \mathrm{~kg} / \mathrm{m}^{2}$ (James et al. 1988), we concluded that at present a universal mean BMI of $21.0 \mathrm{~kg} / \mathrm{m}^{2}$ should be chosen as the optimum for both sexes in populations throughout the world.

Overall, the theoretical-minimum-risk was estimated to occur at a BMI of $21.0 \pm 1.0 \mathrm{~kg} / \mathrm{m}^{2}$ (mean $\pm \mathrm{SD}$ ). It should be noted that this is below the level which some cohort studies have estimated to be the nadir of associations with mortality. This is because of the corrections for effects of disease on BMI that have been employed here and the focus on nonfatal as well as fatal events. This optimum BMI is similar to the lower limit of the range proposed by the WHO Technical Consultation on Obesity (WHO 2000), i.e. $21.0-23.0 \mathrm{~kg} / \mathrm{m}^{2}$. The inclusion of the upper limit of $23.0 \mathrm{~kg} / \mathrm{m}^{2}$ in the original WHO Technical Consultation stemmed from a concern that in some developing countries there might be a need for higher reserves of body energy to cope with potential natural disasters and crop failures leading to food deprivation. In practice, as will become evident, the increase in the rates of diseases associated with increases in BMI is evident from BMIs of about $20 \mathrm{~kg} / \mathrm{m}^{2}$.

### 5.4 Body weight and cardiovascular disease

## CAUSAL RELATIONSHIPS BETWEEN EXCESS WEIGHT AND CARDIOVASCULAR DISEASE

Non-optimum levels of blood pressure, cholesterol and glucose are leading causes of cardiovascular disease. There is strong evidence that excess body weight is associated with adverse levels of these risk factors. A recent Cochrane systematic review focusing on randomized controlled trials (Mulrow et al. 2001) identified 18 trials totalling 2611 hypertensive participants with an average body weight of 84 kg . The data suggested that weight loss in the range of $4-8 \%$ of body weight produced an average reduction in systolic blood pressure of 3.0 mmHg , consistent with earlier reviews (Goldstein 1992; MacMahon et al. 1987). It has also been clearly shown in meta-analyses of intervention trials that losing excess weight improves blood lipid profiles (Dattilo and Kris-Etherton 1992), with a fall in total serum cholesterol and triglyceride levels, and an increase in high density lipoprotein (HDL) concentrations. It is reasonable to expect that such reductions in major intermediate risk factors would translate into reduced incidence of cardiovascular disease. Direct evidence from randomized trials on clinical outcomes is limited, owing to the challenges in the modern environment to achieve and maintain weight loss. Nonetheless, evidence is emerging for substantial reductions in diabetes incidence in trials which have weight loss as a major feature of the intervention in individuals at high risk. A detailed discussion can
be found in, for example, Williamson and Pamuk (1993) and in the latest publications from Sweden, where very large numbers of individuals are currently in the middle of long-term trials of the health impact of weight loss induced by surgical reconstruction of the intestine (Sjöström et al. 1999, 2000).

There is also evidence from prospective observational cohort studies for positive associations between BMI and a range of cardiovascular disease outcomes. These data provide the main source of estimates of hazard size in this analysis and are summarized in the relevant following sections. Some further insight into causality from selected crosssectional and prospective studies is summarized in Figure 8.7, which

Figure 8.7 The relationship between BMI, high blood pressure (systolic pressure $\geq 160 \mathrm{mmHg}$ ) and concentrations of blood lipid in men aged 40-59 years in the United Kingdom

[^31]shows a progressive rise in total cholesterol with increasing BMI, from a BMI of $20 \mathrm{~kg} / \mathrm{m}^{2}$, and a sustained fall in HDL from BMI $20-30 \mathrm{~kg} / \mathrm{m}^{2}$. In addition, there is a clear association between high BMI and increases in serum triacylglyceride (triglyceride) concentration. Many studies have shown that there is a potential independent additional risk of ischaemic heart disease with increases in triglyceride concentrations.

The mechanisms by which increased body weight leads to the induction of cardiovascular diseases and excess mortality are not always clear. The effect is partly related to the frequent concomitant lack of physical fitness and physical activity in the overweight, but it is generally accepted that body-weight gain per se enhances insulin resistance, and thus physical inactivity is not the sole explanation. The development of insulin resistance is a powerful predictor of excess levels of triglycerides in the blood and of the propensity to develop type II diabetes.

In the INTERSALT study (Dyer et al. 1989), a significant association was found between BMI and systolic and diastolic blood pressures, which was independent of age, alcohol intake, smoking habits and urinary sodium and potassium excretion (this excretion rate being taken as an index of intake). Other cross-sectional analyses with measurements of BMI, blood pressure and lipids in West Africa, the Caribbean and the United States have also clearly shown increases in BMI associated with rising blood pressure (Wilks et al. 1996). Several mechanisms may explain why changes in body weight lead to alterations in blood pressure. Physical activity is one contributor, with inactivity tending to promote both weight gain and blood pressure increases. Weight change induced by diet without altering physical activity, however, also leads to changes in blood pressure. The mechanisms by which weight gain promotes a rise in blood pressure may involve the accentuation of insulin resistance, increases in the tone of the sympathetic nervous system control of the arterioles and the production by the adipose tissue itself of a variety of vasoactive cytokines and hormones, such as angiotensinogen, which increase blood pressure (Gorzelniak et al. 2002). These vasoactive compounds act in part by reducing sodium excretion by the kidney, thereby increasing the blood volume and therefore blood pressure.

It is well recognized that physical inactivity is an important contributor to body-weight gain and also increases the risk of diabetes, cardiovascular disease and some cancers. Data on the risks of excess BMI stratified by levels of physical inactivity (e.g. Figure 8.8 and also Paffenbarger et al. 1970) show that the hazards of high BMI are present at all levels of physical activity. This indicates that physical inactivity does not account for the full relationship between BMI and disease.

Figure 8.8 BMI, vigorous exercise and incidence of fatal heart attacks among male British civil servants

Note: This study was based on observations of 17944 male British civil servants aged 40-65 years who self-reported at survey between 1968 and I970. BMI values were taken at age $40-59$ years.
Average follow-up was 8.5 years. Death certificates were supplied by the National Health Service Central Register. Rates were standardized for age. Note that the group with the highest BMI and reporting vigorous exercise was "fewer than five people".
Source: Adapted from Morris et al. (1980) (Table III p. I209). Morris defined vigorous exercise as $>6$ METS (metabolic equivalents, ml oxygen $/ \mathrm{kg} \mathrm{min}^{-1}$ ) or $7.5 \mathrm{kcal}_{\mathrm{min}}{ }^{-1}$, e.g. swimming, hill climbing, gardening, brisk walking, for longer than 30 minutes per day.

## Systematic review of BMI and cardiovascular disease outcomes: the Asia-Pacific Cohort Studies Collaboration (APCSC)

To date, the only available systematic review providing age-, sex- and outcome-specific hazard size as a continuous variable is the APCSC, which included data from 33 cohorts (12 studies from Japan, 11 from mainland China, two from Singapore, two from Taiwan [China], one from Hong Kong Special Administrative Region of China [Hong Kong SAR], one from the Republic of Korea, one from New Zealand and three from Australia) (Table 8.28). The heights and body weights of individual participants were measured in all studies and BMI was calculated. Data from participants recorded as having a BMI of $<12 \mathrm{~kg} / \mathrm{m}^{2}$ or $>60 \mathrm{~kg} / \mathrm{m}^{2}$ were excluded from the analysis.

There was evidence of confounding due to disease at baseline and therefore health events that occurred within the first 3 years of followup were excluded from all analyses. Smokers were not excluded, but smoking was included as a covariate in all analyses. Participants were categorized as "smokers" if they classed themselves as current smokers, former smokers or ever-smokers (people who have smoked at any time), and as "non-smokers" if they indicated that they had never smoked.

Some cohorts included a smoking category entitled "not current"; participants in this category were excluded from the analyses since it was not possible to determine if they were former smokers or never-smokers.

In total, 310283 participants contributed 2148354 person-years of follow-up with a mean duration of 6.9 years. Data on baseline BMI, smoking habits and $>3$ years of follow-up were available for these participants. The mean age of the participants at baseline was 47 years and $41 \%$ were female. Ten per cent of participants were from Japan, $15 \%$ were from mainland China, $55 \%$ were from other parts of Asia (Singapore, Taiwan [China], Hong Kong SAR and the Republic of Korea), and $20 \%$ were from Australia and New Zealand (ANZ). The contributing data sets are set out in Table 8.28.

The overall mean baseline BMI was $23.6 \mathrm{~kg} / \mathrm{m}^{2}$. The mean BMI for the Asian populations was $22.9 \mathrm{~kg} / \mathrm{m}^{2}$ while that for the ANZ populations was $26.4 \mathrm{~kg} / \mathrm{m}^{2}$. Table 8.29 presents the calculated increments in risk of cardiovascular disease associated with a one unit $\left(1 \mathrm{~kg} / \mathrm{m}^{2}\right)$ decrease in BMI and Figure 8.9 summarizes the relationship of BMI with all ischaemic heart disease events (adjusted for age, sex, cohort and smoking).

| 70-79 years | 28 | 28446 | 29 | 0.89 | (0.82-0.98) |
| $\geq 80$ years | 26 | 5979 | 39 | 0.94 | (0.86-I.03) |
| All ischaemic stroke events |  |  |  |  |  |
| 30-44 years | 31 | 137917 | 41 | 0.85 | (0.77-0.94) |
| 45-59 years | 32 | 205109 | 411 | 0.92 | (0.88-0.95) |
| 60-69 years | 33 | 76345 | 345 | 0.94 | (0.91-0.97) |
| 70-79 years | 28 | 28449 | 316 | 0.94 | (0.91-0.98) |
| $\geq 80$ years | 26 | 5967 | 222 | 0.98 | (0.94-1.02) |

Note: The first 3 years of follow-up were excluded and results were adjusted for age, sex, cohort and smoking habits.
a The age pattern of the hazard ratios presented was smoothed and the resulting age-specific estimates were used to derive the estimates of global burden of disease attributable to BMI:
Ischaemic heart disease: $0.88,0.92,0.93,0.95,0.98$.
Hypertensive disease: $0.88,0.91,0.93,0.95,0.97$.
Ischaemic stroke: $0.82,0.85,0.88,0.90,0.93$.

The overall reduction in risk of ischaemic heart disease associated with a reduction in BMI of one unit in the age group 45-59 years in the APCSC data amounted to $9 \%$, a very similar figure to that provided by the large North American and European prospective studies (reviewed in the next section).

The findings for stroke from the APCSC meta-analysis are displayed in Figure 8.10. A continuous relationship between increasing BMI and risk of non-fatal stroke is evident, but little association was seen between BMI and the risk of fatal stroke. In examining stroke subtypes, a continuous relationship between increasing BMI and risk of ischaemic stroke was apparent, but a weaker association was seen between BMI and the

Figure 8.10 The relationship between stroke events and BMI in adults in the cohort studies of the Asia-Pacific Cohort Study Collaboration

risk of haemorrhagic stroke. This suggests that the lack of association seen between BMI and fatal stroke may reflect in part the higher proportion of fatal strokes that are of the haemorrhagic subtype. Therefore estimates of global burden of disease attributable to stroke in this work were based solely on ischaemic stroke for which a continuous association with BMI is evident.

## Other systematic reviews of BMI and cardiovascular outcomes

A systematic review of large cohort studies investigating ischaemic heart disease has recently been completed (Whitlock et al. 2002). These studies were almost all from North America and Europe and are described in Table 8.30. Most of the studies included measured BMI and dealt with
Table 8.30 The relationship between risk of ischaemic heart disease and BMI: large North American and European prospective cohort studies ${ }^{\text {a }}$

| Physicians' Health study (Rexrode 2001) | 548 | Fatal and non-fatal | Self-reported | 40-84 | Positive | 7 |
| Eastern and Southwestern Finland study (Jousilahti et al. 1999) | 520 | Fatal and non-fatal | Measured | 25-64 | Positive or J-shaped | 4 |
| Honolulu Heart Program (Rhoads and Kargan 1983) | 511 | Non-fatal | Measured | 45-68 | Positive | 10 |

[^33]Adapted from Whitlock et al. (2002). The large American Cancer Society (1960-1972) cohort (Calle et al. 1999; Stevens et al. 1998) recorded self-reported height and weight. However, cause-specific associations have not been published. A positive association between risk of all cardiovascular death, steeper in younger age groups, has been shown.
non-fatal as well as fatal outcomes. All but one showed a positive or J-shaped relationship between BMI and the risk of either fatal or nonfatal ischaemic heart disease. When the potential reduction in risk was calculated for each unit decrease in BMI, results were found to be reasonably similar, with most studies indicating a $5-10 \%$ reduction in rates of ischaemic heart disease. The overall unweighted average reduction in risk per unit BMI difference was $6 \%$, with studies using self-reported BMI giving a weighted average of $9 \%$, whereas the weighted average for the studies using measured BMI amounted to a $5 \%$ reduction. The mean age at death for these cohorts was estimated to be age 50-60 years, indicating that these data are highly consistent with those of the APCSC outlined earlier.

The conclusions of other systematic reviews are also consistent with the APCSC results, although comparisons are limited by the use of BMI categories; the main results are summarized in Table 8.31.

### 5.5 Type II diabetes

## Causal relationships between excess weight and type II diabetes

The relationship between excess body-weight gain and type II diabetes is now considered so strong that there is increasing use of the term "diabesity" as a unifying concept. Not only is there a close association between higher BMIs and the risk of developing type II diabetes, but weight gain itself has also been identified as a particularly important risk factor. The impact of weight gain is markedly enhanced if it occurs in young adults who were already overweight or obese when they entered adult life (Colditz et al. 1995). More direct evidence for the importance of increases in weight in the development of diabetes comes from intervention studies. Over $80 \%$ of very obese diabetic adults treated by gastric bypass surgery to induce marked weight loss, for example 30 kg , become non-diabetic and over an 8 -year post-surgery follow-up period, the incidence of new cases of diabetes in these patients is minimal (Sjöström et al. 2000). Four prospective studies, three of which were randomly controlled intervention studies, have also shown that changes in diet and exercise that induce a modest loss of weight in overweight or obese subjects with glucose intolerance can markedly reduce the subsequent development of type II diabetes over periods of 3-6 years (Diabetes Prevention Program Research Group 2002; Eriksson and Lindgarde 1991; Tuomilehto et al. 2001; Xiao-Ren Pan 1997). Weight-loss trials among obese patients with type II diabetes have also shown marked improvements in diabetic states or even a return to normal glucose tolerance. Lean et al. (1990) have also shown that the degree of weight loss achieved in newlydiagnosed patients with type II diabetes predicts their future life span. Williamson and Pamuk (1993) also observed that in the United States overweight and obese women with co-morbidities have not only a reduced overall mortality but also a selective reduction in death from

diabetes-related conditions if they intentionally lose modest amounts of weight of up to 9 kg (Williamson and Pamuk 1993).

The mechanisms whereby weight gain leads to the development of type II diabetes are the subject of intense investigation, with the development of insulin resistance seen as dominant. Type II diabetes develops when the pancreatic capacity to generate insulin cannot maintain the markedly increased demand induced by insulin resistance. Insulin resis-
tance itself is affected not only by increases in weight, particularly if the extra energy is stored in abdominal, i.e. visceral, fat, but also by dietary composition. Dietary fat induces insulin resistance (Marshall et al. 1994; Sarkkinen et al. 1996; Vessby et al. 2001) and there is increasing interest in the possibility that rapidly absorbed carbohydrates, which cause sudden increases in concentrations of blood glucose, place extra demands on the pancreas (Willett et al. 2002). Adipose tissue itself, particularly visceral adipose tissue, secretes cytokines such as interleukin-6 (IL-6) and tumour necrosis factor (TNF $\alpha$ ) which are recognized to be important inducers of insulin resistance. Circulating adiponectin, an adipocytederived hormone which markedly improves insulin sensitivity is reduced as the fat cells expand with body-weight gain, and is also modulated by sex hormones (Nishizawa et al. 2002). Physical inactivity also contributes to insulin resistance, with vigorous exercise leading to a rapid restoration of insulin sensitivity.

The quantitative contributions of each of these components are still uncertain, but the carefully controlled Chinese Prevention study on preventing type II diabetes (Xiao-Ren Pan et al. 1997) provides some information. In this study, three groups of overweight adults with glucose intolerance were assigned to either a low fat, low saturated fat and high vegetable and fruit diet, or to a modest increase in physical activity equivalent to 30 minutes of brisk walking daily, or were advised on both dietary and physical activity interventions. There was a marked and equivalent reduction in the incidence of type II diabetes in all three groups over the 6 years of follow-up. This implies that there is little interaction between diet and physical activity but that both can contribute to the development of insulin sensitivity.

Physical activity is potentially a major confounding effect. Physical activity is recognized as beneficial in enhancing the sensitivity of tissues to insulin, thereby enhancing the body's capacity to handle glucose. As noted above, increasing physical activity alone without dietary change reduced the incidence of diabetes in modestly overweight Chinese adults with glucose intolerance (Xiao-Ren Pan et al. 1997). This finding was consistent with those from a further two major controlled trials from Finland and the United States, which suggested that the combination of changes in diet and activity together with only modest weight losses reduced the incidence of type II diabetes in susceptible adults by $56 \%$, this benefit increasing to $76 \%$ in those aged $>60$ years (Diabetes Prevention Program 2002; Tuomilehto et al. 2001). In these trials, the modest weight loss, for example $5 \%$, was induced by a low-fat diet combined with physical activity. Given the important effect of physical activity, the quantification of any interaction between BMI and physical activity when determining the risk of onset of type II diabetes is necessary. As with coronary disease, the increase in risk of diabetes with increasing BMI is seen at all levels of physical activity (Figure 8.11).

Figure 8.1I The interaction of higher BMIs with physical activity in determining the age-adjusted incidence of type II diabetes per 10000 person-years of follow-up, in males

Note: "Incidence" relates to the age-adjusted incidence of type II diabetes per 10000 person-years of follow-up in male graduates of the University of Pennsylvania.

Sources of hazard size estimates for BMI and type II diabetes

## Incidence studies

The conclusions of systematic reviews from Australia (Anonymous 1999; Mathers et al. 1999) and the United Kingdom of Great Britain and Northern Ireland (National Audit Office 2001) are given in Table 8.32. In one of the Australian reports (Mathers et al. 1999), the risks of developing diabetes were arbitrarily halved in an attempt to take into account the impact of physical activity on diseases relating to obesity (see below). The first three of the four studies (Carey et al. 1997; Colditz et al. 1990, 1995; Njolstad et al. 1998) noted by this report involved very large groups of professionals in the United States (e.g. $>100000$ subjects with individual prospective follow-ups of 12-18 years). Unfortunately, these data are based on self-reported heights, weights and disease. Although weights and heights reported in these study populations are found to have a good correlation with observed measurements, they are still likely to systematically underestimate the actual prevalences of overweight and obesity. The Victoria report (Anonymous 1999) looked at this issue and

Table 8.32 The relative risks of developing type II diabetes associated with overweight and obesity, as assessed by two governmental reviews

| Study | Age (years) | Overweight <br> (BMI 25.0-29.9 kg/m ${ }^{2}$ ) |  | $\begin{gathered} \text { Obese } \\ \left(\mathrm{BMI} \geq 30 \mathrm{~kg} / \mathrm{m}^{2}\right) \end{gathered}$ |  |

a Relative risk values arbitrarily halved to help account for any independent impact of physical activity or residual confounding.
found from its own analysis that "people who are obese selectively underestimated their weight and/or overestimated their height more than others. As a result, the proportion of people who are obese by measurement is $60 \%$ higher than estimates based on self-reported height and weight. The greatest discrepancies are found in adolescent men and older people". How this systematic underestimation of obesity impacts on the estimates of relative risk per BMI unit is unclear, but it may well result in overestimation, i.e. a bias away from the null. This is because the distribution of self-reported BMI is narrower than the distribution of actual BMI, and so the slope of associations between BMI and risk of disease is artificially steep. The use of self-reported disease status is another source of uncertainty in hazard estimates because in many such studies diabetes has been found to be underreported or under-diagnosed (Harris et al. 1998). If undrrecording of diabetes is associated with BMI level, this would also result in bias in hazard estimates (away from the null, if relatively more cases of diabetes failed to be identified among people with low BMI).

The prospective studies on male and female health professionals in the United States (Chan et al. 1994; Colditz et al. 1995) suggest age-adjusted relative risks of self-reported diabetes of between 4 and 14 in men aged $40-75$ years and reporting a BMI of about $30 \mathrm{vs}<23 \mathrm{~kg} / \mathrm{m}^{2}$; whereas the relative risk for self-reported diabetes in the nurses of similar age and with reported BMIs of about 30 was about 28 compared with the rates for nurses with reported BMIs of $<22 \mathrm{~kg} / \mathrm{m}^{2}$. A more robust estimate of the relative risk of developing type II diabetes comes from a detailed Norwegian study based on a sampling system which is representative of their most northern county and in which objective measurements of weight and height as well as measurements of fasting glucose concentrations were made (Table 8.33).

Table 8.33 Relative risk of developing type II diabetes in Norwegian men and women aged 35-52 years, by sex-specific quartiles of baseline BMIs

| Quartiles of baseline <br> $\mathrm{BMI}\left(\mathrm{kg} / \mathrm{m}^{2}\right)$ |  | Relative risk of type II <br> diabetes over I2 years |  |
| :--- | :--- | :--- | ---: |
| Males | Females | Males | Females |
| $<23.2$ | $<22.0$ | 1.0 | 1.0 |
| $23.2-25.0$ | $22.0-24.1$ | 1.8 | 1.8 |
| $25.1-27.0$ | $24.2-27.1$ | 2.5 | 2.1 |
| $\geq 27.1$ | $\geq 27.2$ | 13.0 | 30.0 |

Note: The above relative risk of developing diabetes for both males and females are interpolated from a graph in Njolstad et al. (1998).

By chance, the quartiles of BMI for men again allow an approximate distinction between those with BMIs of $<23.0 \mathrm{~kg} / \mathrm{m}^{2}$ and $<25.0 \mathrm{~kg} / \mathrm{m}^{2}$, i.e. their second quartile, the upper limit of which coincides with the WHO distinction between normal and overweight. The values for women need to be adjusted. These data relate to men and women aged 35-64 years, but were age-standardized. Nevertheless, it is clear that the relative risks of diabetes as derived from these data in general agree with data from the United States prospective studies, and that the values given for the upper quartile will be low estimates of the true risk of diabetes in those Norwegian men and women who have a BMI of $\geq 30.0 \mathrm{~kg} / \mathrm{m}^{2}$.

## Prevalence studies

The ideal source of estimates of the hazard size would be large long-term trials or, in their absence, large, long-term cohort studies with direct measurements of BMI and blood glucose. The principal cause of type II diabetes appears to be excess weight gain in childhood and in adult life, and so relatively short-term prospective studies of the incidence of diabetes may not capture the full impact of persistent excess BMI. Large, nationally representative cross-sectional studies are available that use objective measurements of BMI and diabetes (in contrast to the few large, long-term prospective studies outlined earlier). Although the diagnosis of diabetes may itself lead to a loss in weight, this is likely to result in only a moderate bias to the null, since current BMI correlates so closely with BMI levels over many previous decades. The estimates of hazard size for this analysis of the burden of diabetes attributable to BMI were therefore derived from the age- and sex-specific associations of type II diabetes (based on fasting glucose values) with BMI from the Japanese National survey (Yoshike, personal communication; see Figure 8.12). The incremental risks for the required age categories were estimated on a linear basis (Table 8.34).

Table 8.34 The relative risk of developing type II diabetes, per unit ( $1 \mathrm{~kg} / \mathrm{m}^{2}$ ) increase in BMI

| Disease | Sex | Country source | Age group (years) |  |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |

Males

Females

Note: Based on rates of type II diabetes determined from measurements of fasting blood glucose $\geq 126$ $\mathrm{mg} / \mathrm{dl}$ or where treatment is already being given for type II diabetes (Yoshike, personal communication).

The proportional increases in the prevalence of diabetes associated with a given increase in BMI were consistent in the Japanese national survey with associations observed in a Danish representative survey (Drivsholm et al. 2001; see Figure 8.13). They are also broadly consistent with the results of prospective studies that measured weight and height, that is, the Norwegian study that assessed the risk of diabetes,

Figure 8.13 A comparison of the prevalence of type II diabetes (based on fasting blood glucose concentrations and measured BMI) in Danish and Japanese adults of comparable age

with measurements of blood glucose (Table 8.33) and the United States NHANES III analyses of prevalence rates of diagnosed diabetes (Table 8.35).

A perspective on the overall burden of ill-health associated with higher BMI can be gauged from nationally representative studies of measured BMI and the prevalence of type II diabetes. Thus Must et al. (1999) used the NHANES III study and highlighted the marked 20 -fold increase in prevalence rates of reported type II diabetes in men and women aged $>55$ years compared with those aged $<55$ years, even in people with a measured "normal weight", that is, with BMIs of $<25.0 \mathrm{~kg} / \mathrm{m}^{2}$. Superimposed on this age-related increase was the impact of high BMIs: the prevalence ratios for people aged $<55$ years with high BMI compared with those with a normal weight varied from 3.3 in men and 3.8 in women with BMIs of $25-29.9 \mathrm{~kg} / \mathrm{m}^{2}$, up to $8-11$ in men and women with BMIs of $35-39.9 \mathrm{~kg} / \mathrm{m}^{2}$ (but with very broad confidence limits). Prevalence ratios were lower in the older age groups (1.8 in the overweight men and women, and 4.2 in men and 3.2 in women with BMIs of $35-39.9 \mathrm{~kg} / \mathrm{m}^{2}$ ).

Recently, there has been an interest in the issue of ethnic differences in the incidence of co-morbidities that result from increases in weight, with reports of an increased propensity to diabetes in Pima Indians, in those of Hispanic origin and in Asians, compared to the American Cau-

Table 8.35 Estimated prevalence ratios of type II diabetes by weight status category in adults in the United States-representative NHANES III study

casian population (Edelstein et al. 1997; Seidell et al. 2001a). Figure 8.13 shows that the prevalence of diabetes in the Japanese population markedly exceeds that in the Danish population, for both sexes and for each BMI category, but the gradient of risk appears to be roughly the same in the two communities. Similar enhanced risks of diabetes are evident in Mexicans assessed in the latest national survey of the prevalence of diabetes and other diseases in relation to excess weight in Mexico (Sánchez-Castillo et al. 2003). These data were compared with the recalculated data relating only to those with fasting blood glucose measurements, from the NHANES III study in the United States. Prevalence rates for type II diabetes are $2-3$-fold greater in Mexicans than in non-Hispanic Caucasians in the United States, on an age-standardized basis and, more importantly, prevalences in Mexicans exceed those in people of the United States, when BMI is taken into account. The differences were somewhat smaller, but still statistically significant when the age-dependent prevalences of diabetes were related to the waist circumferences of the two national groups. In the year 2000, the prevalence of abdominal obesity was greater in Mexicans than in non-Hispanic Caucasians in the United States, as measured in the NHANES III study (Sánchez-Castillo et al. 2003). Similar data are now emerging from mainland China Hong Kong SAR and India. In the near future, these comparisons may be extended so that the increment in risk for each pop-
ulation at each BMI level, taking age into account, can be obtained with some assurance on the basis of measured body weights, heights and fasting glucose levels. It will also be necessary to take into account the relationship between BMI and diabetes in Pacific Islanders, which may well prove to be different from that in other peoples, given their greater lean tissue : fat ratios (Bell et al. 2001). Nevertheless, it seems reasonable on present evidence to conclude that although in Asians and some other populations the absolute risk of type II diabetes is amplified, the incremental gradient of risk of diabetes in relation to increasing BMI is approximately the same as that found in Caucasians. On this basis, similar values for relative risk can be applied to all subregional groups.

### 5.6 Osteoarthritis

There is a well-documented association between high BMI and the development of osteoarthritis in both men and women (Cicuttini and Spector 1998). Osteoarthritis is an abnormality which involves damage to and eventually the destruction of the articular cartilage of the joint. New bone is formed at the joint surfaces, probably in response to the cartilaginous damage. The relationship between excess weight and the development of osteoarthritis has been studied in a number of population-based prospective, cross-sectional and retrospective trials, showing excess weight as the most important preventable risk factor for osteoarthritis. Cross-sectional studies have consistently reported increased risks of osteoarthritis in association with body-weight gain, with early studies suggesting a $2-7$-fold greater risk in those individuals in the top compared with the bottom tertile of BMI (Table 8.36) and, in some studies, a greater risk in women than men (Cicuttini and Spector 1998). As the data were adjusted for race, ethnicity and smoking as well as age, no age-related data were available, but these are the best nation-

Table 8.36 Prevalence of osteoarthritis by weight status category, in adults

Source: Table 3 in Must et al. (1999).
ally representative data available for assessing the quantitative impact of BMI increases on the prevalence of osteoarthritis.

A number of mechanisms have been proposed to explain the association of adult body-weight gain with osteoarthritis. The physical burden associated with an increased load on the joints seems straightforward, but changes in movement and gravitational stresses as weight gain occurs are also a factor. Other mechanisms have, however, been invoked, including systemic changes in metabolism associated with hypertension, raised blood glucose and cholesterol concentrations, insulin resistance and elevated concentrations of blood uric acid, as well as hormonal changes induced by the metabolic effects of additional adipose tissue (Cicuttini and Spector 1998). Several of these factors could be acting on the metabolic integrity of the articular cartilage, as could other dietary factors, such as high fat intake, which have also been linked to this disease. The associations with hypertension tend to disappear once concomitant increased body weight is taken into account, and the link with hypercholesterolaemia is not sufficiently robust to warrant special consideration. Abnormal glucose metabolism is a more plausible mechanism, with the possible involvement of growth hormone (Cicuttini and Spector 1998), but epidemiological studies have not shown a consistent link between type II diabetes and osteoarthritis. Raised uric acid concentrations have been associated with osteoarthritis, but again data supporting the relationships are inconsistent.

It is clear that excess weight gain precedes the development of osteoarthritis rather than the reverse. This was initially reported in retrospective recall studies of reported former weights (Anderson and Felson 1998; Hart and Spector 1993), but three studies (Anderson and Felson 1998; Cicuttini et al. 1996; Hart and Spector 1993) have shown a strong association of excess weight gain with asymptomatic radiological evidence of osteoarthritis, such radiological evidence having been clearly shown to be a predictor of future disability (Acheson et al. 1974; Hochberg et al. 1989). Twin studies have shown that the heavier twin has a greater risk of developing osteoarthritis (Cicuttini et al. 1996), and the incidence of osteoarthritis is markedly enhanced in overweight women (Schouten et al. 1992). In population studies, the incidence of disability once osteoarthritis has developed is also particularly marked if the subjects are obese (Verbrugge et al. 1991). In addition to predicting the greater risk of developing osteoarthritis, weight gain has also been shown to enhance the progression of the disease. Among middle-aged women with early stage unilateral knee damage, those who were overweight had a $34 \%$ chance of developing osteoarthritis in the contralateral knee within 2 years and $22 \%$ also showed radiological progression of the disease in the initially affected joint (Cicuttini and Spector 1998).

Detailed population studies regarding the incremental risk of developing osteoarthritis of any joint over a wide range of BMIs are rare,
however, with Must et al. (1999) being the principal source of data. Must et al. used the NHANES III study with measurements of BMI and with reported rates of disability from osteoarthritis to derive risk values. Given the need to consider the linear relationship between BMI and disabilities rather than the type of categorical analyses shown in Table 8.36, the Must et al. (1999) study was used here. This study, as well as several others, shows that the absolute risk of osteoarthritis is greater in women than in men, but that the incremental risk of osteoarthritis per unit increase in BMI is approximately the same in both sexes. On the basis of this survey in the United States, the relative risks of osteoarthritis were derived without regard to adult ages or sex, as shown in Table 8.37. These analyses were not adjusted either for age or smoking status, but Must et al. (1999) found that there were no interactions between weight class and race or ethnicity for either sex.

## Gout

Gout is a metabolic disease of uric acid metabolism, which has a genetic component and which involves acute episodes of arthritis leading to chronic arthritis and disability. Although much less common than osteoarthritis, gout has also been linked with excess weight gain in both cross-sectional and longitudinal studies (Cicuttini and Spector 1998). The abdominal distribution of body fat seems to be a particularly important risk factor, in keeping with mechanistic studies which suggest that hormonal or other agents which alter uric acid metabolism, such as diet and alcohol, are involved in precipitating an attack of gout. Although multivariate analyses have shown the importance of BMI from as early as age 35 years and excess weight gain as distinct risk factors (Roubenoff et al. 1991), with other large studies suggesting that excess weight as early as in adolescence is predictive of gout, there is no clear picture of the prevalence of or associated disability linked to gout on an international basis. Thus, although weight reduction is clearly recognized as potentially important in avoiding and limiting the risk of gout and its associated handicaps, it was decided not to include estimates of the

Table 8.37 The relative risk of developing osteoarthritis per unit ( $1 \mathrm{~kg} / \mathrm{m}^{2}$ ) increase in BMI

- No data.
effects of excess BMI on gout and only to use data on weight gain in association with osteoarthritis.

### 5.7 Cancer

There have recently been two major re-analyses, incorporating systematic reviews, of the associations between excess weight gain and the development of different forms of cancer (Bergström et al. 2001; IARC 2002), which supersede those of Australia (Mathers et al. 1999) and the United Kingdom (National Audit office 2001). The latest review by the International Agency for Research on Cancer (IARC) lists the risk of different cancers in relation to both body weight and physical activity (IARC 2002). These analyses concluded that cancers of the colon, breast (postmenopausal), endometrium and kidney were statistically related to weight gain, each analysis being usually based on a systematic review of a large number of both case-control and prospective studies. The present analysis also drew heavily on the recent series of meta-analyses conducted by IARC staff and colleagues, which provided estimates of the coefficient of risk per unit BMI increase (Bergström et al. 2001). Since this chapter used continuous rather than categorical data, the conclusions of the main IARC report on statistically significant findings are used to select the cancers to be considered, but the coefficients of risk are taken from Bergström et al. (2001). Table 8.38 sets out these estimates. In view of the much lower incidence of and the uncertainty of the global statistics for kidney cancer, the estimates of the burden of cancer were confined to cancers of the breast in postmenopausal women, colon and endometrium.

## Breast cancer

A distinction needs to be made between the risks of developing breast cancer before and after the menopause. Premenopausal breast cancer is less likely to develop in women with high BMIs, but this effect is only seen at BMIs of about $>28 \mathrm{~kg} / \mathrm{m}^{2}$ and rates of mortality are not lower among women with higher BMIs. For the present analyses, the role of excess weight gain in the development and the burden of disease from breast cancer was confined to cases arising in postmenopausal women. Over 100 studies conducted in many populations have found that women with higher BMIs are at greater risk of postmenopausal breast cancer (IARC 2002). Bergström et al. (2001) used 27 of these studies to quantitatively evaluate the impact of excess weight. Age, age at menarche, parity, alcohol intake and diet are recognized confounders, but when all of these were taken into account the coefficient of risk per unit BMI was still statistically significant (Table 8.38). Furthermore, there are studies which overall suggest that those women who have limited their weight gain or have lost weight in early adult life tend to have a reduced risk of postmenopausal breast cancer (IARC 2002). Over 50 studies (e.g. Huang et al. 1997; Tretli 1989; Törnberg and Carstensen 1994) also

Table 8.38 The relative risks of developing cancer associated with increases in BMI, as calculated for European populations

| Cancer | Coefficient ( $\pm 95 \%$ Cl) ${ }^{\text {a }}$ (Increase in incidence rates per unit [ $1 \mathrm{~kg} / \mathrm{m}^{2}$ ] increase in BMI ) | Relative risk of developing cancer |  | No. of studies |
| :---: | :---: | :---: | :---: | :---: |
|  |  | Overweight ${ }^{\text {b }}$ | Obesity ${ }^{\text {c }}$ |  |
| Postmenopausal breast | 1.03 (1.02-1.04) | 1.12 | 1.25 | 13 |
| Colon | 1.03 (1.01-1.05) | 1.15 | 1.33 | 6 |
| Endometrial | 1.10 (1.07-1.14) | 1.59 | 2.52 | 4 |
| Kidney | 1.06 (1.03-1.08) | 1.36 | 1.84 | 2 |

a Coefficient describes the increase in incidence rates per unit increase in BMI irrespective of age (and includes the $95 \%$ confidence intervals) based on covariance analysis.
b Defined as BMI $25.0-29.0 \mathrm{~kg} / \mathrm{m}^{2}$; the relative risk is calculated from each study's provision of the distribution of BMIs within the studied population.
c Defined as BMI $\geq 30.0 \mathrm{~kg} / \mathrm{m}^{2}$; the relative risk is calculated from each study's provision of the distribution of BMIs within the studied population.
Notes: 27 eligible studies but analysis restricted to cohort studies with incident cases only; adjustment for age, reproductive factors, alcohol and diet did not materially affect the relationship.
No effect was seen when restricting the data to incident cases; all studies accounted for age, diet (where data were available), alcohol and/or physical activity.
Data provided for men but the data were almost identical for women (I.07, CI I.05-I.09). Studies were restricted to incident cases, with age adjustment and allowance for smoking but these restrictions did little to influence the results from the seven studies considered.

Source: Bergström et al. (2001).
suggest that women with a higher BMI at the time of diagnosis have poorer survival and an increased likelihood of recurrent breast cancer, irrespective of their menopausal status and after adjusting for the stage of cancer development and the type of treatment used.

Mechanistically, it seems clear that the risk of developing postmenopausal breast cancer is increased in women with raised plasma and tissue concentrations of estrogens. The activity of these hormones is greater when there are lower circulating concentrations of the sex hormone-binding globulin (SHBG). Obesity, with its associated insulin resistance, lowers SHBG levels; overweight women are also found to have higher circulating concentrations of total and bioavailable androgens and estrogens. Confirmation of the importance of these hormonal changes comes from the observation that women exposed to combined estrogens and progesterones as part of postmenopausal hormone replacement therapy subsequently have increased rates of breast cancer, the risk being greater in those on combined compared with estrogen-alone treatment (Weiderpass et al. 1999). The reduced risk associated with a late menarche and in women with anovulatory cycles is considered to relate to the lower exposure of the breast to bioactive estrogens (IARC 2002).

## Colon cancer

Bergström et al. (2001) considered 19 studies, 12 of which were prospective, which generally tended to show a stronger relationship between excess weight and incidence of cancer in men than in women. The studies also allowed an assessment to be made of the confounding effects of physical activity, age, family history of colon cancer, ethnicity, social class and diet. For the full quantitative analyses, only six studies could be included (Gerhardsson et al. 1990; Giovannucci et al. 1995; Kune et al. 1990; Lee and Paffenbarger 1992; Martinez et al. 1997; Thun et al. 1992); and in these studies no sex-specific differences could be found, nor did restricting the analysis to incident cases alter the estimate. The same general relationships of weight to the development of large colonic adenomas were found in the IARC analyses (IARC 2002), the development of adenoma being seen as part of the progression of cellular changes leading to the development of colon cancer. Although fewer studies have considered rectal cancers separately, no relationship was found between BMI and rectal cancer.

The mechanisms by which weight gain might accentuate the risk of developing large adenomas and colon cancer are unclear, but the stronger association of high BMIs with large rather than small adenomas suggests that excess weight operates at a relatively late stage in the promotion of tumour formation. Excess weight is associated with a wide range of hormonal and metabolic effects that may be involved in the promotion of cancer. Dietary factors could, in theory, be confounders with high meat intake, especially processed meat, and a low intake of fibre-rich vegetables and fruit being particularly linked to colon cancer and also being part of a weight-gain-inducing, energy-dense diet. However, several of the studies also assessed diet and the impact of higher BMIs seemed to be independent of the direct dietary effects.

## ENDOMETRIAL CANCER

Both case-control and cohort studies have shown a relationship between higher BMI and increased risk of developing endometrial cancer, even after adjusting for other risk factors relating to the reproductive system, such as age at birth of first child and parity (Le Marchand et al. 1991). There was a remarkably consistent relationship between high BMI and risk of endometrial cancer in 22 of the 25 studies assessed by IARC (2002), studies which considered only cancer incidence and adjusted for all suggested confounders showing similar relationships. Bergström et al. (2001) used four of the seven cohort and 17 case-control studies reviewed by IARC (2002) to calculate by meta-analysis the incremental risk shown in Table 8.38. The overall risks of endometrial cancer appeared to be equivalent at different ages, but adult weight gain seems to be particularly important whatever the early adult weight status. Upper body fatness may be particularly conducive to the process of car-
cinogenesis, but the standard measures of abdominal fatness have given inconsistent results.

The dominant mechanistic theory relates to the unopposed estrogen hypothesis, according to which estrogenic contraceptives or hormone replacement therapy enhance the risk of endometrial cancer, whereas progesterone-containing preparations confer protection. Estrogens are known to induce endometrial proliferation via local production of insulin growth factor (IGF-1), whereas progesterone induces the production of an endometrial IGF-1-binding protein. Women with low levels of plasma SHBG, high levels of androgens and, after the menopause, elevated levels of total and bioavailable estrogens have an increased risk of endometrial cancer, as have younger women with the polycystic ovarian disease, which is associated with chronic anovulation and therefore low rates of production of progesterone. All these findings, therefore, fit the concept of excess available bioactive estrogen, which induces endometrial cell proliferation. Insulin resistance and higher concentrations of circulating IGF-1 induced by the lower concentrations of IGF-binding proteins in women who gain weight may also be involved. The IARC report notes that, given the substantial changes in insulin resistance, IGF-1 and estrogen status which accompany weight loss, it is possible that weight reduction quite late in life could reduce the risk of the estrogen-promoted cancers of the postmenopausal breast and endometrium.

### 5.8 Body weight and total mortality

Clearly, the net associations of BMI with total mortality will depend crucially on the component causes of death, which vary substantially by age, sex and population. Effects on total mortality were not estimated directly in these analyses for this reason, only cause-specific estimates being made. However, for completeness, data relating BMI to total mortality (usually derived from middle-aged North American populations) are reviewed here.

An extensive review of the relationship between BMI and total allcause mortality, based on a detailed systematic review, was published by Troiano et al. (1996). About 1000 citations dating from 1861 to 1991 were identified; of these, 22 suitable studies were selected, with 56 substudy groups (e.g. in relation to age, ethnicity, sex and smoking status) and 354 BMI groups. Most of the studies dealt with Caucasian men, but 14 substudies assessed Caucasian women. Only two substudies in Asian men (not women) were available and one substudy in Samoan men and women combined was assessed. The authors distinguished data derived from insurance companies from data derived from other populations because they demonstrated that insurance data, particularly those from the United States, were associated with lower mortality in relation to BMI than that found in the general population. It was inferred that these data, which formed the basis of many earlier official reviews on the
impact of obesity for governments, for example, in the United States and the United Kingdom, related to groups in society who were relatively affluent and therefore, for a variety of reasons, able to sustain better health.

Troiano et al. (1996) demonstrated evidence of a U-shaped curve of mortality in relation to BMI, but this curve varied depending on whether the data were derived from the United States or elsewhere (predominantly northern Europe and Scandinavia). When all data were included, as shown in Table 8.39, there was clear evidence of a minimum mortality at BMIs of $24-27 \mathrm{~kg} / \mathrm{m}^{2}$, the lower value being that obtained with longer, i.e. 30 -year follow-ups of adults. Most of these data relate to individuals who were aged about 50 years and were followed for 30 years. The table dealing with all the studies shows a statistically significant increase of $z$-scores when the $z$-scores exceed 1.65 . Clearly, even BMIs of $\leq 23$ and $\geq 28 \mathrm{~kg} / \mathrm{m}^{2}$ are associated with higher mortality in these overall groups. It is noteworthy, however, that these analyses included

Table 8.39 The probability of death associated with BMI level, for either 10 or 30 years of follow-up (smokers and nonsmokers included)

| 32 | 2.23 | 3.49 | 3.13 | 5.03 |

[^34]both smokers and non-smokers. Non-smokers, considered over the 30 -year period, had systematically lower risks at any BMI than smokers and Troiano et al. (1996) used these data for their baseline mortality curves.

There has been extensive discussion over the last 30 years regarding the repeated finding of higher mortality rates associated with lower BMIs. It was recognized that the original inclusion of data from smokers in such calculations had a marked effect because smokers are at greater risk of mortality, but tend to be thinner because of their reduction in appetite and their increased metabolic rate, that is, increased total energy expenditure, which leads to lower body weights when these effects are in energy balance. Thus the excess of smokers in the group of "thin" adults imposes higher mortality rates on the group overall, despite the lower BMIs.

Further, the mortality rates of the groups with low BMIs may be enhanced by the presence of individuals with as yet undiagnosed diseases, for example, cancer, who may have lost weight before symptoms emerged or a diagnosis was made. A convention has therefore developed whereby the early deaths are excluded and only those deaths that occur $2-5$ years after the initiation of any study are considered. By doing this, it is frequently found that the U-shaped curve converts to a J-shaped curve or $\log$-linear relationship.

The data previously considered were standardized to men and women aged about 50 years. Stevens et al. (1998) have recently presented a detailed analysis based on about 325000 men and women taking part in the American Cancer Society's Cancer Prevention Study. As already noted, this analysis in the United States relates to a relatively affluent fraction of the population and unfortunately used reported, not measured, weights and heights. Nevertheless, the sample is valuable in indicating the likely effect of age when assessing total mortality rates over a 12 -year follow-up period. For this purpose, data were expressly chosen which related only to life-long non-smokers. Figure 8.14 shows the agerelated risk of death from all causes. Note that men and women with a BMI of $19.0-21.9 \mathrm{~kg} / \mathrm{m}^{2}$ had the lowest total mortality. Small increases in risk were apparent at BMIs of $22.0-27.0 \mathrm{~kg} / \mathrm{m}^{2}$, but the increase in relative risk was more obvious in men than in women and in those aged $<75$ years. The risk of death from cardiovascular disease related to BMI was more clear-cut than the relative risk for all causes of death, as found in many studies (see below).

Figure 8.15 shows the decline in relative risk per unit increase in BMI with age. A very clear trend is seen, with the incremental risks being statistically significantly above those for the reference group up to the age of 75 years.

From Figure 8.14, it seems reasonable to conclude that the ideal BMI should be between 19.0 and $21.9 \mathrm{~kg} / \mathrm{m}^{2}$. These values relate to the individual risk of death in groups within a single population (in this

Figure 8.14 The relative risk of death from all causes, according to age and BMI: American Cancer Society's studies using selfreported weights and heights for BMI calculations

[^35]Figure 8.15 The change with age in the relative risk of death from all causes associated with a one-unit ( $1 \mathrm{~kg} / \mathrm{m}^{2}$ ) increase in BMI, in never-smokers

Note: The bars represent $95 \%$ confidence intervals and the trends are significant in all cases.
Source: Taken from Stevens et al. (1998) with the reference group having a BMI of $19.0-21.9 \mathrm{~kg} / \mathrm{m}^{2}$ in each age group.
case, the United States) and seem to apply to all age groups considered in the CRA analysis, from age 30-79 years. These findings are in keeping with the earlier analyses of the relationship between mean BMI and the minimizing of the prevalence of overweight, but would allow a higher proportion of underweight, which in a developing country would be a disadvantage. Given that the circumstances encountered by thin adults in the United States are probably different to those in developing countries, it seems reasonable to conclude that the data reinforce the choice of a low value for the minimum population mean BMI of $21.0-22.0 \mathrm{~kg} / \mathrm{m}^{2}$.

### 5.9 Excluded health outcomes

A number of other conditions have been widely quoted as concomitants of body-weight gain in affluent societies, including breathlessness, sleep apnoea, back pain, dermatitis, reactive depression and social isolation, menstrual disorders, infertility and gall bladder disease. The reasons for excluding these conditions are as follows.

Breathlessness: this is hard to quantify on an international basis and comparable data to those obtained in affluent societies in relation to excess weight are difficult to find in many parts of the world. It is also not clear to what extent different degrees of physical fitness in different parts of the world might affect an assessment of perceived breathlessness in those with excess weight.

Sleep apnoea is a well-described clinical complication of excess weight, which affects very obese children and adults. There are few data on its prevalence however, and it is generally considered to occur in those with more extreme forms of obesity.

Back pain: there are many causes of back pain, which is a very prevalent condition with substantial economic implications. Few studies however provide reliable estimates of hazard due to any specific risk.

Dermatitis: skin problems occur commonly in people who are obese, but few data are available other than from the developed world. Again, the description of skin problems associated with obesity is largely clinical and therefore this condition is not included.

Reactive depression and social isolation: it is well recognized that the societal response to obese individuals varies widely across the world. In some developing countries, the overweight and obese have traditionally been seen as successful individuals who are sufficiently wealthy or resourceful to have acquired enough food. In these circumstances, there is little indication of any social isolation or ensuing depression resulting from the overweight and obese being excluded from social interactions. This is quite different from accounts widely reported in North America and Europe where being obese, particularly for children and young women, is a social stigma which has clearly been related to poorer access to employment opportunities, lower earning power, a tendency to marry less affluent partners and a tendency to become personally distressed and socially isolated. Given the diversity in cultural perceptions of the benefits or handicaps of being overweight or obese, no attempt has been made at this stage to use representative data on body weight in adults in relation to mental health outcome.

Menstrual disorders and infertility: although severe underweight and anorexia nervosa have classically been associated with amenorrhoea and infertility, obesity is now increasingly recognized as a major feature of, for example, polycystic ovarian disease, which is associated with menstrual abnormalities, hirsutism and infertility. Weight loss markedly improves the condition of patients with this disorder and restores fertility. Little is known about the prevalence of this disease in different societies. The issue of infertility does not seem as yet to be of great societal concern if considered simply in terms of the probability of maintaining the population size. There is also no suggestion that the marked decline
in fertility seen, for example, in Europe (France, Italy and Spain), relates to the increasing prevalence of adiposity. Societal and social issues appear to be of far greater importance, so this outcome is also excluded from the current analysis.
Gallbladder disease: it has been recognized for several decades that excess weight gain is associated with a greater propensity to the development of gallstones and gall bladder disease. This relationship is clearcut in developed societies, but as data on gall bladder disease are not collected systematically in many countries it is not possible to undertake an appropriate international analysis of the risk associated with weight gain.

### 5.10 Risk reversibility

The evidence on the reversibility of health hazards after reducing excessive BMIs has been given in each section setting out the relationship between increases in BMI and the development of individual diseases such as type II diabetes, ischaemic heart disease, hypertension and stroke, as well as cancers. The speed of reversibility depends on the condition. Thus an elevated blood pressure associated with weight gain can start to reverse within days of the beginning of weight loss; in association with other dietary measures and increased physical activity, lower body weights can also then limit the incidence of hypertension for 10 years (Stamler et al. 1980). Changes in blood lipids also begin within days of weight loss, although the restitution of low concentrations of HDL cholesterol to normal requires a period of several weeks at a stable lower body weight (Dattilo and Kris-Etherton 1992). The impact of weight loss on the development of ischaemic heart disease is more difficult to distinguish from other dietary changes accompanying the intended weight loss. Thus when individuals at a high risk of suffering a myocardial infarction are trained to markedly reduce their intake of fat, together with their intake of salt and sugars, as well as undertaking exercise training, they lose substantial amounts of weight and show a marked decrease not only in the principal risk factors for ischaemic heart disease (i.e. hypertension, dyslipidaemias and glucose intolerance) but also show a reduction within weeks in the incidence of angina and then in rates of myocardial infarction (Ornish et al. 1990); this is clearly evident within a 5 -year period. The time needed to alter insulin resistance is also short (i.e. within a few days to weeks) and the resulting reduced incidence of type II diabetes becomes evident within 1 or 2 years, although to obtain statistically robust data in most studies about 3 years is needed (Tuomilehto et al. 2001).

## 6. Results

Tables $8.40-8.42$ show the proportion of the included diseases, the number of deaths and disease burden attributable to increases in BMI
above $21.0 \mathrm{~kg} / \mathrm{m}^{2}$ in the different subregions of the world in 2000. Figure 8.16 summarizes the contributions of the diseases considered in this analysis to the total global burden of ill-health attributable to the effect of high BMI in 2000.

No lives are lost because of arthritis, but the global total mortality for cancers is appreciable, amounting to 74000 for colon cancer, 47000 for breast cancer and 32000 for endometrial cancer, i.e. a total of 153000 cancer deaths in 2000. However, these figures are dwarfed by the 491000 deaths from diabetes, 489000 from ischaemic stroke, 1168000 from ischaemic heart disease and 290000 from hypertensive disease. Thus by considering only the major diseases affected by high BMI, a total of 2592000 deaths in 2000 were attributable to this risk factor. There are marked regional differences in this mortality burden, some of which reflect major differences in population sizes.

It is evident from the impact of weight gain on risk of arthritis that those subregions with a large proportion of adults with high BMIs, for example, AMR-A, AMR-B, EUR-A and EUR-B, are likely to have more of a burden linked directly to the physical demands of weight bearing, but much depends on the quality of the documentation of degrees of handicap associated with arthritis globally. The proportions of diabetes attributable to BMI increases range from $38-88 \%$ according to subregion. For diabetes and cardiovascular diseases, while the gradient of

Figure 8.I7 Selected subregional differences in the age-related proportion of type II diabetes attributable to increases in BMI in women

relative risk was considered the same in the different subregions, the absolute risk varied substantially because of other determinants of these diseases such as dietary variation, which causes additional changes in both serum cholesterol levels and blood pressure.

Figure 8.17 presents subregional differences in the age-related proportion of type II diabetes attributable to high BMI in women. The picture of differences is magnified and the clear downward gradient in the attributable fraction with increasing age is evident. Similar relationships are observed for all three cardiovascular end-points, but not for the cancers or osteoarthritis, where relative risks were independent of age.

## 7. Discussion

These analyses highlight the very substantial burden of ill-health incurred by increases in adult BMIs with the greatest impact in disease specific terms being the burden associated with the development of type II diabetes. The attributable fraction for high BMIs does vary markedly by subregion, which implies that other factors contribute to or interact with increases in BMI. The overall burden by subregion, however, depends on
the prevalences of both high BMIs and of the particular disease (e.g. ischaemic heart disease) as well as the overall size of the population. The current analyses do not take account of the interactions with other risk factors, for example, physical inactivity, which could confound the estimated burden attributable to high BMIs per se. However, increases in body weight also amplify other major risk factors such as blood pressure and blood cholesterol levels, and so discriminating a selective effect of high BMIs from dietary factors and physical activity is not straightforward. Nevertheless, on the basis of the current data, the impact of increases in BMI on the development of type II diabetes and on cardiovascular diseases and cancers in most parts of the world is substantial.

This is the first global analysis of the risks attributable to high BMIs and the results reinforce the recent recognition by WHO (2000) that this is one of the largest unrecognized public health problems that now need to be addressed. With the seemingly inexorable rise in mean BMIs in various populations, the projected impact on the global health burden will be very substantial by 2030 unless effective public health measures can be introduced soon.

## 8. Future exposure

### 8.1 Regional time trends in adult BMIs

There are as yet only a modest number of studies dealing with BMI changes in different populations, the most comprehensive being that conducted by Pelletier and Rahn (1998). In this study, a series of small data sets were found for several countries within different regions of the world. The data sets differed by sex, age and setting, i.e. whether they were studied in a clinical context, were related to urban or rural groups or differed in terms of their economic status. By specifying these variables, Pelletier and Rahn (1998) were able to identify the magnitude and significance of these variables and still develop generic equations for the overall BMI changes with time in different regions. These estimates of time trends per decade are presented in Table 8.43.

Given the fact that these data relate to the 1980s and that the equations are often based on data from clinics or other small groups, more recent evidence from larger and more representative samples was sought, again with the specification that the BMIs should be measured and that mean BMI values were available.

Popkin et al. (2002) have recently presented valuable new data on annual increments in the prevalence of overweight and obesity. Unfortunately this approach does not use the continuous approach to BMI-risk relationships and extrapolating from the equations for the curvilinear relationship between the mean BMI and the prevalence of

Table 8.43 Predicted regional rates of change in BMI per decade for adults

| Country or area | Mean BMI change per decade |
| :--- | :---: |
| Sub-Saharan Africa | 0.207 |
| South and South-East Asia | 0.169 |
| India | 0.048 |
| Australasia | -0.295 |
| Polynesia and Micronesia | 0.957 |
| Latin America and the Caribbean | 0.112 |
| China | 0.106 |

obesity at BMIs of $\geq 30 \mathrm{~kg} / \mathrm{m}^{2}$ (see Figure 8.2 ) proved too inaccurate, given the data provided on annual increment in obesity and the need to extrapolate to 2030.

There is, however, a series of recent analyses that attempt to look at changes in body weight over the last 10-40 years. Some of these analyses, for example from Brazil (Monteiro et al. 1995), several European countries (Molarius et al. 2000), India (Shetty 2002), Japan (Yoshiike 2002), and the United States (Flegal and Troiano 2000), are based on repeated national representative data and allow some preliminary subregional estimates to be developed. To these data it was possible to add background data sets while recognizing that many were not representative of a country, let alone a subregion and that sex-specific rates may well be very different in different societal settings.

The uncertainty associated with assuming that both sexes and all age groups are likely to respond in the same way over the next 30 years is illustrated by Figure 8.18, which sets out the detailed age- and sex-based time trends in mean BMI for the Japanese population (Yoshiike 2002). It is evident that whereas the mean BMI for men has increased in a linear fashion between 1977 and 1995 in all age groups, the mean BMI for women aged $<50$ years has shown a progressive reduction amounting to about 0.3 BMI units per decade. Given that the mean BMI is now $20.4 \mathrm{~kg} / \mathrm{m}^{2}$ for young women aged $20-29$ years and $22.2 \mathrm{~kg} / \mathrm{m}^{2}$ for women aged $30-49$ years, it is clear that predicting a continuation of this trend for the subsequent 35 years, that is, to 2030, would mean that the average BMI of the younger women would fall to $19.1 \mathrm{~kg} / \mathrm{m}^{2}$; this in turn would imply an appreciable increase in the proportion of underweight women with potentially increased morbidity (Shetty and James 1994). Yet we know that Japanese children, both girls and boys, are becoming heavier. Therefore modelling the changes in BMI by age and sex for the next 30 years presents difficulties. What is clear, however, is that the age-related changes in BMI were

Figure 8.18 Annual changes in mean BMI, by age and sex

Note: Adjusted for age distribution by use of the new world population (WHO 1993).
Source: The National Nutrition Survey, Japan, 1976-1995.
maintained from 1976 to 1995 so these are unlikely to change, unless the weights of Japanese children have shown a particularly acute recent increase.

Bearing in mind the uncertainty of these predictions, the assumption was made that the current trends in any subregion would persist in unremitting manner for the next 30 years. It was assumed that data obtained from a country within a subregion would apply to the whole adult population within that subregion. Where more than one data set was available, the values were adjusted not only for the intervals of study and the date on which measurements were made, but also for the differential population numbers in the countries being measured, with appropriate adjustments to the overall population numbers in the subregion. Only adult data were considered; no allowances were made for
children's BMIs since this would have additionally required the prediction of the probability that the current BMIs of children, expressed in percentiles of BMI for age and sex, would be maintained on the same percentiles into adult life on the basis of the BMI percentile charts produced by the IOTF (Cole et al. 2000). Where the data only covered adults aged $\leq 60$ years, it was assumed that the same delta changes were also occurring in the older age groups, thus maintaining the current agerelated differences in mean BMI within the subregion.

## Different subregional approaches

Given the paucity of data, the following extrapolations proved necessary for certain subregions.
$A F R-D$ : The data relied predominantly on the observed changes in BMI in Ghanaian women, with additional data being available from Mauritius and the Seychelles. The latter two island data sets for both sexes were then used in conjunction with data from South Africa to assess the differential sex-specific trends. These differentials were then used in conjunction with the Ghanaian female data to derive male values for the subregion.
$A F R-E$ : Here it proved necessary to use data on the secular increases found in rural South African men and women (Temple et al. 2001). It was expected that urban trends might have been greater, but given categorical analyses suggesting more modest increases in the prevalence of overweight in the United Republic of Tanzania and Zambia, the rural South African data were applied to the whole subregion.
$A M R-A$ : This was relatively straightforward given the availability of data sets from both Canada (Tremblay et al. 2002) and the United States (Flegal and Troiano 2000). The changing prevalence of overweight and obesity in Cuba was noted (Rodriguez-Ojea et al. 2002), but it was not possible to obtain suitable data on mean BMI changes. Therefore the North American data sets were applied to the whole subregion.
$A M R-B$ : There are ample Brazilian data on secular trends and a series of unpublished analyses from other countries, but the only published and available Brazilian data were those giving overall adult values (Monteiro et al. 1995). However, new analyses from a national survey carried out in Mexico in 2000 were made available (Sánchez-Castillo et al. 2003), together with earlier representative Mexican data provided by Arroyo and colleagues (Arroyo et al. 2000).
$A M R-D$ : In the absence of satisfactory data, the equations of Pelletier and Rahn (1998) were applied.
$E M R-B$ : Kuwaiti data (al-Isa 1997) were applied to the whole subregion, it being recognized that there were numerous published data sets from small clinical and other studies available, as well as several recent unpub-
lished national data sets which highlight the marked secular trends in the subregion.
EMR-D: Moroccan categorical analyses (Benjelloun 2002) having suggested marked BMI increases, the Kuwaiti data were also applied to this subregion.

EUR-A: There were ample data sets from Belgium, Denmark, Finland, Germany, the Netherlands and the United Kingdom that could be used to derive an overall set of population-adjusted, sex-specific and agerelated predictions.

EUR-B: Reliance was placed on data on secular trends in Poland.
EUR-C: Although some categorical Hungarian trends data were available, it was concluded from subregional cross-sectional data that the Polish trends data should be applied to this subregion.

SEAR-B: In the absence of data on mean BMI trends, Pelletier and Rahn's equation (1998) for south and east Asia was used.

SEAR-D: Indian data from the repeated nationally-representative surveys were used for this subregion.

WPR-A: Both Australian and the extensive Japanese representative data could be used for this subregion.

WPR-B: Although new data sets are becoming available for the numerically dominant country (China), comparable data sets with mean BMIs from a variety of adult men and women were only available from Zhou (2002). To these data sets were added information from Malaysia, the Republic of Korea and Samoa.

The predicted mean BMIs for the different subregions in 2030 are set out in Table 8.44. As already indicated, these predicted values encompass considerable uncertainties but do suggest that if current trends continue then in some subregions (e.g. AMR-A, AMR-B, EUR-A and EUR-B) half of the adults in each of several age groups will have estimated BMIs of $>30 \mathrm{~kg} / \mathrm{m}^{2}$, that is, the WHO classification of obesity. Given that there is now intense concern about escalating rates of obesity, it is very likely that new public health measures will be adopted to limit this rise, but so far the efforts of millions of people in affluent societies to either slim or limit weight gain seems to have been of only modest success. The challenge is to arrest the current trends towards increases in BMI and, if possible, to reverse the public health burden associated with weight gain. Although traditionally the prevalence rates of overweight and obesity are used as an index of the health burden, the current analyses show that the full range of BMIs should be considered. This in turn emphasizes the need to take population-based approaches to preventive strategies for minimizing the hazards of excess weight gain.

Table 8.44 Predicted mean BMIs in each subregion in 2030, by sex and age
$\left.\begin{array}{lllllll}\hline & & & & \left.\text { BMI (kg/m}{ }^{2}\right) \\ & & & & \\ \text { Age (years) }\end{array}\right]$
a Figures in parentheses refer to the percentage increase over the 2000 estimate.

### 8.2 The implications of excessive weight gain among children

The foregoing analyses of the disease burden associated with increases in BMI relate only to adults aged $\geq 30$ years. However, there is now rapidly mounting concern regarding the increasing prevalence of overweight and obesity in children (Ebbeling et al. 2002). The impact of psychosocial, physical and metabolic problems has not been incorporated in the current analyses, but may well have to be considered within the next $5-10$ years. Overweight children in many countries are handicapped by the social stigma of being considered overtly fat by their peers. In
addition, these children have a propensity to bone and joint deformation during their growing phase, as well as breathlessness and, in more extreme cases, sleep apnoea arising from the mechanical handicap of being heavy. It is now clear that overweight children also have higher blood pressure, serum lipid abnormalities and increasing insulin resistance, all of which are hallmarks of early metabolic disease and susceptibility to atherosclerosis and other cardiovascular problems (DiPietro et al. 1994; Must et al. 1992; Unger et al. 1990). Within the last 5 years, paediatricians have observed that clinics for children with type I diabetes now include a remarkably increasing number of very overweight children with type II diabetes. In many parts of the world, type II diabetes occurring in adolescence is now a more prevalent condition than type I diabetes (Rosenbloom et al. 1999). As with adult type II diabetes, these children show a remarkable improvement in their glucosehandling capacity and in other risk factors if they lose weight, but many soon develop a need for insulin therapy and their condition becomes difficult to control. Children with poorly controlled diabetes are known to have accelerated atherosclerosis with microvascular disease leading to blindness and renal failure in their early 30s. Concern regarding obesity and type II diabetes in children is now being accentuated by the recognition that mothers who develop gestational diabetes produce larger babies who are then very susceptible to pre-adolescent obesity and to the development of type II diabetes in adolescence (Silverman et al. 1998).

People who are overweight in childhood are more prone to be obese when they enter adult life and these individuals are also likely to continue to gain weight in adulthood. Such individuals then have up to a 100 -fold increased risk of developing type II diabetes compared with normal weight children who do not gain excessive weight once they are adults (Colditz et al. 1995). Early data from insurance companies also showed that heavy young adults had a much greater likelihood of suffering premature deaths (Blair and Haines 1966) and this is now recognized to be related to their greater propensity to hypertension, dyslipidaemia, glucose intolerance with insulin resistance and accelerated cardiovascular disease. These observations are relevant to any assessment of the future burden of disease arising from high BMIs in adults because the rapidly rising prevalence of overweight and obesity in children is likely to amplify the currently predicted risks of excess weight in young adults.

## Acknowledgements

We are most grateful for the support of numerous individuals and institutions in gathering data for this analysis. In addition we wish to acknowledge the assistance of Mrs Jean James in preparing the manuscript for this chapter.

The following contributed invaluably by providing re-analysed data to assist in the IOTF's analyses: N. Adra, P. Arroyo, K. Babinska, G. Biro, A. Deev, T.P. Gill, N. Hwalla, M. Lahti-Koski, B. Lajos, A. Ferro-Luzzi, A. Kaic-Rak, G. Mensink, J.C. Montero, A. Nielsen, I. Palczewska, G. Pekcan, N. Rak, C.P. Sánchez-Castillo, G. Whitlock and the Asia-Pacific Cohort Studies Collaboration.

In addition, the following assisted by allowing access to data or suggesting sources:
T. Athanassouli, W. Becker, Z. Brazdova, W. Chen, W. Freire, V. Gudnason, K. Habibullah, U. Hagman, B. Heitman, N. Katsilambros, J. Luthy, V. Lambert, A.O. Musaiger, A. Neilson, L. Ovesen, R. Prattala, W. Rand, K.S. Reddy, A. Robertson, J. Seidell, L. Steingrimsdottir, M.Q.-K. and K. Talukder, R. Uauy, and M. Vasconcellos.

## Notes

1 See preface for an explanation of this term.
2 The standard deviation (SD) was sometimes missing for different sexes and age groups. This problem was dealt with as follows:
SD missing for one sex; for example, there were some subregions where SDs were available only for females

For all subregions with SDs available for both men and women, SDs were in general higher in females than males. The mean difference between the SDs of females and males varied from $0.24-2.25$ units, with the largest differences observed between higher SD values. For example, subregions with SDs of $>5-6$ units in women tended to have SDs in these women which were $>1$ unit higher than those in men, whereas with female SD values of $3-4.5$, the sex differences in SDs were $<1$.

The mean of the differences when the SD values were $<1$ unit was 0.6 units, and for those $>1$ unit was 1.63 . As a result, to estimate male SD from female SD in subregions where SD values were $<5$ in most age groups, a simple subtraction of 0.6 from the SD for females was used to estimate the male SD. In other subregions where SDs were higher in females, a value of 1 was subtracted from the female SD to estimate the corresponding male SD. The same approach was applied to all age groups. These differences in SDs by sex are then reflected in the differences in prevalences of overweight and obesity in men and women with the same mean BMI.

For example, in AMR-D an SD was available for females only and the values varied from 3.8-4.6 units. Subtracting 0.6 from these gave the corresponding values for men of 3.2, 3.8 and 4.0. In EMR-D, again only SDs for women were obtained with values varying from 6.4 to 8.5 . In this case, the correction factor of 1.6 was applied to obtain the estimates for men.
SD missing for some age groups
There was no clear pattern of SD by age group. For the age groups where no SDs were available, it was assumed that the SD was equal to an average
of the observed SD for the subregion. For example, in AMR-D, the mean SD for females aged $18-59$ years was $(3.4+4.4+4.6) / 3=4.13$.

This figure was then applied to the remaining age groups where no SDs for females were available.

## Chapter 9

# Low fruit and vegetable CONSUMPTION 

Karen Lock, Joceline Pomerleau, Louise Causer and Martin McKee

## Summary

This analysis assessed the levels of mean dietary intakes of fruit and vegetables (excluding potatoes) measured in grams per day. The theoretical-minimum-risk distribution for fruit and vegetable intake was estimated to be $600 \mathrm{~g} /$ day in adults, $480 \mathrm{~g} /$ day in children aged $5-14$ years, and $330 \mathrm{~g} /$ day in children aged $0-4$ years. It is proposed to use set intervals of $80 \mathrm{~g} /$ day of fruit and vegetables (equivalent to one serving) to elaborate the distributional transition.

The effect of fruit and vegetable consumption in preventing ischaemic heart disease (IHD), cerebrovascular disease, lung cancer, stomach cancer, colon and rectum cancers and oesophageal cancer was estimated. The choice of outcomes was guided mainly by previous reviews of the literature (Law and Morris 1998; Ness and Powles 1997; World Cancer Research Fund and American Institute for Cancer Research 1997), which suggested a protective effect of fruit and vegetables for IHD, stroke and cancers of the lung and digestive tract.

Health outcomes that could be reconsidered for inclusion in the next revision of the Global Burden of Disease (GBD) study include cancers of the larynx, pancreas, bladder, ovary, endometrium, thyroid and prostate; type II diabetes; chronic obstructive pulmonary disease; and cataract.

Estimates were based primarily on representative population-based surveys of dietary intake identified using a comprehensive search of the literature and contacts with experts. Data were obtained for 26 countries from nine subregions ${ }^{1}$ and pooled statistically within each subregion. When no survey data were available in a subregion, per capita food supply statistics were combined with estimates of the distribution of intakes by sex and age. Systematic extrapolations were made when the original data did not meet the comparative risk assessment (CRA) categories and when part of the estimates were unavailable.

Estimates of fruit and vegetable intake were highest in EUR-A, followed by WPR-A. The lowest intakes were found in AMR-B, EURC, SEAR-B, SEAR-D and AFR-E. Intakes varied by age groups, with children and the elderly generally having lower intakes than middle-aged adults.

Standard deviations varied considerably by subregion, sex and age group, with a median of $223 \mathrm{~g} /$ day. Estimates tended to be, on average, lower in women than in men (but with variations by age group), and they were generally lower in young children. In some subregions, standard deviations were also slightly smaller in the elderly.

Risk factor-disease relationships for each selected outcome were estimated based on the results of a systematic review of the literature combined with meta-analysis. The relative risk estimates derived were applied to all age groups between the ages of 15 and 70 years. To take account of age attenuation the relative risks were reduced by a quarter for ages $70-79$ years, and by half for the age group $\geq 80$ years. For those aged $<15$ years, a relative risk of 1 was applied.

Due to the limited information available on subregional differences in risks, constant estimates were applied to all subregions. Risks were assessed relative to the chosen theoretical-minimum-risk distribution fruit and vegetable intake.

The protective effects of fruit and vegetables were expressed as relative risk estimates associated with an $80 \mathrm{~g} /$ day increase in fruit and vegetable intake. The relative risk estimates were as follows: 0.90 (95\% CI $0.82-0.99)$ for IHD, $0.94(0.89-0.99)$ for ischaemic stroke, 0.96 (0.93-0.99) for lung cancer, 0.94 ( $0.86-1.03$ ) for gastric cancer, 0.99 (0.97-1.02) for colorectal cancer and 0.94 (0.88-1.01) for oesophageal cancer.

CRA found that the lack of dietary fruit and vegetables contributes an important share of the worldwide disease burden. It was estimated that increasing individual fruit and vegetable consumption up to the theoretical-minimum-risk distribution could reduce the worldwide burden of disease for IHD and ischaemic stroke by about $31 \%$ ( $30 \%$ in men and $31 \%$ for women) and $19 \% ~(18 \%$ in men and $19 \%$ in women), respectively. For stomach and oesophageal cancer, the potential reduction in disease attributable to an increase in fruit and vegetable intake was $19 \%$ and $20 \%$, respectively. Attributable risk fractions were lower for lung and colorectal cancer ( $12 \%$ and $2 \%$ ). The total worldwide mortality attributable to inadequate fruit and vegetable consumption is estimated to be 2.726 million deaths or 26.662 million disabilityadjusted life years (DALYs) per year.

Although these results need to be interpreted in the light of the limitations of the current methods, including the potential for residual confounding and misclassification of exposure, they clearly highlight the importance of increased fruit and vegetable consumption in improving public health worldwide.

## 1. Introduction

### 1.1 Definition of risk factor

In this chapter, the selected risk factor is the mean dietary intake of fruit and vegetables. Intake is treated as a continuous variable and is measured in grams/person per day. The estimates provided exclude potatoes in order to be consistent with current international recommendations for the intake of fruit and vegetables (WHO 1990).

### 1.2 Choice of exposure variable, reasons and implications

Accumulating epidemiological evidence has suggested that fruit and vegetables in the diet can reduce the risk of major diseases such as cardiovascular diseases and certain cancers, thus reducing premature deaths (Klerk et al. 1998; World Cancer Research Fund and American Institute for Cancer Research 1997). This consistent pattern of findings has led several national and international bodies to advocate an increase in intake to at least $400 \mathrm{~g} /$ day (excluding potatoes) (WHO 1990; World Cancer Research Fund and American Institute for Cancer Research 1997).

While the first round of the GBD study did not look explicitly at the overall impact of nutrition on the global burden of disease, an attempt was later made in Sweden to estimate the burden of disease that could be attributed to different causal factors in the European Union (EU) (National Institute of Public Health 1997). It was estimated that dietrelated factors directly contributed to $8.3 \%$ of the estimated number of DALYs lost, almost half of this being attributed to low fruit and vegetable intake ( $3.5 \%$ compared with $3.7 \%$ for overweight and $1.1 \%$ for high saturated fat intake). However, these figures do not take account of potential interactions between the different factors. In comparison, tobacco smoking accounted for $9 \%$ of the burden of disease in the EU. These findings are similar to those of recent studies from Australia and New Zealand (Mathers et al. 1999; Tobias 2001). In these countries, it was estimated that about $3 \%$ ( $2.8 \%$ in Australia and $2.4 \%$ in New Zealand) of the burden of disease could be attributed to low fruit and vegetable consumption. The Australian study also reported that approximately $10 \%$ of all cancers could be due to an insufficient intake of fruit and vegetables.

### 1.3 CHOICE OF THEORETICAL-MINIMUM-RISK DISTRIBUTION

The CRA project estimates the effects of shifting risk factor distributions towards a counterfactual distribution, rather than the difference between "exposed" and "unexposed" groups. Fruit and vegetable consumption is unusual in the CRA project in that there is a suggested inverse risk factor-disease relationship (i.e. the potential protective effect of fruit and vegetables for various disease outcomes is considered). Hence, the
theoretical-minimum-risk distribution (the distribution of exposure that would yield the lowest population risk) involves estimating an upper consumption that is protective.

For this exercise, we chose limits that could be realistically attained. However, we do not know what the true upper intakes that would give the highest level of protection would be; they could reflect levels of intakes that are much higher than current consumption patterns. Thus, choosing a theoretical-minimum-risk distribution is currently difficult to do with certainty. Evidence has clearly shown that those in the highest categories of fruit and vegetable consumption have lower risk compared with those in the lowest consumption categories. It is not yet clear whether there is a threshold effect for fruit and vegetable consumption (although many studies have presented a linear dose-response relationship). Nor is it clear whether the same threshold would apply to all protective effects (e.g. there appears to be some evidence to suggest a lower threshold for colorectal cancer from research in individuals with very low intake) (Terry et al. 2001). However, due to the current uncertainty in this area, the same threshold was used for all selected health outcomes. Better information on threshold effects is a priority for future work.

In this project, the counterfactual was chosen to be a constant level using a minimum risk approach based on the following information.

- Most studies showing risk differences between the highest and lowest quartiles or quintiles of intakes have been performed in western Europe and North America. In the absence of other evidence, it was decided to base the counterfactual on the ranges of intakes observed in these populations.
- According to food balance sheet data, the amounts of fruit and vegetables available for consumption by the populations of these subregions range from about 300 to $1200 \mathrm{~g} /$ person per day (FAO 1998a). The highest availability is found in Greece where the quantity of fruit and vegetables available to consumers is $1100-1200 \mathrm{~g} /$ person per day. Assuming approximately $33 \%$ waste at the household level (Joffe and Robertson 2001), the mean daily intake of fruit and vegetables could be estimated to be approximately $700-800 \mathrm{~g} /$ person. However, dietary survey data gathered for this study showed that the mean intakes in adults of any given country rarely went above $500 \mathrm{~g} /$ day, and never above $550 \mathrm{~g} / \mathrm{day}$, even in countries known for their high intakes of fruit and vegetables (Israel and Italy). It was thus decided to limit the theoretical-minimum-risk distribution to $600 \mathrm{~g} /$ day in adults.
- As described in section 2.5 , it was assumed that children consume less fruit and vegetables than adults ( $45 \%$ less in children aged $0-4$ years and $20 \%$ less in children aged $5-14$ years).
- As data gathered for this project showed almost no difference in fruit and vegetable intake between men and women (see section 2.5), it was decided to use the same theoretical-minimum-risk distribution for both sexes.
- In order to allow for slight population variability, it was decided to apply around the theoretical-minimum-risk distribution, a margin of uncertainty of $50 \mathrm{~g} /$ day.

The final theoretical-minimum-risk distribution levels used in this project are listed in Table 9.1.

It is proposed to use set intervals of $80 \mathrm{~g} /$ day of fruit and vegetables for the elaboration of the distributional transition. This amount has been estimated in nutritional studies to be equivalent to approximately one serving of fruit and vegetables and would constitute a plausible and feasible change for individuals towards the selected counterfactual level (World Cancer Research Fund and American Institute for Cancer Research 1997).

Most studies to date that have investigated the relationship between fruit and vegetable intake and risk of diseases were performed on populations that reported only a relatively narrow range of intake which in most cases did not reach the selected theoretical-minimum-risk distribution. As a result, it is not possible to know whether the same relative risks would apply in populations where high amounts are consumed. It is expected that future epidemiological studies incorporating populations with wider range of intakes, such as the European Prospective Investigation of Cancer (EPIC) study, may shed light on the impact of high fruit and vegetable intakes (higher than those investigated in current studies) on the risk of cardiovascular disease and cancer.

Table 9.I Theoretical-minimum-risk distribution by age group

| Age group (years) | Theoretical-minimum-risk distribution and SD <br> (fruit and vegetable intake g/person per day) |
| :--- | :---: |
| $0-4$ | $330 \pm 50$ |
| $5-14$ | $480 \pm 50$ |
| $15-29$ | $600 \pm 50$ |
| $30-44$ | $600 \pm 50$ |
| $45-59$ | $600 \pm 50$ |
| $60-69$ | $600 \pm 50$ |
| $70-79$ | $600 \pm 50$ |
| $\geq 80$ | $600 \pm 50$ |

## 2. Estimating risk factor levels

### 2.1 Methods

The methods used to obtain estimates of risk factor levels are described in the following sections.

### 2.2 Criteria for considering sources and studies

Potential sources of data on intake and supply
Data on dietary intake and supply of fruit and vegetables may be available at the national, household and individual level. The following subsections briefly describe these potential sources of information and whether they were used for the CRA project.

## National level

The most commonly used source of information at the national level is food balance sheet data published by the Food and Agriculture Organization of the United Nations (FAO) for over 175 countries (1983). Food balance sheets provide standardized estimates of the average amount of food available per person on a daily basis. They are calculated by estimating the quantity of food produced in a given country added to the quantity of food imported (adjusted for changes in stocks), and subtracting the food exported, lost in storage, transport, and processing, fed to livestock or used for seeds and non-dietary purposes. The estimated national food supply is then divided by population size estimates to derive per capita figures (in $\mathrm{kg} / \mathrm{person}$ per year). The main limitation of food balance statistics is that they tend to reflect national food availability patterns rather than actual dietary intake and are thus a reflection of both intake and wastage at the retail, food service and household levels (Kantor et al. 1997). As a result, they cannot provide information on the dietary intake of different population subgroups and they tend to overestimate food consumption, particularly in developed countries. However, time trends in food availability tend to parallel those observed with household surveys (Sekula et al. 1991), so FAO food balance sheets constitute a useful tool for international comparisons and time trend analysis.

## Household level

Household-based surveys, where the unit of measurement is the household rather than the individual, are often performed to explore the diversity of food consumption patterns among communities. They can give information about dietary patterns of groups, making distinctions between geographical regions, income brackets and family structures. The most frequently used types of household surveys are the food account method, the inventory method, the household food record
method and the list-recall method (Nelson and Bingham 1997). Household surveys have several limitations: they cannot provide information on individuals; they are subject to sampling errors; they sometimes exclude foods consumed outside the home or certain food groups (e.g. sweets, alcoholic beverages, etc.); and some methods are subject to recall bias. In addition, they are available for only a limited number of countries and the diversity of the methods used make international comparisons difficult. Due to these limitations, data from household surveys were not used in this project.

## Individual level

It is generally agreed that there is a considerable lack of internationally comparable data at an individual level. This is partly due to the difficulties associated with measuring the dietary intake of individuals, including potential measurement error and bias. In spite of this, data collected at the individual level provide invaluable information on the mean dietary intakes of population subgroups (e.g. stratified by age and sex) and variability in intakes. They are thus essential for stratified intake estimates.

Data on present or recent food consumption are collected using four main techniques: (i) the 24-hour recall; (ii) food records (with or without weighing of foods); (iii) food frequency questionnaires; and (iv) food history. Details of these methods and their limitations can be found elsewhere (Nelson and Bingham 1997; Willett 1998a). The choice of a method to collect data at the individual level will normally depend on the objectives of the study and on the resources available. When the main objective is to obtain the mean consumption of a large group of individuals, it is generally sufficient to use a single 24 -hour recall or a oneday food record. This approach is often used in large national surveys of dietary intake as it represents a relatively small burden for the respondents and is associated with relatively low costs. The main caveat of using only one day of information is that it tends to artificially increase the standard deviation of the estimates due to large intra-individual variation in intakes (Cameron and van Staveren 1988). Thus, the observed distribution of intakes has extreme values that are higher and lower than any of the true long-term averages for any individual. Including several days of data collection for each respondent will normally dampen day-to-day variation, but it will also increase the burden on the respondents and the costs. If the objective of the study is to assess the distribution of food consumption in a group or the position of an individual's intake within the population, more complex methods such as repeated 24 -hour recalls or food records, food frequency questionnaires or dietary history are needed. These approaches have been used mostly in cohort studies or smaller, more focused surveys of dietary intake; they have less frequently been used in national surveys of dietary intake.

## Sources of data used in this project

Only dietary surveys with data collected at the individual level can provide information on mean intakes and variability in intakes (standard deviations) in population subgroups. Thus, we set out to identify data from at least one valid and representative population-based survey of dietary intake for each of the 191 countries covered by the CRA.

However, this was not realistically possible as currently only a few countries (mainly economically developed) have conducted representative national or regional surveys of dietary intake at the individual level, and a few others have performed surveys in selected sections of the population only. Conversely, for the majority of countries in the world, yearly estimates of available food supply exist in the form of the FAO food balance sheets. These food balance sheets were used to complement data collected at the individual level, when required. The methods used and the subregions to which they were applied are described in section 2.5.

## Criteria for including sources of individual level data

The main criteria used for including sources of individual level data of fruit and vegetable intake were as follows:

## Time frame

- The study was relatively recent-defined as having been performed since 1980.

## Study sample

- The reference population was described.
- The sampling strategy was as close as possible to random sampling.
- The sample was representative of the reference population.
- The sample size was large (sample size calculation ideally included).
- As wide an age range as possible was included.
- The level of non-response was ideally documented.

## Study design

- Only population-based cross-sectional studies, baseline assessment of large cohort studies (sample representative of the general population) or large interventions (sample representative of the general population) were considered for inclusion.
- Case-control studies were excluded from the selection process.

## Validity of the methods

- The methods used to collect data were as free of bias as possible.
- Data were collected at the level of the individual.
- The statistical analysis of the data was appropriate.

## Type of dietary information

- Data on fruit and vegetable intake had to be available as grams per day and not as frequencies (e.g. $<1$ serving a day, $1-2$ servings a day, every day, etc.).

### 2.3 Search strategy for the identification of studies

Dietary intake data were identified using a comprehensive worldwide search which included computerized databases of published articles, library catalogues, hand-searching of bibliographies, an Internet search of possible sources of data, and extensive contact with experts in the field, national governments and nongovernmental organizations.

## Computerized Databases and library Search

The following computerized sources of information were included in the search process: Medline, CAB abstracts and Embase. MESH terms used to search in Medline and HealthStar included "fruit", "vegetables", "nutrition-surveys", "diet-surveys" and "food-habits" (each term included all subheadings). Similar search terms were used in the other databases but adapted to the specific database search facilities. The search was restricted to human studies published in all languages since 1980.

Articles were rejected on initial screen if the reviewer could determine from the title and abstract that the article did not provide estimates of fruit and vegetable intake of a population or did not report data from a representative population-based survey of dietary intake. When a title or abstract could not be rejected with certainty, the full text of the article was obtained for further evaluation. Citation lists in the articles retrieved were reviewed. A second reviewer performed random checks.

The following catalogues were searched for other publications and conference proceedings that could provide appropriate data: the University of London; the British Library; the Resource Centre of the Public Health Nutrition Unit at the London School of Hygiene and Tropical Medicine; Libraries at FAO, Rome and the Ministry of Agriculture, United Kingdom of Great Britain and Northern Ireland. Food and Fisheries were also consulted. Citation lists in the documents retrieved were reviewed.

## INTERNET SEARCHES

Internet searches (using the Google search engine-http://www. google.com) had two objectives: to locate original sources of food intake data available on the Internet, and to identify national and international organizations that could identify possible data sources including acade-
mic departments of nutrition or dietetics, food and nutrition agencies and ministries of health.

Messages requesting help in identifying data sources were also posted to four scientific mailing lists: NUTEPI@listserv.gmd.de (nutritional epidemiology); food-for-thought@jiscmail.ac.uk (nutrition); publichealth@jiscmail.ac.uk (public health); and epidemio-1@cc.umontreal.ca (epidemiology).

## Contacts with experts

Numerous direct contacts were made with nutrition officers from the World Health Organization (WHO) regional offices and experts for references to published or unpublished data sources or for the identification of appropriate contact persons. Experts were defined as contact authors for large population-based studies of dietary intake, or contact persons in governmental agencies or country-specific nutrition organizations (this included existing networks from WHO and the International Obesity Task Force, and other international nutritional networks).

### 2.4 Methods for obtaining estimates of national intake WHERE MORE THAN ONE DATA SOURCE EXISTS

The following hierarchy of data quality was used to select one source of data for a given country where more than one was available:

- national survey of individual dietary intake;
- large sample survey of good quality-its quality being assessed from how well the survey met the list of criteria for including sources of individual level data (section 2.2); and
- small sample survey of good quality-its quality being assessed as above.

### 2.5 Methods for obtaining estimates where no data SOURCE EXISTED <br> Data on mean intakes not available for some age or sex groups

Attempts were made to contact the original investigators to obtain data broken down by the required age categories. However, this was not always possible and so indirect estimates were made using the following approaches.

## Data not available for children

Few of the available dietary intake surveys had data for children aged $<18$ years. Extrapolations for the intakes of children were on the basis of two observations.

- Using data from the surveys collected for this project, it was estimated that boys and girls aged $5-14$ years and those aged 0-4 years
consume, respectively, about $20 \%$ and $45 \%$ less fruit and vegetables than adults aged 30-59 years.
- Published estimates on energy requirements for infants and children (WHO 1985, 1990) suggested that girls and boys aged 5-14 years require approximately $15 \%$ and $20 \%$ less dietary energy than adult women and men, respectively. The figures for girls and boys aged 0-4 years are about $40 \%$ and $50 \%$ less than adults of the same sex, respectively. These estimates, however, may vary among countries and they depend on the true energy expenditure of the children.

Assuming that fruit and vegetable consumption decreases proportionally to energy intake in children compared with adults, the two sources of information tend to agree. Thus, the following adjustment factors were used.

- Children 5-14 years: $20 \%$ lower fruit and vegetable intake than adults aged 30-59 years.
- Children $0-4$ years: $45 \%$ lower fruit and vegetable intake than adults aged 30-59 years.

## Data not available for the elderly

Many surveys were only for adults up to age 60-65 years. Once again, available survey data on fruit and vegetable intakes collected for this project and published estimates of energy requirements (WHO 1985, 1990) were used to derive an adjustment factor.

- Information on fruit and vegetable intakes from survey data indicate that men and women aged 70-79 years consume daily approximately the same amount of fruit and vegetables, on average, as their counterparts aged $30-59$ years, while individuals aged $\geq 80$ years consume approximately $10 \%$ less fruit and vegetables than middle-aged adults.
- Figures based on energy requirements suggest that men and women in older age groups require approximately $10-15 \%$ less energy than middle-aged adults do.
Based on these observations, the following assumptions were made.
- Individuals aged 70-79 years consume the same amount of fruit and vegetables as individuals in the closest age group (60-69 years).
- Individuals aged $\geq 80$ years consume $10 \%$ less fruit and vegetables than those aged $30-59$ years. However, when the resulting estimates were greater than the reported intakes of survey participants aged 70-79 years, a different approach was taken: it was assumed that individuals aged $\geq 80$ years had an intake of fruit and vegetables similar to the intake observed in the 70-79-year age group.

Cases where the age groups did not correspond to the CRA AGE GROUPS
In these cases, the results available for the most similar age categories (greatest overlap of ages) were applied, weighing for population sizes when necessary.

## Data on mean intakes available for only one sex or for men and WOMEN TAKEN TOGETHER

In the case of Mexico, adult data were available only for women. In the case of France, only the overall mean intakes by age group (men and women taken together) were accessible.

Using data available from the surveys gathered for this project, it was estimated that, on average, men consume approximately only $1 \%$ more fruit and vegetables than women. It was thus assumed that Mexican and French males consume similar amounts of fruit and vegetables as do their female counterparts.

## Data on standard deviations not available

In some cases, survey information did not include standard deviation estimates. The authors of the studies were contacted and, for some countries, the required estimates were provided. When this was not possible, the following assumptions were made.

- When standard deviations were missing for one or more age groups and for one or more countries within a subregion (usually for children or the elderly), data were pooled based on the information available (all countries with information for these age groups).
- When standard deviations for all age groups were missing for a country, the standard deviations of the country-within the same sub-region-displaying the most similar mean intakes and method of data collection were applied. For example, for the United Kingdom, the standard deviations from Germany were used. However, since data on sample size are required for the estimation of the pooled standard deviation (and its confidence interval), pooled estimates were based only on the information available from the surveys.

## Data on standard deviation and sample size not available for all COUNTRIES IN A SUBREGION

For two subregions (SEAR-D and EMR-B), the survey data available included only mean intakes. As a result, it was not possible to extrapolate standard deviations from other countries within the same subregion. Thus, the pooled standard deviations of the subregion displaying the closest subregional mean intakes were applied (EUR-C for SEAR-D and EUR-B for EMR-B).

Another approach for the extrapolation of missing standard deviations may have been to use the standard deviations of a subregion that
is close geographically, that has similar economic characteristics, and for which data were available. For SEAR-D, for example, a possible choice may have been to use the standard deviations of WPR-B. However, as the standard deviations obtained for WPR-B are smaller than those of EUR-C, we preferred to choose the largest standard deviations and thus keep those obtained for EUR-C. For EMR-B, there was no obvious choice among the subregions for which data were available and thus the standard deviations of EUR-B were kept.

## Data on mean intakes unavailable for a subregion

When survey data were unavailable for all countries within a subregion, it was originally planned to apply the results obtained for another subregion displaying the most similar fruit and vegetable availability (from FAO food balance sheets information) and demographic and health characteristics (using data from the World bealth report 2000 [WHO 2000], the World Bank classification of economies based on gross national product [World Bank 2000], and the CIA World Factbook [Directorate of Intelligence 2000]).

However, it became clear the dietary patterns and socioeconomic characteristics of the African country mortality groupings (AFR-D and AFRE), and of the EMR-D, SEAR-B and AMR-D groupings are too different from those found in the other subregions to allow for any correct extrapolation. We have thus used FAO food balance sheet data combined with survey information to obtain FAO-derived proxy mean intakes by age group and sex for the five subregions for which no individual survey data were identified (as described in the next section). We concluded that this approach was likely to provide more representative estimates of mean subregional fruit and vegetable intakes than extrapolations from other subregions, as the basis of the calculations was information collected directly from within each country within the subregion, that is, countryspecific FAO food balance sheet data.

## Obtaining FAO-derived proxy mean intakes

Country-specific data on availability of fruit (excluding wine-FAO code 2919) and vegetables (excluding potato-FAO code 2918) and population size estimates were downloaded from the FAOstat database on the FAO web site (FAO 1998a). Three-year averages (1996-1998) were calculated in order to reduce the effect of yearly variations. These data were then used to calculate subregional population-weighted average fruit and vegetable availability in grams/person per day. For seven relatively small countries, no estimates were available (Bahrain, Bhutan, Equatorial Guinea, Oman, Qatar, Samoa, Singapore). Estimates of calculated subregional food availability (1996-1998) are listed in Table 9.2.

As mentioned in section 2.2, food balance sheets provide information on the amounts of foods available for the consumers and are thus a reflection of both intake and waste at the retail, food service and house-

a 1996-1998 averages.
Source: FAO (2001).
hold levels. Therefore, it has been reported that the balance sheets tend to overestimate intakes in developed market economies (Joffe and Robertson 2001). In developing countries, such as those included in the five subregions for which no survey data were obtained (World Bank 2000), it has been suggested that food balance sheets are likely to underestimate food availability as they do not take account of food grown for home consumption or wild food collected. However, few studies have tested this hypothesis. In Nepal and Pakistan, the average energy consumption from intake surveys was found to be about $10 \%$ higher than that from FAO food balance sheets (FAO 1998a, 1998b).

Using survey data obtained for this project, it was estimated that food balance sheet data tend to overestimate the national mean fruit and vegetable intake by $20 \%$ in India (FAO $=252 \mathrm{~g} /$ day vs survey $=209 \mathrm{~g} /$ day ), and underestimate intakes by $74 \%$ in Bangladesh (overall weighed mean $=+10 \%)$. However, the results for Bangladesh were based on very small availability estimates ( $\mathrm{FAO}=59 \mathrm{~g} /$ day vs survey $=226 \mathrm{~g} /$ day ) that appear peculiar. In view of these contradictory results and because of the lack of further available information, we did not apply any correction factor to the FAO estimates in our calculations of the FAO-derived proxy mean intakes for the five subregions with no available survey data.

As food balance sheets do not provide information on food intake by sex and age group, an attempt was then made to estimate how the total availability of fruit and vegetables in a subregion would be distributed among the different sex and age groups. To reach this objective, a twostep process was used.

Step 1: We calculated the proportion of total fruit and vegetable intake consumed by the different age-sex groups for each subregion with available survey data. As expected, the distributions of intakes were strongly influenced by the population structures of the subregions.

Step 2: For each subregion with no available data (AFR-D, AFR-E, AMR-D, EMR-D and SEAR-B), we then applied to the FAO availability data the calculated distributions of intakes (Step 1) of the sub-

| EMR-D | EMR-B |
| SEAR-B | SEAR-D |

region displaying the most similar population structure (Table 9.3).
As a result, we obtained FAO-derived proxy mean intakes by age and sex.

## Obtaining standard deviation estimates for FAO-derived proxy mean intakes

In order to obtain estimates of standard deviations when FAO-derived proxy mean intakes were used, we took the following approach. We first compared proxy intakes with all other subregional mean intakes (stratified by age and sex). We then applied to AFR-D, AFR-E, AMR-D, EMRD and SEAR-D, the standard deviations of the subregion displaying the most similar subregional intakes and closest level of socioeconomic development (see Table 9.4).

### 2.6 Description of Studies, including METHODOLOGICAL QUALITIES

The 26 countries for which data were obtained are shown in Table 9.5, along with the proportion of the subregional population covered by these countries. This proportion is generally high or acceptable except for two subregions (EMR-B $=1.4 \%$; EUR-B $=3.8 \%$ ).

Details of the studies included in this project are described in Table 9.6. Twenty-two were from national surveys. For Argentina, a compila-

- No data.
a Percentage of subregional population covered by countries for which survey data were obtained.
tion of small representative surveys was provided-these cover the majority of the country. All but two studies were from the 1990s. Most studies used information from one 24-hour dietary recall or food diary. Other methods of data collection included multiple 24-hour recalls, 7day weighed food records, food-frequency questionnaires and food history. The majority of the surveys attempted to provide nationally representative samples; most used multistage random sampling techniques. Sample sizes ranged from about 1000 people (Argentina) to over 22000 (Belgium).

### 2.7 Characteristics of excluded studies

Due to the paucity of available information on fruit and vegetable intake at the individual level, few studies were excluded. Reasons for exclusion included the following.

- Another source of data was used for the country (e.g. more representative sample of the population or better method of data collection).
- The amounts consumed in grams per day could not be derived from the survey.
Table 9.6 Details of the dietary intake studies used

| Subregion | Country | Contact/ reference | Name of survey (if any) | Sample | Dietary data collection method | Data collection period | Sample <br> size | Sex | Age range (years) | Limitation |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |

- The data were not representative of the population of the country.
- Estimates included potato.

### 2.8 Estimates by subregion, age and sex

Obtaining subregional estimates from dietary survey data
The following approach was used to obtain subregional estimates of fruit and vegetable intake using available data from individual dietary surveys.

Obtaining estimates for subregions where data are available for two or more countries

In order to obtain subregional means and standard deviations (and obtain $95 \%$ confidence intervals for these estimates) when data were available for two or more countries within a subregion, means and standard deviations were pooled. It is assumed that each subregion is a stratified sample with the strata being countries. ${ }^{2}$ Because of the lack of information on the shape of the distributions of intakes, it was also assumed that intakes follow a normal distribution (this assumption is discussed in more detail in section 2.8).

It is important to note that if there is substantial heterogeneity among countries in a subregion, these methods tend to underestimate the true standard error of the pooled mean and pooled standard deviation. In addition, pooling is based on only a few countries within a subregion. We have thus assumed that the pooled subregional mean intakes and standard deviations are representative of the true estimates, and that differences between the pooled estimates and estimates for which data are not available would tend to cancel each other out. Finally, using data for only a few countries may underestimate the true variation of intakes within a subregion. However, for most subregions with available data, a large proportion of the total subregional population was covered by the surveys (see Table 9.5).

## Obtaining estimates for subregions where data are available for only one country

In four subregions (AMR-A, EMR-B, EUR-B and WPR-B), only one source of intake data was available. For AMR-A and WPR-B, the surveys were conducted in the United States of America and China, respectively. As these countries represent $84-88 \%$ of the total subregional population (Table 9.4), it was assumed that intake data from these countries were representative of subregional intakes. For EMR-B and EUR-B, however, the surveys were conducted in countries that represented only a very small proportion of the total subregional population $(1.4 \%$ and $3.8 \%$ respectively). For this reason, a different approach based on pooling survey and FAO food balance sheet data was used.

EMR-B: First, FAO-derived proxy mean intakes for the subregion were calculated using the method described previously (when no survey data were available for a subregion). As it has been reported that FAO food balance sheet data tend to overestimate intakes in developed countries, a correction factor was applied to the subregional three-year average FAO fruit and vegetable supply. The chosen correction factor corresponded to the difference between FAO food balance sheet data and subregional intake data for AMR-A. The subregional fruit and vegetable supply in AMR-A is the closest to that observed in EMR-B. It was assumed that the age-sex subregional distribution of intakes was similar to that observed in Kuwait. Second, the FAO-derived proxy mean intakes were pooled with intake data from Kuwait to obtain mean intakes for EMR-B.

EUR-B: First, FAO-derived proxy mean intakes for the subregion was calculated using the methods described previously (when no survey data were available for a subregion). As for EMR-B, a correction factor was applied to the subregional three-year average FAO fruit and vegetable supply. The chosen correction factor corresponded to the difference between FAO food balance sheet data and pooled survey data for the subregion EUR-C (assumed to be the most similar in terms of intakes, demographic and health characteristics). It was assumed that the distribution of intakes among age-sex groups was similar to that observed in Bulgaria. Second, the FAO-derived proxy mean intakes were pooled with intake data from Bulgaria to obtain pooled mean intakes for EUR-B.

## Final estimates

Estimates of fruit and vegetable intakes stratified by subregion, age and sex are given in Tables 9.8 to 9.11 . Results are presented as means with $95 \%$ CI for the mean, and as standard deviations with $95 \%$ CI for the standard deviation.

Estimates of fruit and vegetable intakes were highest in EUR-A followed by WPR-A (Table 9.7). Surprisingly, reported intakes in AMR-A-the other highly economically developed subregion-are on average only $74-82 \%$ of those observed in EUR-A and WPR-A. The lowest intakes were found in AMR-B, EUR-C, SEAR-B, SEAR-D and AFR-E. As expected, intakes varied by age group, with children and the elderly generally having lower intakes than middle-aged adults. However, in a few subregions elderly individuals appeared to have higher intakes than younger adults do in our calculations. This was the case particularly for AFR-E, AFR-D and EMR-D, three groupings where FAO-derived proxy mean intakes were calculated using the distribution of total intakes from another grouping with available data. Because the true age-sex distribution of AFR-E, AFR-D and EMR-D is slightly different from that of the chosen proxy grouping, the calculation of mean intake within each
Table 9.7 Mean intake of fruit and vegetables ${ }^{\text {a }}(95 \% \mathrm{Cl})$ by subregion, sex and age

[^36]age-sex strata and the balance among strata was affected. This is observed particularly in the smaller age strata (particularly the elderly in these subregions). As a result, the FAO-proxy mean intakes are less reliable in population strata with relatively smaller sample size and must be interpreted with caution.

Pooled standard deviation estimates were available from only seven subregions (AMR-A, AMR-B, EUR-A, EUR-B, EUR-C, WPR-A and WPR-B). For the other subregions, we applied data from the subregion displaying the most similar intakes by age and sex, and when appropriate, method of data collection. These extrapolations need to be taken with caution, as the standard deviations of one subregion may not represent well the standard deviations of another subregion despite similarity in overall mean intakes. The results shown in Table 9.8 indicate that standard deviations varied considerably by subregion, sex and age group, with an overall median standard deviation of $223 \mathrm{~g} / \mathrm{day}$. Estimates tended to be lower in women than in men on average (but with variations by age group), and they were generally lower in young children. In some subregions, standard deviations were also slightly smaller in the elderly.

It is assumed that the reported fruit and vegetable intakes were normally distributed, due to the general lack of available information on the skewness of the distributions (except for the United States). However, this is unlikely to be true as dietary intakes are typically skewed towards higher values (Willett 1998b). Assuming a normal distribution creates the problem that some individuals will be recorded as having negative consumption when estimating impact fractions. As this is impossible, the normal distribution is truncated at zero, with all those falling below this value allocated a value of zero. The results of a sensitivity analysis, described below, based on data from the United States suggest that the approach used is likely to be conservative.

## Sensitivity analysis: skewed distributions and calculation of the attributable fraction

Data from the United States were used to evaluate the possible effects of skewness in the distribution of fruit and vegetable intake on the calculation of the attributable fraction for AMR-A. The data indicated a positive skewness ranging from 1.5 to 3 . To approximate this type of skewed distribution, the Weibull probability distribution function (PDF) was utilized by varying the shape and scale parameters (decreasing the shape parameter of a Weibull increases positive skewness away from a normal distribution).

Figure 9.1 illustrates a normal distribution (dashed line) with a fruit and vegetable mean intake of $300 \mathrm{~g} /$ day and standard deviation of $300 \mathrm{~g} /$ day. A significant part of the population with a normal distribution is truncated at zero consumption (approximately $10 \%$ of the population in this example). The skewed distribution (solid line) is the

Figure 9.I Illustration of skewed and normal distribution based on data from the United States

approximation of what the actual intake data resemble (skewness is 2 in this illustration). Note that all data in the skewed distribution are nonzero (even though it appears that there are zero values).

The attributable fraction was then calculated, for the two different distributions, for IHD. The result for the truncated normal distribution with probability mass at zero was $35 \%$. Incorporating a skewness value of 2 resulted in an attributable fraction of $38 \%$, thus suggesting that our general approach is conservative.

### 2.9 Quantitative and qualitative sources of uncertainty in measuring dietary intake

One major source of uncertainty is that the collective term "fruit and vegetables" comprises a very heterogeneous group of foods in different countries or cultures. In a Western-type diet alone, fruit and vegetables include roots, leaves, stems, fruit and seeds from more than 40 botanical families (Lampe 1999). They can be consumed fresh or cooked in many different ways that will influence their biochemical content. Bio-
chemical composition also varies among different types of the same fruit. For example, the vitamin C content of different types of apple varies tenfold. Composition is also subject to differences in growing conditions, such as soil composition, and storage conditions, a factor of increasing importance as commodities are transported globally to ensure yearround supply in developed countries. It was decided to keep fruit and vegetables as a single entity for two main reasons. First, there remains uncertainty as to which components of fruit and vegetables would confer a protective effect. Even if the relevant effective constituents had been correctly identified, the nature of their relationship to disease risk would still need to be correctly specified. Second, obtaining intake data for specific foods (for this project) would have been even more difficult than for fruit and vegetables taken together.

Seasons also influence the amounts and variety of fruit and vegetables consumed. Indeed, evidence is emerging to link seasonality of consumption of fresh fruit and vegetables to the pattern of cardiovascular disease mortality in some countries (Powles et al. 1996). It is possible that the consequences for disease of an annual cycle of seasonal excesses and out-of-season shortages (as in the less economically developed countries of the former Soviet Union) may be quite different to the effects of consuming a similar annual level where counter-seasonal supplies ensure that there is no period of very low consumption (as in the affluent countries of north-west Europe). However, in the absence of information on national variations in fruit and vegetable intake and epidemiological evidence, it was assumed that it is the long-term annualized average of fruit and vegetable intake that best predicts disease risk. The need for caution is illustrated by the case of alcohol, where risk of cardiovascular disease appears to be more sensitive to the pattern of alcohol consumption over time as well as the total amount consumed (Kauhanen et al. 1999; Rehm et al. 2001). It is also assumed that the estimates obtained for this project represent annualized mean intakes, although some surveys collected data during only one or two seasons.

The choice of data sources may also have influenced the final estimates. It was decided that dietary surveys of representative population samples would be used as the primary source of information for this project. However, the quality and validity of individual level data depend on the ability (and willingness) of each individual to provide accurate information on his/her dietary intake (Johansson et al. 2001; Nelson and Bingham 1997). If the aim is to assess current diet, the procedure involved in measuring dietary intake may lead to changes in behaviour. If the aim is to measure past diet, then the reliability of the information provided will depend on memory and on the conceptual abilities of the respondents. The high intakes observed in AMR-A and WPR-A suggest that reported consumption could have been inflated by conscious (social desirability bias) or unconscious over-reporting of fruit and vegetable intake by the survey respondents (Hebert et al. 1995). The reported
intakes in some countries within these subregions are greater than expected. This is particularly the case for the United Kingdom and Germany where the estimated mean national fruit and vegetable consumption was higher than in Mediterranean countries such as Italy and Israel. It is possible that recent public health campaigns, such as those that took place in Finland (Puska 2000), coupled with changes in the retail trade, and thus in marketing and distribution of fruit and vegetables, have improved the dietary habits and increased the fruit and vegetable intake of these populations. This would be consistent with the striking improvements in cardiovascular mortality that they have experienced. Conversely, it is possible that the inclusion of fruit juices in the estimates of fruit and vegetable intakes made the estimates appear larger than expected. Other difficulties include the conversion of food frequencies into mean intakes in surveys that used food-frequency questionnaires, and the limitations and completeness of the various food analysis software programs used in different countries. Finally, it is possible that the survey respondents were not entirely representative of the reference populations, even though most data were from national surveys of dietary intakes.

In dietary surveys, variation as measured by standard deviations is influenced by the method used to collect data (see section 2.2). Most of the surveys used in this study were based on only one day (sometimes two days) of information. It is thus expected that standard deviations were overestimated. However, as described earlier, the method used to pool data from two or more surveys tends to underestimate the level of uncertainty surrounding the pooled standard deviation for the subregion based on a subsample of countries if there is substantial between-country variation.

Although we aimed to obtain dietary survey data for each country, these do not exist and thus food availability statistics were used for subregions where no or few data were available. The validity of food balance sheet statistics depends on the availability and validity of the basic national data on which they are based, including statistics of population, production, stock, import and export. These are known to vary among countries, and from one year to another, both in terms of coverage and accuracy (Kelly et al. 1991). The net availability of vegetables is affected by factors such as non-commercial production and uncertain losses to animal feed, spoilage and waste. However, the FAO performs external consistency checking using supplementary information such as household survey results as well as the application of relevant technical, nutritional and economic expertise in an attempt to eliminate these potential deficiencies. In this study we have used at least three years of FAO data in order to try to reduce the effect of potential yearly variations in coverage and accuracy. However, the current lack of information on adjustment factors to apply to FAO food balance sheet data in developing countries is a source of uncertainty. Finally, extrapolation among coun-
tries would be an important source of uncertainty, especially in the presence of inter-country heterogeneity.

## 3. Estimating risk factor-disease RELATIONSHIPS

### 3.1 OUtcomes to be assessed, evidence of causality, EXCLUDED OUTCOMES AND REASONS FOR EXCLUSION

## Selected outcomes

The outcomes to be assessed are those for which the best evidence of a risk factor-disease relationship is available for fruit and vegetable intake. These include:

- IHD;
- cerebrovascular disease;
- lung cancer;
- stomach cancer;
- colon and rectum cancers; and
- oesophageal cancer.

## EVIDENCE OF CAUSALITY AND EXCLUDED OUTCOMES

A general discussion of the evidence of causality for the association of fruit and vegetable intake with health outcomes follows. Specific details of evidence for each outcome are included in section 3.7.

The choice of outcomes was guided mainly by previous reviews of the literature, including those of Ness and Powles (1997) and Law and Morris (1998) that suggested a protective effect of fruit and vegetables for IHD and stroke. The review from the World Cancer Research Fund (WCRF) and the American Institute for Cancer Research (AICR) for a wide range of cancers (1997) concluded that the evidence for fruit and vegetables decreasing cancer risk was convincing for lung and digestive tract cancers. In the present study, cancers of the lung, oesophagus, stomach, colon and rectum were examined, leaving cancers of the mouth and pharynx for future work. Cancers for which the WCRF/AICR review reported only a probable association (larynx, pancreas and bladder cancers) or limited evidence of an association (cancers which may have a hormonal etiology including ovary, endometrium, thyroid and prostate) were not included in the CRA project at this stage.

Although there is also limited evidence for other health outcomes such as type II diabetes, chronic obstructive pulmonary disease and cataract (Sargeant et al. 2001; Smit et al. 1999; Tavani et al. 1996b), it was decided not to include these in the 2000 revision of the GBD
project because the number of published studies is currently too limited to draw conclusions on the size of the effect for these health problems. The evidence for these will be reconsidered in the future. Although other cardiovascular disease outcomes such as peripheral vascular disease share most risk factors with IHD and occlusive stroke, these outcomes were also excluded from the present report due to the current lack of information on a possible relationship with fruit and vegetable intake.

GENERAL DISCUSSION OF CAUSALITY FOR THE SELECTED EXPOSURE VARIABLE
Bradford Hill's criteria of causality, comprising biological plausibility, temporality, strength, consistency, dose-response, and experimental evidence, were considered in order to determine the likelihood of causality for the association of fruit and vegetable intake with the six selected health outcomes (Hill 1965).

## Biological plausibility

Evidence of causality for the relationship between fruit and vegetable consumption and health can be obtained from the identification of possible biological mechanisms. A number of mechanisms have been proposed (Lampe 1999). They generally involve specific nutrient and non-nutrient constituents of fruit and vegetables, including antioxidants and various other micronutrients in fruit and vegetables. Nutrients are substances in food that the body can use to obtain energy or synthesize tissues (Insel et al. 2003). Non-nutrients are substances, which may not have a known nutrient function but are still important for biological mechanisms such as regulatory functions. Few attempts have been made to simultaneously explore a combination of potential mechanisms.

The issue of biological plausibility is thus extremely complex and evidence remains fragmentary. There are several reasons for this. First, it is very difficult, in conventional epidemiological studies, to specify precisely exposure to different types of foods or food components over a prolonged period of time. As mentioned, obtaining valid information on individual dietary intake is very difficult. Even where this is possible, it is likely that the true content of the reported foods will have varied according to variations within particular types of food (such as different brands of oranges), differences in methods of food preparation, and seasonal variation in food composition. Second, while the growth in understanding of molecular mechanisms of disease is identifying many new factors, in particular non-nutrient components of food which may be important in preventing specific diseases, in many cases their existence, let alone their possible importance, was not known at the time when cohort studies now reporting results were established (e.g. glucosinolates in brassicas [van Poppel et al. 1999] and isoflavones in soya [Messina 1999], both of which appear to reduce the incidence of some types of cancer). The incompleteness of current food composition tables is a
major limitation to the assessment of the possible effect of varying intakes of these substances.

Consequently, much of the available research for the assessment of biological mechanisms is based on studies in animals and often involves the administration of pharmacological, rather than physiological, doses of various substances. This raises important questions about the applicability of such studies to humans. These reservations must therefore be borne in mind when interpreting the evidence discussed below.

## Cancer

The immediate cause of cancer is damage to DNA at some stage during the cell cycle (Weinberg 1996). At the risk of over-simplification, this can arise from one of three broad mechanisms: genetic (e.g. certain childhood cancers), cancers linked with endogenous hormonal patterns such as breast cancer and the action of exogenous carcinogens. This last group includes compounds produced from tobacco and a wide range of other chemical agents, such as asbestos or benzene, ionizing radiation, and, as is being increasingly recognized, many infectious agents (e.g. Helicobacter pylori as the leading cause of stomach cancer).

From this brief review it is apparent that fruit or vegetable consumption might only be expected to influence directly the risk of certain cancers and not others, and even where they do have a role, this is likely to be modulated by a wide variety of other factors, the importance of which will vary in different populations.

The substances present in fruit and vegetables that might have an impact on cancer incidence can be divided into agents that block the action of carcinogens (Table 9.9), agents that suppress carcinogenesis (Table 9.10) and antioxidants, which can prevent oxidative DNA damage. Some of these agents have both complementary and overlapping mechanisms of action.

Antioxidants include certain vitamins, such as vitamins C (Gershoff 1993) and E (Brigelius-Flohe and Traber 1999), carotenoids (Haegele et al. 2000) (including beta-carotene and other compounds such as

## Table 9.9 Selected carcinogen-blocking agents present in fruit and vegetables

| Component | Fruit/vegetable |
| :--- | :--- |
| Terpenes (Schut et al. 1997) | Citrus fruit |
| Organosulfides (Singh et al. 1996) | Allium vegetables: onion, leek, garlic, scallion, chives |
| Indoles (Oganesian et al. I999) | Cruciferous vegetables |
| Flavonoids (Malaveille et al. 1996) | Onion, apple, citrus fruit, tea, coffee, cola, alcoholic <br> beverages <br> Yellow and orange fruit and vegetables, green leafy <br> vegetables |
| Carotenoids (Sengupta and Das 1999) | (Sand |

Table 9.10 Selected carcinogenesis-suppressing agents present in fruit and vegetables

| Component | Fruit/vegetable |
| :--- | :--- |
| Protease inhibitors (Kennedy 1998) | Legumes, potato, spinach, broccoli, cucumber |
| Terpenes | Citrus fruit |
| Isothiocyanates | Cruciferous vegetables |
| Plant sterols (Awad et al. 2000) | Vegetables, beans, seed |
| Carotenoids | Yellow and orange fruit and vegetables, green <br> leafy vegetables |

flavonoids) and selenium. These act by scavenging free radicals that would otherwise damage DNA. In doing so, they would reduce the impact of certain exogenous carcinogens.

In general, any protective effect that fruit and vegetables might exert is more likely to be apparent with cancers where exogenous carcinogens play a major part. Examples include lung, stomach and colorectal cancer. Evidence from observational studies seems to support this. The WCRF/AICR review of the literature (World Cancer Research Fund and American Institute for Cancer Research 1997) concluded that the evidence for fruit and vegetables decreasing cancer risk was convincing for oral-pharyngeal, lung and digestive tract cancers; that there was a probable association for larynx, pancreas and bladder cancers; and that the evidence was limited for cancers which may have a hormonal etiology including ovary, endometrium, thyroid and prostate.

Most human research investigating cancer risk has examined either the effect of a specific compound or of overall fruit and vegetable consumption. Research into the former has yielded mixed results. While many studies have shown an association between high beta-carotene intake and reduced risk of cancer, especially lung and stomach cancer (van Poppel and Goldbohn 1995), a highly publicized study among smokers receiving vitamin supplements, including beta-carotene, found that supplementation was associated with an increased rate of lung cancer. Similarly, while a recent meta-analysis found a small reduction in the risk of breast cancer with high levels of fruit and vegetable consumption (Gandini et al. 2000), some large studies looking at vitamin supplements have found no effect (Watkins et al. 2000; Wu et al. 2000). However, the effect of dietary composition on cancers with hormonal etiologies is likely to be greatest in the pre-pubertal years, as diet during this phase of growth may influence breast cancer risk substantially via its effect on body size, age of menarche, etc.

Given the many substances potentially involved in protecting against cancer, and the diverse mechanisms involved, these mixed results have highlighted the need to look at non-nutrient components of fruit and
vegetables. More research is now investigating, among others, the potential impact of other food components such as bioactive compounds (allium compounds, dithiolthiones, isothiocyanates, terpenoids, isoflavones, protease inhibitors, phytic acid, polyphenols, glucosinolates and indoles, flavonoids, plant sterols, saponins and coumarins) (Verhagen et al. 1995).

In summary, there are many possible mechanisms by which fruit and vegetable consumption might reduce the risk of cancer. However, our knowledge is handicapped by the uncertainty with regard to the many pathways involved in carcinogenesis and the relative quantitative importance of each of the mechanisms that, on current knowledge, could plausibly be involved. However, it appears that the impact of diet is likely to be greatest for cancers caused by specific external carcinogens, such as gastrointestinal and lung cancer, and less important for cancers where endocrine factors play a greater role, such as breast and prostate cancer. Furthermore, the overall importance of diet in a given population will clearly reflect the prevalent pattern of exposure to specific carcinogens as well as differences in genetic susceptibility. Thus, an agent that acts to protect against the effects of a particular carcinogen will have less of an effect in a population where exposure to that carcinogen is rare than where it is common.

## Cardiovascular disease

As with cancer, the multiple mechanisms by which fruit and vegetable consumption might act on the risk of cardiovascular disease are difficult to disentangle because of the inadequate understanding of the determinants of disease. Most research has concentrated on atherosclerosis. Other potential mechanisms by which fruit and vegetables could impact indirectly on cardiovascular risk include a link with blood pressure modulation, through the high potassium content of some fruit and vegetables (Ascherio et al. 1998; Lampe 1999), or with chronic respiratory disease (associated with fruit and vegetables-and their constituents) and vascular disease risk. For the sake of simplicity, this short review will focus on IHD, although some issues are also relevant to cerebrovascular disease.

Atheroma is thought to arise as a result of monocytes adhering to endothelial cells and migrating into the arterial intima where they become macrophages, taking up low density lipoprotein, subsequently becoming foam cells. The role of fruit and vegetable constituents in monocyte adhesion is increasingly well understood. Methionine, derived from dietary protein, is converted within cells to homocysteine. Deficiency of folic acid, vitamins $B_{12}$ and $B_{6}$ will give rise to an elevated level of homocysteine (Chambers et al. 2001). High levels of homocysteine contribute to the generation of free radicals, and thus oxidative damage, in enthothelial cells, leading to the aggregation of monocytes and platelets, as well as vasoconstriction (Kojda and Harrison 1999). These,
in turn, promote atherogenesis. There is now compelling epidemiological evidence to link homocysteine and vascular disease. A recent metaanalysis showed that the risk of cardiovascular disease increased with plasma homocysteine, with odds ratios of 1.6 (1.4-2.3) and 1.8 (1.4-2.3) per $5 \mathrm{~mol} / \mathrm{l}$ increment in plasma homocysteine in men and women, respectively. The relationship was similar for cerebrovascular disease (Boushey et al. 1995).

It has been suggested that other components of fruit and vegetables, in particular antioxidants, act at other stages in the process of atherogenesis. Such compounds could act by reducing the oxidation of lowdensity lipoprotein, thus reducing the formation of fatty streaks and plaques. These antioxidant compounds include vitamin C, which is involved in free radical scavenging, haemostasis and in the stabilization of lipid membranes (Witztum 1994), and beta-carotene, which neutralizes singlet oxygen molecules and prevents chain formation, so reducing oxidative processes that are important in atherogenesis (Gaziano and Hennekens 1993). Flavonoids also inhibit the oxidation of low density lipoprotein and reduce thrombotic tendencies.

Observational studies support a strong inverse association between plasma levels of vitamins C and E and cardiovascular mortality (Daviglus et al. 1997; Gale et al. 1995; Gey 1995; Manson et al. 1992; Yokoyama 2000). However, only a few studies have reported a significant inverse relationship between vitamin C specifically and cardiovascular risk (Khaw et al. 2001). Several reviews have found no significant benefit from vitamin C after controlling for other antioxidant intake or multivitamin use (Price and Fowkes 1997; Rexrode and Manson 1996). Even those that reported a benefit from vitamin C differ with regard to the point at which an effect appears and the potential magnitude of the relationship. Some studies indicated an increased risk of cardiovascular disease only at very low levels of plasma vitamin C, with no effect within the range seen in most populations. Other studies have reported a significantly reduced risk only in persons with the highest levels or with supplemental intake. However, a recent study showed a significant decrease in cardiovascular and IHD risk throughout the normal plasma range (Khaw et al. 2001). Similarly, although results from many observational studies suggest that higher serum levels of beta-carotene reduce the risk of cardiovascular disease, systematic reviews have concluded that evidence for a protective effect is inconsistent (Jha et al. 1995; Rexrode and Manson 1996).

As with studies of cancer, there is no clear evidence from intervention trials that antioxidant supplements reduce the risk of cardiovascular disease (Collins et al. 2002; Gaziano 1996; Greenberg and Sporn 1996; Hennekens et al. 1996; Lonn and Yusuf 1999). In the case of betacarotene there is even some evidence of harm. Several trials were not, however, designed specifically to assess cardiovascular disease risk and did not provide data on non-fatal cardiovascular end-points. Some
authors have suggested that the apparent protective association found in observational studies would be due to residual confounding by differences in socioeconomic status, health behaviour and dietary intake (Ness 2001).

Many of the same challenges that arise with studies of the etiology of cancer also apply to IHD. First, if fruit and vegetables do affect atherogenesis, then their effect will be modulated by other important factors that are involved in atherogenesis and are also influenced by diet. This is particularly the case for high density and low density lipoproteins. These are determined primarily by the amount and nature of fat in the diet, but are also influenced by alcohol consumption, with the precise effect determined by the pattern of drinking. In addition, it is important to remember that atherogenesis is only one factor involved in myocardial infarction. Another is thrombosis, which may also be influenced by certain dietary factors (Chen et al. 2000).

Second, and less well recognized, cardiovascular disease embraces a wide variety of different processes. In particular, it is becoming clear that some myocardial infarctions in young people have a different etiology. Even within the more conventional understanding of IHD, there are clearly differences between those whose atheroma predominantly takes the form of plaques that are lipid-rich, and thus likely to lead to plaque rupture and so to acute infarction, and those that are predominantly fibrous, with smooth muscle proliferation, which are more likely to cause progressive angina (Kharbanda and Vallance 2001).

## EXPERIMENTAL EVIDENCE

## Trials of dietary changes

There is little experimental evidence for the health effects of increasing fruit and vegetables in the diet. Obviously foods that are part of a usual diet are not easily amenable to traditional trials in the general population. Although no trial examined just giving advice to eat more fruit and vegetables on the disease outcomes considered in this report, a few trials of dietary advice in secondary prevention of IHD have included advice to eat more fruit and vegetables (Burr et al. 1989; de Lorgeril et al. 1994, 1999; Rinzler 1968; Singh et al. 1992).

The Diet and Reinfarction Trial (DART) was set up to examine the effect of diet on the secondary prevention of myocardial infarction. Participants were randomized to receive advice or no advice on each of three dietary factors: a reduction of fat intake and an increase in the ratio of polyunsaturated to saturated fat; an increase in fatty fish intake; or an increase in cereal fibre intake. Although the fat advice arm of the trial was associated with an increased fruit and vegetable consumption of about $50 \mathrm{~g} /$ day, no effect on total mortality at two years was observed ( $\mathrm{RR}=1.00,95 \% \mathrm{CI} 0.77-1.30$ ) and there was no effect on IHD events (IHD deaths plus non-fatal myocardial infarction: $\mathrm{RR}=0.91,95 \% \mathrm{CI}$
0.71-1.16) (Burr et al. 1989). It is possible, however, that the follow-up period was too short to allow for an effect to be detected or that the increase in fruit and vegetable consumption was too small to produce a detectable effect.

The Lyon Diet Heart Study investigated whether a Mediterraneantype diet compared with a prudent Western-type diet could reduce the rate of recurrence after a first myocardial infarction. Intermediate analysis showed a marked protective effect after 27 months of follow-up ( $73 \%$ reduction in rate of recurrence and death from cardiovascular causes; $R R=0.27,95 \%$ CI $0.11-0.65)$, which was maintained for four years after infarction ( $\mathrm{RR}=0.28,95 \% \mathrm{CI} 0.15-0.53$ ) (de Lorgeril et al. 1999). The increase in fruit and vegetable consumption in the intervention group was thought to be an important factor in risk reduction. However, as in the DART study, diet changed in a number of ways during the trial and it is thus impossible to estimate the specific influence of increased fruit and vegetable intake in either trial.

Evidence that increasing fruit and vegetable intake alone may be important as a dietary intervention in reducing cardiovascular disease risk comes from the Indian Experiment of Infarct Survival (IEIS) (Singh et al. 1992). This randomized controlled trial showed that the consumption of a low-fat diet enriched with fruit and vegetables compared with a standard low-fat diet was associated with about $40 \%$ ( $R \mathrm{R}=0.60$, $95 \%$ CI $0.31-0.75)$ reduction in cardiac events and $45 \%(R R=0.55$, $95 \%$ CI $0.34-0.75$ ) reduction in mortality in 406 men with acute myocardial infarction after one year. These findings suggest a very rapid effect of dietary change on incidence and mortality from IHD that would appear to be difficult to explain.

Some recent trials also assessed the impact of increased fruit and vegetable intake on blood pressure. In the Dietary Approaches to Stop Hypertension (DASH) trial, hypertensive participants were fed a control diet for three weeks, and then were randomized to receive for eight weeks either the control diet, a diet rich in fruit and vegetables, or a combination diet rich in fruit and vegetables, and reduced in saturated fat, fat and cholesterol (Conlin et al. 2000; Obarzanek et al. 2001). Both the combination diet and the fruit-and-vegetables diet significantly reduced systolic and diastolic blood pressure. After eight weeks, $70 \%$ of the participants on the combination diet had a normal blood pressure, $45 \%$ of those on the fruit and vegetable diet, and $23 \%$ of those on the control diet. Unsurprisingly the fruit and vegetable diet produced few changes in blood lipids and had less effect on blood pressure reduction than the combination diet. Both diets showed that they could potentially help reduce IHD risk. However, studies with a longer follow-up would be required to assess the true long-term effect of such changes.

Another trial assessed the specific effect of increased guava intake in hypertensive individuals (Singh et al. 1993b). After four weeks, the diet rich in guava ( $0.5-1 \mathrm{~kg} /$ day) was associated with $7.5 / 8.5 \mathrm{mmHg}$ net
decrease in mean systolic and diastolic pressures compared with the control group, a significant decrease in serum total cholesterol ( $7.9 \%$ ), triglycerides $(7.0 \%)$, and an insignificant increase in high density lipoprotein (HDL) cholesterol ( $4.6 \%$ ) with a mild increase in the ratio of total to HDL cholesterol. The authors suggested that an increased consumption of guava fruit could cause a substantial reduction in blood pressure and blood lipids without a decrease in HDL cholesterol. These changes were attributed to its high potassium and soluble fibre content, respectively. Further research is needed to confirm this hypothesis with more easily applicable dietary changes.

## Nutrient supplement trials

Due to the lack of trials of increased fruit and vegetable intake on health outcomes, most data from intervention studies relate to studies of nutrient supplements. Unfortunately, these trials have generally been of small sample size and relatively short duration (Lampe 1999).

In contrast to the results of observational studies, findings from trials of antioxidant and vitamin supplementation have mostly shown no effect on mortality, cardiovascular events or cancer (Blot et al. 1995; Correa et al. 2000; Egger et al. 1998; Hooper et al. 2001; Ness et al. 1999a). There has even been some concern following two trials that showed an increased risk of lung cancer mortality with beta-carotene and vitamin A supplements in the Alpha-Tocopherol, Beta-Carotene and Cancer Prevention (ATBC) study (Anonymous 1994) and the Beta-Carotene and Retinol Efficacy Trial (CARET) (Omenn et al. 1996a, 1996b). However, the recent Heart Protection study (HPS) showed neither benefit nor harm of supplementation with antioxidant vitamins after 5.5 years follow-up. This double-blind randomized trial with a $2 \times 2$ factorial design investigated, in over 20500 persons, the use of simvastatin and antioxidant vitamins (vitamin E, vitamin C and beta-carotene) (Collins et al. 2002).

One exception is the Linxian trial in China (Blot et al. 1995). This trial showed reduced total mortality in the group supplemented with beta-carotene, alpha-tocopherol and selenium compared with the placebo group after six years. However, it is not possible to identify which antioxidant contributed most to the trend towards lower mortality. Some trials have also suggested that vitamin E supplementation may prevent ischaemic stroke in high-risk hypertensive patients (Leppala et al. 2000).

These generally null findings, while initially surprising, are not entirely unexpected given the large number of potentially active compounds in food and the scope for interactions, both with other exogenous substances and genetic status. Given that there are very few randomizedcontrolled trials that investigated the association of fruit and vegetable consumption with disease outcomes, current evidence of causality is mainly based on observational studies.

## Strength of association

The review of the evidence from cohort and case-control studies for this project generally supports the hypothesis that a high dietary intake of fruit and vegetables is protective for cardiovascular disease and the selected cancer (see results of the systematic review in sections 3.6 and 3.7). We consider this to be a relatively strong association for the outcomes presented in this chapter, especially taking into account the potential dilution inherent in dietary exposure measurement.

## Consistency

The review of the literature performed for this project shows that most studies of fruit and vegetable consumption demonstrated a generally consistent inverse relationship with the six disease outcomes in different populations (see section 3.7). There were virtually no studies of whole foods (thus excluding nutritional supplements) that showed harmful associations, and many of the studies that reported a null association reported in fact insignificant inverse trends. The major caveat to this statement is that there have been few studies in populations from developing countries.

## Temporality

It is virtually axiomatic that fruit and vegetable consumption will precede disease outcomes. The many cohort studies reviewed here that have long follow-up periods provide more convincing evidence for temporality, as they are less likely to have been affected by information bias, a major source of bias in case-control studies (e.g. recall bias).

## Dose response

Evidence from the literature shows that in general, people in the highest categories of fruit and vegetable consumption have lower risk of cardiovascular disease and cancers compared with those in the lowest consumption categories. Many of the studies also reported a significant trend between the quartiles, quintiles or tertiles of consumption and disease risk, and a few studies have reported significant effects with fruit and vegetable treated as a continuous variable (see sections 3.6 and 3.7).

## Summary

There are still many uncertainties with regard to the mechanisms that lead to common diseases, to the roles that fruit and vegetables could play in these mechanisms, and to the specific substances in fruit and vegetables that are particularly important. Different studies have suggested that flavonoids, carotenoids, vitamin C, folic acid, and fibre could play a protective role. However, it must be kept in mind that studies based on single food constituents may underestimate the effects of exposures such as foods, which are chemically complex. Also, single constituents can be a
marker for other active constituents (as the conflicting results between observational studies and trials have suggested for beta-carotene) (Egger et al. 1998), or even for a combination of constituents that are responsible for the protective effect. Until these mechanisms are better understood, it will not be possible to determine, with any certainty, what precise role specific components of fruit and vegetables might play. What can be said with some confidence is that there are a wide variety of substances within fruit and vegetables that appear to play a role in the etiology of cardiovascular disease and some cancers.

### 3.2 OvERVIEW OF METHODS FOR ESTIMATING RISK FACTOR-DISEASE RELATIONSHIPS

The associations reported in this study were based on a systematic review of the literature. This provided evidence for the direction and size of the relationship between fruit and vegetable consumption and the selected disease outcomes. This was complemented with meta-analyses for four disease outcomes as described in section 3.7.

### 3.3 Criteria for identifying relevant studies

All studies that satisfied the following criteria were included in the systematic review of the literature:

- studies that measured dietary intake of fruit and/or vegetables;
- studies of vegetarians that measured food intake; and
- a special focus was placed on studies that explored associations of fruit and vegetable intake with diseases. However, for completeness we have also included studies that used as their exposure variable proxy measures of intake derived from the measurement of intermediate variables (such as dietary fibre) or biological markers (such as carotenoids, folate, flavonoids, vitamins A and C not due to supplements) where there was a high correlation with the specific food type.

### 3.4 Search strategy and inclusion criteria for the LITERATURE REVIEW

Studies were identified through a systematic review of the literature. The following databases were searched: Medline, Embase, Cochrane On-line, CABHealth and CABAbstracts using the keywords "fruit" or "vegetables" and "coronary heart disease", "cerebrovascular disorder", "lung", "colorectal", "stomach" and "esophageal", "neoplasms" and "cancer". All search terms were linked to MESH headings and exploded. Searches were limited to human studies in English from 1980 onwards (for the CABabstracts, however, the search was from 1987 to 2000).

The outcomes included in this systematic review were the following.

- Cardiovascular diseases: symptomatic heart disease, cerebrovascular disease and total circulatory disease. Studies of peripheral vascular
disease, all-cause mortality and cardiovascular risk factors were excluded.
- Cancer: all histological types of the site-specific cancers were included but not reviewed separately.

Relevant studies for inclusion were determined through the review of titles and abstracts. If there was any doubt regarding study relevance, the full text of the study was retrieved.

This search was complemented with a hand search of citations from books, reviews and citations of references already located. Authors who had published key studies and reviews in the field were also approached to help us identify any other studies, published or unpublished.

### 3.5 Characteristics of excluded studies

Studies were excluded if any one of the following criteria was satisfied.

- The measurement of risk was based solely on blood biochemical markers with no measure or estimate of dietary or nutrient intake.
- The study focus was on investigating the effect of non-dietary supplements.
- The outcome measure was prognosis, pre-cancerous lesions or predisease markers rather than incident cases or mortality.
- The statistical analyses of the study were not adjusted for major confounding factors such as age, sex and smoking.

### 3.6 Description of studies

## Characteristics of included studies

A short summary of the number of studies included in the systematic review is given in Table 9.11. All studies included in the review of the literature are described in section 3.7, where the assessment of causality for each outcome is discussed. Details of the studies included for each specific outcome are provided in Tables 9.21 to 9.28.

## Limitations of the studies included in the review of the literature

The studies included in the review of the literature differed in many ways, including:

- the type of study design;
- the sex, age range and ethnicity of the study population;
- the method and validity of measurement of the dietary exposure;
- the method of reporting the dietary exposure (qualitative vs quantitative);

Table 9.II Summary of the studies included in the review of the literature

| Outcome | Case-control studies |  | Cohort studies |  |
| :---: | :---: | :---: | :---: | :---: |
|  |  |  | Number | Countries/areas covered |
|  | Number | Countries/areas covered |  |  |
| Ischaemic heart disease | Not assessed | $\ldots$ | 27 | Japan, USA and Europe (north) |
| Ischaemic stroke | Not assessed | $\ldots$ | 21 | Japan, USA and Europe (north) |
| Lung cancer | 32 | Canada, China, Brazil, India, Japan, USA and Europe (east, north and south) | 21 | Japan, USA and Europe (north and south) |
| Colorectal cancer | 33 | Argentina, Australia, Canada, China, Japan, Russian Federation, Singapore, Uruguay, USA and Europe (north and south) | 15 | Japan, USA and Europe (north) |
| Gastric cancer | 32 | Canada, China, Japan, Mexico, Republic of Korea, Turkey, USA, Venezuela and Europe (north and south) | 14 | Japan, USA and Europe (north) |
| Oesophageal cancer | 28 | China, India, Japan, USA, Europe (north and south) and South America | 4 | China, Japan and Europe (north) |

- the period of follow up;
- the outcome measured;
- the range of intake of fruit and vegetables of the study population;
- the underlying disease risk of the population (i.e. high vs low); and
- the potential confounders that were adjusted for.

These differences often made results incomparable among studies. The fact that the majority of studies came from Japan, the United States and Europe is another limitation as it restricts the generalizability of the data for use in the CRA project.

## Steps to assess and reduce random error

Most measures of association presented in this report include confidence intervals as a measure of uncertainty. The number of outcome events on which the measures of association are based is also given in the tables.

## Methods used to obtain the estimates of relative risks

To date, there have been few reported meta-analyses of the association of fruit and vegetable intake with disease. In 1998, Law and Morris
reported the results of a meta-analysis of published cohort studies of the relationship of different markers of fruit and vegetable consumption, including dietary intake of fruit and vegetables, on the risk of IHD, adjusted for other factors (Law and Morris 1998). However, the results of this study were criticized by some researchers who suggested that potential residual confounding and heterogeneity among studies could have influenced the results (Ness et al. 1999b).

More recently, a group of researchers reported the results of metaanalysis of previously published case-control and cohort studies. This estimated the association of total fruit or total vegetable consumption with oesophageal, gastric and colorectal cancer (Norat et al. 2001). The methodology used had limitations: studies were included if there was information necessary for the statistical analysis, but there was no assessment of study quality or potential confounding. The studies had measured fruit and vegetable intake in a range of ways, both quantitative and qualitative. If intake data were only available as a qualitative amount (i.e. a subjective categorization into high vs low consumption), the amount of fruit and vegetables consumed in grams was estimated from average consumption in other studies or data sources, including FAO food balance sheets. The methodology used in that meta-analysis highlights the difficulties in obtaining an accurate summary measure of association for studies of fruit and vegetable intake.

## Selection of studies

Considering the large variations among studies with regard to study design, study quality and measurement of both exposure and outcome, it would be methodologically inappropriate, and potentially misleading, to pool results statistically from all the separate studies identified in the systematic review to obtain summary measures of association. This view has also been taken by other researchers who believe, given the quality and heterogeneity of the evidence for fruit and vegetable consumption and the substantial potential error in the measurement of diet, that metaanalyses are not appropriate for pooling observational studies and will only serve to attenuate the error without exploring the heterogeneity which may be important in diet-disease relationships (Ness and Powles 1997, 1999; Wiseman 2002).

In this study, it was decided first to apply strict criteria to select only the best quality and most representative studies for the association of fruit and vegetable intake with each disease outcome. Only the studies meeting these criteria were then eligible for inclusion in a meta-analysis.

The following selection criteria were applied to the studies identified in the systematic review.

- Results from cohort studies were considered as more reliable evidence of association than results from case-control studies. So case-control studies were excluded from the analysis.
- The sample size of the study was large and ideally representative of the population.
- The study population ideally included a broad age range.
- The methodology for data collection and analysis was robust and clearly documented.
- The study collected data on total fruit and vegetable consumption and not just by selected groups of fruit or vegetables (e.g. citrus fruit, green leafy vegetables, raw and cooked vegetables).
- Dietary measurement had been validated and was detailed enough to quantify fruit and vegetable consumption accurately (e.g. a food frequency questionnaire having more than 40 items of fruit and vegetables is likely to be better than one that includes only four items).
- Dietary assessment performed using one 24 -hour recall or food record/diary was excluded.
- The statistical analyses were adjusted for important potential confounders.
- The information was available to enable the estimation of relative risk and confidence intervals with intake treated as a continuous variable for meta-analysis.

The number of studies that met the selection criteria for each outcome is given in Table 9.12.

## Data preparation

The final relative risk estimates are expressed as the unit of change in relative risk associated with an 80 g increase in fruit and vegetable con-sumption-this amount representing a recognized standard serving size (World Cancer Research Fund and American Institute for Cancer

Table 9.I2 Number of cohort studies meeting the selection criteria for inclusion in a meta-analysis

| Outcome | Number of cohort studies reviewed | Number of studies meeting <br> selection criteria |
| :--- | :---: | :---: |
| Ischaemic heart disease | 27 | 4 |
| Ischaemic stroke | 21 | 2 |
| Lung cancer | 21 | 4 |
| Colorectal cancer | 15 | 3 |
| Gastric cancer | 14 | 1 |
| Oesophageal cancer | 4 | 0 |

Research 1997). When data from the selected studies were not presented in this format, the following methods were used.

- Where food consumption was expressed in frequencies (e.g. number of servings per day), these were multiplied by 80 g to give daily intake in grams per day.
- Where the relative risk estimates were reported for various increments in intake (e.g. for 100 g or 1 g increase in intake), the relative risk estimates were first transformed onto a log scale and then divided by the comparison difference to give the log relative risk/gram per day; these were then multiplied by 80 to give final estimates expressed as per 80 g increase.
- Where an overall relative risk was not reported for consumption over the entire population range, two methods were used to obtain the relative risk estimates. In method 1 , we estimated the additional gram per day for which the relative risks given applied (details are given later in the text for each selected study). In method 2, the method of Greenland and Longnecker (1992), implemented in Stata 7, was used to estimate the weighted regression slope over the published relative risks, allowing for correlations due to a common reference category. This method uses all the published relative risks, and should coincide approximately with method 1 if the log relative risks are linear on consumption. When there is non-linearity, the two methods will differ, with the second giving the best "average" slope over the whole consumption range, while the first gives a better estimate of slope over a smaller consumption range. Where there is a tendency for risk reduction to be less marked at higher consumption levels, method 2 will give a more conservative estimate of the relative risk per consumption increase.
- Standard errors were calculated on the log scale by taking the upper (log) confidence limit minus the (log) estimated relative risk and dividing this by 1.96 ; standard errors were also scaled in the same way as estimates to apply to an $80 \mathrm{~g} /$ day comparison difference.

## Meta-analysis

Where more than one study was identified using our strict selection criteria, a meta-analysis was conducted to combine estimates and obtain a summary estimate of the relationship between fruit and vegetable intake and the selected outcome (DerSimonian and Laird 1986). Meta-analysis was performed using study log relative risks and the corresponding standard errors and implemented in Stata 7 ("meta" macro). Heterogeneity between studies was tested using the chi-squared statistic. The randomeffects result was pre-specified conditional on evidence of heterogeneity. When only two studies were available, fixed-effect meta-analysis was
used. Forest plots, showing the results for individual studies, were prepared.

## Extrapolations of the relative risk estimates

Subregion. For each outcome, the same relative risk estimates were applied to all subregions, assuming no interaction between the level of intake and subregion on the associations. However, it is not possible to verify whether this assumption is true, as the study populations covered by the literature reviews were from limited geographical areas, which did not allow subregional comparisons.

Sex. Another issue is the fact that several studies pooled data for men and women. Due to the limitations of the evidence for men and women separately, it was decided to apply the same relative risk estimates to both sexes for each outcome.

Age group. Many of the studies covered only limited age ranges, with most being from middle-aged or elderly populations. None of the studies included in the review were of children aged $<16$ years. Results from the Boyd Orr cohort suggest that childhood fruit consumption may have a long-term protective effect on cancer risk in adults (Maynard et al. 2003). This study measured intake of fruit and vegetables, energy, vitamins C and E, carotene, and retinol during a study of family diet and health in 16 rural and urban areas of England and Scotland from 1937 to 1939 , and followed participants for up to 60 years. However, apart from this cohort, there are currently very few studies which have looked at the impact of childhood intake. A previous review for the New Zealand burden of disease and injury study proposed that the agespecific relative risks for fruit-and-vegetable disease associations describe an inverted u-curve, which assumes that the relative risk is one at the extremes of age ( $<25$ years and $>75$ years) (Tobias 2001). The authors of the review argued that they do not expect individuals aged $<25$ years to be at risk given that the outcomes are chronic diseases, that such outcomes are rare in children, and that children have probably had insufficient duration of exposure. They also applied reduced relative risks to older age groups (i.e. applying a relative risk of 1 to everyone aged $>75$ years), as there are high competing mortality risks at these ages. In this project, it was decided to apply the same relative risks to all age groups between the ages of 15 and 69 years. It is reasonable to postulate that there may be age attenuation in the relative risks at both extremes of age. However, due to the current lack of information on how this would influence the relative risks at varying intakes of fruit and vegetables, approximate age attenuations were applied as follows: at older age groups, the excess risks were reduced by a quarter for ages $70-79$ years, and by half for the age group of $\geq 80$ years. For those
aged $<15$ years, a relative risk of 1 was applied as in the New Zealand study.

Steps to assess and reduce bias and to assess causality
There are a number of generic methodological issues that could lead to the introduction of bias in nutritional epidemiological studies. The following paragraphs briefly describe confounding and the major sources of measurement, recall and selection biases common to these studies, with a particular focus on issues that are specific to studying fruit and vegetables as a risk factor.

## Confounding

Well-known potential confounders of the association of fruit and vegetable intake with cardiovascular disease and cancer include, among others, sex, age and smoking. It is possible that a high intake of fruit and vegetables may be associated with other healthy behaviour, for example lower consumption of saturated fat or non-smoking that also has a protective effect on the selected outcomes.

High intakes of fruit and vegetables may also displace other foods from the diet, causing reduced intake of potentially harmful substances such as saturated fat and salt. Results from the DASH trial suggested that changes in dietary fats do not necessarily accompany an increase in fruit and vegetable intake. In this trial, hypertensive participants were fed a control diet for three weeks and then randomized to receive for eight weeks either the control diet, a diet rich in fruit and vegetables, or a combination diet rich in fruit and vegetables and reduced in saturated fat, fat and cholesterol (Conlin et al. 2000; Obarzanek et al. 2001). Both the combination diet and the fruit-and-vegetables diet significantly reduced systolic and diastolic blood pressure. After eight weeks, 70\% of the participants on the combination diet had a normal blood pressure, $45 \%$ of those on the fruit-and-vegetables diet did and $23 \%$ of those on the control diet did as well. The fruit- and-vegetables diet produced few changes in blood lipids but was still likely to reduce IHD risk independently. Sodium/salt is perhaps an underacknowledged potential confounder for IHD and stroke. Persons who consume more salads may consume less salt. The lack of evidence of confounding by salt mainly relates to the difficulty of measuring sodium exposure in individualsnot to its intrinsic importance.

In order to account for the potential effect of confounding on the relative risk estimates, all studies that were identified in the review of the literature must have performed some statistical adjustment for potential confounders. Most studies adjusted for the basic confounding factors, age and sex. The majority of recent studies also statistically controlled for a range of other variables including smoking, alcohol consumption, total energy intake, other foods and food constituents (including saturated fat intake for heart disease), body mass index (BMI) and vitamin
supplementation. Some studies also adjusted for socioeconomic status, educational level, ethnicity, occupation and place of residence. The potential confounders that are specific to each of the selected disease outcomes are discussed in more detail in section 3.7. It is important to note that statistical adjustment for potential confounding implies accepting that the instruments used to measure these potential confounders did this reasonably well. This may not be the case for all potential confounders (e.g. energy intake or physical activity level). In addition, even where there is a high degree of statistical control for potential confounding, the possibility remains that part of the association estimated is due to uncontrolled (residual) confounding (Ness et al. 1999b).

## Selection bias

The issues related to selection bias in the studies reviewed for this project are similar to those of studies investigating other risk factor-disease relationships. For example, it is generally accepted that the selection of controls in case-control studies is likely to influence the study results. Study participation is usually high for cases but lower for controls; those who participate are more likely to be more health conscious, and thus perhaps consume more fruit and vegetables (Michels et al. 2000).

There were a variety of approaches used to reduce selection bias in the studies reviewed. For example, many studies tried to match controls to their cases as closely as possible in terms of age and sex. The generalizability of the results is also influenced by the source of controls, with population-based controls being better than hospital-based controls.

## Information bias

Exposure. In the studies included in the review of the literature, data on dietary intake were collected using some form of diet history, food frequency questionnaire, 24-hour dietary recall(s) or diary/food record. Measurement of exposure will thus be influenced by the different limitations, sources of error and bias affecting each method. Some of these were described in sections 2.2 and 2.9.

Measurement error is an issue in all studies of dietary exposure (Smith-Warner et al. 1997). In general, this imprecision leads to a substantial attenuation of diet-disease associations, and an underestimation of potential thresholds in these associations (Marshall and Chen 1999). This is the case, for example when a single 24 -hour recall is used as the method of dietary assessment (as in a few studies included in our review of the literature). A single 24 -hour recall has a high degree of intra- to inter-individual variability and cannot accurately represent an individual's usual intake (Bingham et al. 1988). This may lead to important misclassification (likely to be non-differential) error.

Food frequency questionnaires are more commonly used in nutritional epidemiology. However, most food frequency questionnaires can be
criticized because of their limitations in collecting detailed accurate information on the intake of fruit and vegetables (Bingham et al. 1994; Michels et al. 2000). Little is known of the measurement error structure for reported fruit and vegetable intake in food frequency questionnaires. Many early estimates based on comparisons with different questionnaires or diet records had problems, underestimating both the degree of error and the correlation between the sources of errors (Day and Ferrari 2002; Thompson et al. 1997). Various problems are apparent. The level of measurement error is large compared with the true variation of intake in many study populations; there may be systematic bias in reporting at the individual level; and lack of independence of the measurement errors between the food frequency questionnaire and reference instrument (Day et al. 2001; Willett 2001). This may lead to considerably greater relative risk attenuation than has been previously realized, making modest decreases in relative risks difficult to detect (Kipnis et al. 1999). Null results of the diet-disease relationship in studies may thus be misleading, and controlling for a number of correlated dietary variables when exploring the diet-disease association of a specific dietary item can lead to uninterpretable or unpredictable results.

Other factors that can bias diet-disease relationships include the frequent assumption of unchanged dietary intake over long follow-up periods, particularly affecting long-term cohort studies, and recall bias, which is a major problem in case-control studies (Willett 1998b). In some cases, surrogate interviewees (spouses or immediate family members) are asked to provide information for the cases and controls in case-control studies; but this might also lead to misclassification bias. Another important issue to consider is the validity and reliability of extrapolating results from studies based on micronutrient intakes or status to the effect of intakes of fruit and vegetables. In this review, we have thus tried to select only studies with data based on food consumption rather than biomarkers of intakes. Where no appropriate foodexposure data existed, it was decided to include proxy nutrients (such as vitamin C from diet) when this was validated by consumption studies. This approach was necessary, as there were a large number of studies that framed their hypotheses in terms of nutrients, and reported only associations with nutrients. For example, studies such as the EPICNorfolk study (Bingham et al. 1997) have tried to reduce the subjective nature of dietary assessment by using biological indicators such as plasma ascorbic acid, which they correlated with food intake. The use of plasma ascorbic acid measurement is thought to represent dietary intake in the preceding few weeks and may overcome some of the issues involved with dietary assessment (Bates et al. 1991). However, biomarkers are also prone to measurement error that could also explain the lack of consistency in studies in which such biomarkers have been used. In addition, these proxy measures of intake are not ideal, as it is clear that any beneficial effect of fruit and vegetables involves many nutrient
and non-nutrient factors. They would tend to underestimate the impact of a mixed intake of fruit and vegetables.

Finally, there is substantial variability among studies in the categorization of exposure groups, not only in terms of what constitutes the "fruit and vegetables" measured, but also the actual levels of intake within these groups. Exactly what level of intake represents a high or a low intake will vary significantly among populations and will be influenced by the method of data collection. This was discussed in section 2.9. This literature review does not comment on the association of disease risk with specific fruit and vegetables, although several studies have attempted to do this in their analyses.

Outcome. The best studies reviewed for this project were those that utilized more than one method to identify cases to avoid any losses to follow up in the final analysis. The methods used included death certificates, hospital records, living relatives, self-report and cancer registries.

### 3.7 Structured assessment of causality for each OUTCOME CHOSEN

## ISCHAEMIC HEART DISEASE

A detailed description of the studies included in the review of the literature follows.

## Previous reviews of the literature

Three recent reviews of the association between fruit and vegetable consumption and IHD were identified (Klerk et al. 1998; Law and Morris 1998; Ness and Powles 1997). The review by Klerk et al. (1998) concluded that high vs low consumption of fruit and vegetables (increasing from 250 to $400 \mathrm{~g} /$ day) is likely to reduce the risk of IHD by $20-40 \%$ in men and women; however, the methods used to derive the final estimates are unclear.

Law and Morris (1998) performed a meta-analysis of cohort studies of the relationship between IHD and markers of fruit and vegetable consumption, namely dietary intake of fruit, vegetables, carotenoids, vitamin C, fruit fibre and vegetable fibre, and serum concentration of carotenoids and vitamin C, adjusted for other factors. They estimated that the risk of IHD is about $15 \%$ lower at the 90 th than at the 10th percentile of fruit and vegetable consumption.

The review by Ness and Powles (1997) identified 10 ecological, three case-control and 16 cohort studies investigating IHD. Of these, nine ecological studies, two case-control studies, and six cohort studies reported a statistically significant negative relationship between IHD and the consumption of fruit and vegetables or proxy nutrients. Ness and Powles did not attempt to arrive at a summary statistic for the association as the measures of exposure and disease varied considerably between
studies. They concluded that the results are consistent with a protective effect of fruit and vegetables for IHD.

## Current review of the literature

The literature review identified 27 references of prospective studies that investigated the association of IHD risk with fruit and vegetable consumption. Details of the study characteristics are given in Table 9.13. In summary, the study populations were all from Japan, the United States and Europe (Finland, the Netherlands, Norway, Sweden and the United Kingdom). Five of the studies each gave rise to more than one report; 14 studies included men and women, nine studied men only and four studied women only. The follow-up time varied between four and 25 years. The method used to measure fruit and vegetable intake differed considerably among studies, ranging from one 24 -hour dietary recall and a seven-day prospective weighed food diary to a variety of food-frequency questionnaires.

Sixteen of the 27 studies reported a statistically significant inverse association between intake of fruit and vegetables and IHD. Thirteen of these showed an association with food intake, while the other three showed an association with a proxy diet measure that was correlated with fruit and vegetable intake. Nine further studies also reported an inverse association; seven of these were not statistically significant, two others not reporting confidence intervals or measures of statistical significance. The actual relative risks for the studies included in the metaanalysis are given in Table 9.23. Relative risks for the studies in the systematic review are not given here due to the wide variation in how fruit and vegetables were reported and analysed.

## Confounding

Most of the studies reviewed adjusted for some potential confounding factors shown to be associated with the risk of cardiovascular disease. All adjusted for age, and most studies adjusted for sex and smoking. Very few of the older studies had adequately addressed the issue of confounding, and this cannot be discounted as an explanation for an observed association in some studies. However, most recent studies have dealt with a comprehensive range of confounding factors, including the majority of the following: smoking, alcohol, total energy intake, saturated fat intake, cholesterol, BMI, hypertension, type II diabetes, physical activity, hormone replacement therapy, educational status or social class and nutritional supplement use. Measurement of some of these candidate confounders will potentially have substantial error (e.g. energy intake).

## Summary

In summary, the review of the literature suggests that there is a strong inverse relationship between fruit and vegetable intake and

cardiovascular disease in over half the prospective observational studies in many different populations. The relationship remains after some adjustment for confounding. This result needs to be interpreted in the light of findings with regard to the more favoured diet hypotheses. In a review of the evidence for the classic diet-heart hypothesis, Willett found a positive association with saturated fat intake in only two of the 12 cohort studies reviewed, and a positive association with cholesterol intake in two (Willett 1998b).

## IsCHAEMIC STROKE

This analysis is confined to ischaemic stroke. Most of the studies in the systematic review had only considered outcomes of ischaemic stroke. Although a few studies had analysed ischaemic and haemorrhagic stroke separately, there was insufficient evidence to draw any conclusions on the association of differential outcomes with fruit and vegetable intake. As it is more biologically plausible that the relationship of fruit and vegetable protection is with ischaemic stroke, we decided to limit our analyses to this outcome. For the attributable burden calculations, stroke was divided into ischaemic and haemorrhagic using the method described in chapter 7.

## Previous reviews of the literature

Three recent reviews that previously studied the association between fruit and vegetable consumption and stroke were identified (Klerk et al. 1998; Ness and Powles 1997, 1999). The review by Klerk et al. (1998) concluded that the risk of stroke is reduced by $0-25 \%$ with higher intakes of fruit and vegetables. The reviews by Ness and Powles (1997, 1999) identified five ecological, one case-control and eight cohort studies reporting measures of association between the intake of fruit and vegetables and stroke. Of these, three ecological studies and six cohort studies reported a statistically significant negative association with the consumption of fruit and vegetables or proxy nutrients. The authors concluded that the results were consistent with a strong protective effect of fruit and vegetables for stroke, but they did not calculate a summary statistic for the association as the measures of exposure and outcome varied considerably among studies.

## Current review of the literature

As with IHD, evidence from case-control and ecological studies was not reviewed because the number of cohort studies identified was sufficiently high (cohort studies represent a stronger study design), and because the general pattern of findings observed was consistent among studies. Overall, the evidence suggests a strong protective effect of fruit and vegetable consumption on ischaemic stroke risk.

Twenty-one references of prospective studies of the association between stroke and the consumption of fruit and vegetables were iden-
tified. Details of the study characteristics are described in Table 9.14. In summary, the study populations were all from China, Japan, the United States or Europe (Finland, the Netherlands, Norway, Sweden and the United Kingdom). Three of the studies gave rise to more than one report. Ten studies had populations of men and women, eight studied men only and four studied women only. The follow-up period varied between five and 28 years. The method used to measure dietary intake of fruit and vegetables also varied considerably, including postal diet survey, 24-hour dietary recall, seven-day prospective weighed diet record, and various food-frequency questionnaires of differing length and quality.

Thirteen studies showed a statistically significant inverse association between the intake of fruit and vegetables and stroke. Six studies showed an association with food, while the other eight showed an association with a nutrient considered to be a proxy for fruit and vegetable intake.

## Confounding

As discussed for IHD, the observed protective association for fruit and vegetables and stroke could, in theory, be explained by confounding. All studies included in the literature review adjusted for age and sex, and most recent studies reviewed also dealt with a comprehensive range of major measured confounders.

## Summary

There is a strong inverse relationship between the level of fruit and vegetable consumption and stroke risk in prospective observational studies in many populations. The relationship persists after adjustment for major confounders.

## LUNG CANCER

A detailed description of the studies included in the review of the literature follows.

## Previous reviews of the literature

Five recent comprehensive reviews of the association of fruit and vegetable intake with lung cancer risk were identified. Three concluded that there was convincing evidence that a diet rich in fruit and vegetables decreases the risk of lung cancer.

One of these three reviews was that of the WCRF/AICR (1997), which reviewed seven cohort and 17 case-control studies. Of the seven cohort studies, after adjustment for smoking, all showed a protective association for some fruit or vegetable. Most of the relative risks (23 of 31) they presented were for a protective association, although not all were statistically significant. No studies showed a statistically significant increase in risk for any type of fruit or vegetable. Sixteen of the case-control studies reported statistically significant inverse associations for one or more vegetable or fruit categories. The evidence was most abundant for

green vegetables and carrots. Results of an analysis of dose-response relationship between vegetable intake and risk of lung cancer estimated that the relative risk decreases by about $50 \%$ as intake increases from $150 \mathrm{~g} /$ day to $400 \mathrm{~g} /$ day. An intake of $>400 \mathrm{~g} /$ day is always associated with a lower risk than $100 \mathrm{~g} /$ day or less.

In their review, Ziegler et al. (1996b) asserted that the results of observational studies of diet and lung cancer suggest strongly that an increased fruit and vegetable intake is associated with a reduced risk in men and women; in various countries; in smokers, ex-smokers, and neversmokers; and for all types of lung cancer.

The review by Klerk et al. (1998) concluded that high vs low consumption of fruit and vegetables (an average difference of $150 \mathrm{~g} /$ day ) is likely to reduce the risk of lung cancer by $35-55 \%$ in men and women.

Koo (1997), in contrast, concluded that epidemiological studies performed over the last 20 years do not provide overwhelming evidence of an inverse association between fruit and vegetable consumption and lung cancer risk. Koo proposed the imperfect control of smoking-associated dietary correlates and "lifestyle" differences as the major problems with the perceived associations between diet and lung cancer.

## Current review of the literature

The literature review identified 21 cohort and 32 case-control studies that examined the association of fruit and vegetable intake with the risk of lung cancer incidence and mortality. Details of the studies are provided in Tables 9.15 and 9.16 . Overall, the evidence appears to support an inverse relationship between fruit and vegetable consumption and lung cancer risk (both incidence and mortality).

The cohort studies identified were conducted in a range of countries including Finland, Japan, the Netherlands, the United States and other southern and northern European countries included in the Seven Countries study. The study populations were not necessarily nationally representative as some studies were limited to religious groups or those with particular lifestyle characteristics (Fraser et al. 1991; Key et al. 1996), specific occupational groups (Feskanich et al. 2000; Michaud et al. 2000) or very narrow age groups such as the elderly (Shibata et al. 1992). Three studies from the United States analysed national survey data and are therefore perhaps more nationally representative. Very few studies were of young people.

It should be noted that, of the 21 cohort studies, five of the study populations were each used in more than one study. The studies differed in their analysis by reporting different risk factors (i.e. carotenoids vs fruit and vegetables) or using different outcome measures (mortality vs incidence).

Twelve studied incidence of lung cancer as the outcome measure, while eight studied lung cancer mortality. Follow-up periods varied between
Table 9.15 Summary of cohort studies reporting association between intake of fruit and vegetables and lung cancer

four and 25 years, with 16 studies having follow-up periods longer than 10 years. Twelve of the studies investigated populations of men and women, seven studies had male-only cohorts and two studies were entirely female. Most studies have pooled the results for men and women, the explanation being that the number of lung cancer cases in women is too small to justify a meaningful separate analysis. Only a few studies have analysed men and women separately, usually where the entire study cohort was either men or women. More detailed characteristics of all studies are given in Table 9.15.

Eleven studies showed a statistically significant inverse association between a diet high in fruit or vegetables (one of these was significant for dietary carotenoids) and lung cancer. The remainder of the studies showed an inverse association that was not statistically significant. In some studies with non-significant results for total fruit and vegetables, subcohort analyses were reported as having significant associations.

Of particular interest are studies of lung cancer incidence and mortality that considered non-smokers, former smokers and smokers separately in the analyses. It appears that the benefit conferred through a high intake of fruit and vegetables more often reaches statistical significance in current smokers than in non-smokers (however, confidence intervals are often large and overlap). In summary, eight of the cohort studies reviewed for this project stratified the analyses by smoking status. Three of these showed a significant relationship between fruit and vegetable consumption and lung cancer incidence in smokers but not in nonsmokers (but for one of these, the relative risks of both groups were similar) (Fraser et al. 1991; Knekt et al. 1991; Yong et al. 1997), while only one study showed an inverse relationship in non-smokers only (Knekt et al. 1997). The other studies showed non-significant results (Feskanich et al. 2000; Mulder et al. 2000; Steinmetz et al. 1993; Voorrips et al. 2000b) for both smokers and non-smokers. These results would tend to agree with the hypothesized biological mechanisms for the benefits of fruit and vegetables in lung cancer through late stage modification of carcinogenesis following an initial carcinogen exposure. Further research is needed to consider the current inconsistencies in findings, including exposure among non-smokers to environmental tobacco smoke and the range of other lung cancer risk factors.

The literature review identified 32 case-control studies that satisfied the inclusion criteria. These are summarized in Table 9.16. As the case-control studies were not used in the meta-analyses, fewer study details are provided here for conciseness. These studies were conducted across a range of populations including Brazil (1), Canada (13), China (4), Greece (1), India (1), Italy (1), Japan (2), Poland (2), Spain (1), Sweden (2), the United Kingdom (2) and the United States. Of the studies, 19 collected data from men and women, seven from men only and six from women only.

Eighteen found an inverse relationship between a high intake of fruit or vegetables and lung cancer. When separate associations with fruit and vegetables were analysed, there seemed to be a greater number of studies finding significant associations with vegetables as a group compared to fruit as a group. Four of the studies found significant associations only with specific types of vegetables, such as pumpkin and onion (Sankaranarayanan et al. 1994), or tomato (Brennan et al. 2000), or carrot (Pisani et al. 1986) or in specific age groups such as men aged 60-79 years (Byers et al. 1987). The results of these subgroup analyses should be treated with caution.

Of the four case-control studies that specifically collected and analysed data on non-smokers, two found no association, while two found a significant inverse association between fruit or vegetable consumption and lung cancer. But due to the inherent limitations of case-control studies, the results do not necessarily imply that dietary modification after quitting smoking is effective in reducing risk. Exsmokers with elevated vegetable and fruit consumption could have been high consumers while they were smokers as well. However, the results of case-control studies seem consistent with the results of the cohort studies.

Although outside the criteria of this review, it is important to mention some of the evidence from experimental studies that may appear to contradict the protective relationship of fruit and vegetables on lung cancer. The CARET study (Anonymous 1994) and the ATBC study (Omenn et al. 1996b) were randomized control trials designed to investigate the effect of beta-carotene high-dose supplementation on lung cancer. The results of these trials suggested a harmful effect (increase in incidence and mortality) of beta-carotene supplementation in current smokers. This suggests that raised beta-carotene may be a marker associated with other protective factors found in foods (Lonn and Yusuf 1999), and that the status of the antioxidant hypothesis might need to be re-evaluated critically (Ness et al. 1999a).

## Confounding and interactions

All studies of lung cancer adjusted for age, sex and smoking in their analyses, except for one case-control study from Poland (Rachtan and Sokolowski 1997), which did not adjust for smoking. Other potential confounders dealt with statistically included: environmental tobacco smoke; previous lung disease; occupational exposure (arsenic, asbestos, chloromethyl ethers and nickel); radon; air pollution; total energy intake; intake of other macronutrients; BMI; physical activity; and socioeconomic status (using educational level or occupation used as a proxy). The actual adjustment varied among studies.

Smoking is the most important potential confounder to consider given the strength of the association between smoking and lung cancer. There is also the possibility of smoking being an effect modifier but published
results are contradictory. The studies reviewed here have dealt with smoking in a number of ways. Some studies have not only adjusted for current smoking status, but have also considered the intensity of current smoking behaviour (as the number of cigarettes smoked per day), age of starting smoking and duration of smoking. For current non-smokers, several studies have also adjusted for time since quitting (including intensity) in ex-smokers. A couple of studies also adjusted for time since quitting for subjects who quit during follow-up.

An important issue, highlighted by Ziegler et al. (1996b), is that several studies have shown that consumption of fruit, vegetables and carotenoids is higher in non-smokers compared with current smokers, and that consumption is inversely related to smoking intensity in smokers. Thus, those studies that only considered smoking status without smoking intensity might have generated inflated estimates of the protective effect of fruit and vegetables.

The interpretation of these studies is difficult given the strong misclassification bias and the strong association between lung cancer and tobacco use, making it difficult to ensure that all the confounding effects from smoking have been removed (Boshuizen et al. 2002).

## Summary

There is some evidence of an inverse relationship in many populations between lung cancer risk and fruit and vegetable consumption. There is currently not enough evidence to justify stratifying the results by smoking status.

## GASTRIC CANCER

A detailed description of the studies included in the review of the literature follows.

## Previous reviews of the literature

Four recent reviews of the literature concluded that epidemiological evidence shows a consistent protective effect of fruit and vegetable intake on stomach cancer risk (Klerk et al. 1998; Kono and Hirohata 1996; Steinmetz and Potter 1996; World Cancer Research Fund and American Institute for Cancer Research 1997).
The report from the WCRF/AICR (1997) reviewed six cohort and 32 case-control studies. Three of the six cohort studies and 27 of the 32 case-control studies reported a statistically significant protective association for one or more vegetable or fruit categories. The evidence for raw vegetables, allium vegetables and citrus fruit in particular is consistent with a protective effect. Any contradictory evidence related entirely to salted and pickled vegetables. Analyses of dose-response relationships suggested that the risk of stomach cancer decreases by about $50 \%$ as fruit and vegetable intake increases from $50 \mathrm{~g} /$ day to $300 \mathrm{~g} / \mathrm{day}$. An intake of $>150 \mathrm{~g} /$ day is always associated with a lower risk than $100 \mathrm{~g} /$ day or
less. In comparison, the review by Klerk et al. (1998) concluded that high vs low consumption of fruit and vegetables (an average difference of $150 \mathrm{~g} /$ day ) is likely to reduce the risk of stomach cancer by $40-55 \%$ in men and women.

A recent meta-analysis by Norat et al. (2001) of previously published case-control and cohort studies examined the association of total fruit or total vegetable consumption with gastric, colorectal and oesophageal cancer. It included all studies published in English from 1973-2000 and referenced in Medline that provided data on total fruit or vegetable intake. There was no assessment of study quality, adjustment for confounders was not assessed and studies were included as long as they could provide the information necessary for the statistical analysis. For gastric cancer, 32 studies were included that analysed total fruit intake and 22 studies were included for total vegetable intake. The pooled relative risks associated with an increase of consumption of $100 \mathrm{~g} /$ day were 0.75 ( $95 \%$ CI $0.67-0.83$ ) for fruit and $0.80(0.74-0.86)$ for vegetables.

## Current review of the literature

The current literature review identified 14 cohort and 32 case-control studies that investigated the association between gastric cancer risk (incidence and mortality) and the consumption of fruit and/or vegetables. Overall, the evidence seems to support an inverse association between fruit and vegetable consumption and gastric cancer risk.

The 14 cohort studies were conducted in populations from both developed and developing countries including one from China, two from Japan, two from mainland USA, three of Japanese descendants in Hawaii and six from Europe. The Asian populations had a relatively high risk of stomach cancer. The results of the studies are summarized in Table 9.17.

Of these studies, nine investigated the effect of fruit and vegetable intake on gastric cancer incidence, while the remaining five studied mortality. Two cohorts were investigated in more than one study (the Netherlands Cohort study, and Japanese descendants in Hawaii in the Honolulu Heart Program). Seven cohorts consisted of both men and women, six studies investigated men only and one study focused exclusively on post-menopausal women. Follow-up of cohorts ranged from five to 25 years.

A statistically significant inverse association between gastric cancer and fruit and vegetable intake was reported in four studies. This inverse relationship was found in populations of both European and Japanese origin. The 10 other studies showed inverse relationships, but they were not statistically significant for fruit and vegetable, or nutrient intake.

The 32 case-control studies, summarized in Table 9.18, represented a wider range of populations and geographical areas than the cohort studies. Studies were conducted in Canada and the United States (5), China (3), Japan (4), Mexico (1), Poland (1), the Republic of Korea (1),

Turkey (2), Venezuela (1) and northern and southern Europe (14). All but two of these studies were carried out on both men and women. Not all the populations were at high risk of stomach cancer.

Of the 32 studies, 20 reported a significant inverse association between total fruit or vegetable consumption and gastric cancer risk. A further nine studies found an inverse association only with specific food types or within a subcohort. Particular attention was placed on the consumption of allium vegetables (onion, leek, garlic and chives). One study (from Venezuela) found that the risk of gastric cancer incidence was inversely related (protective effect) with vegetable intake but directly related (harmful effect) with fruit intake. This is the only study reporting a significant positive (harmful) relationship (Munoz et al. 2001). Despite the inherent limitations of information bias in case-control studies, the evidence is strong and consistent for a protective effect from a diet high in fruit and vegetables, and supports the findings of the cohort studies.

## Confounding

Most studies appear to have adjusted adequately for potential confounding factors. All adjusted for age and sex, and most studies adjusted for smoking and alcohol consumption. Other factors, considered particularly in prospective studies, were previous history of stomach illness, family history of stomach cancer, other dietary components and socioeconomic status. Protective associations remained even after adjustment for other dietary factors such as salty foods or starchy foods in some studies (Coggon et al. 1989; Hansson et al. 1993; La Vecchia et al. 1987; Lee et al. 1995; Ramon et al. 1993; Risch et al. 1985).
H. pylori infection is a major risk factor for gastric cancer, yet few studies were able to collect this information given the retrospective nature of many studies and the recent ability of testing to confirm infection.

## Summary

There is an inverse relationship between fruit and vegetable intake and gastric cancer risk in both cohort and case-control studies in different populations worldwide. The relationship remains after adjustment for confounding. Some of the variations in the findings from separate studies could be due to the between-country differences in the varieties of fruit and vegetables consumed, the methods of consumption (raw or cooked), the number of specific fruit or vegetable items included in the questionnaires used or the validity of the dietary assessment methods.

Although H. pylori infection is an established risk factor, its relationship with fruit and vegetable consumption remains inadequately understood. A multistage model of gastric carcinogenesis is now accepted, according to which different dietary and non-dietary factors, involving genetic susceptibility, are involved at different stages in the cancer
process. A protective effect of supplementation of vitamin $C$ and betacarotene in the progression of pre-malignant gastric lesions was found in Latin America (Correa et al. 2000), but alpha-tocopherol and betacarotene supplement trials in Finland showed no effect. In spite of this, results from the observational studies suggest a protective effect of diets rich in fruit and vegetables.

## Colorectal cancer

A detailed description of the studies included in the review of the literature follows.

## Previous reviews of the literature

Four recent comprehensive reviews of the literature investigating fruit and vegetable consumption and risk of colorectal cancer were found. They all concluded that the evidence is consistent in supporting a decreased risk of colorectal cancer with higher consumption of vegetables, and that data for an association with fruit consumption are inconsistent (Klerk et al. 1998; Norat et al. 2001; Potter 1996; World Cancer Research Fund and American Institute for Cancer Research 1997).

The review by Klerk et al. (1998) estimated that high vs low consumption of fruit and vegetables (an average difference of $150 \mathrm{~g} /$ day) is likely to reduce the risk of colorectal cancer by $20-45 \%$ in men and women.

The meta-analysis by Norat et al. (2001) (see description above in the section on gastric cancer) included 13 studies assessing the effect of total fruit intake and 28 studies assessing the effect of total vegetable intake. The pooled relative risks associated with an increased intake of $100 \mathrm{~g} /$ day were 0.94 ( $95 \%$ CI $0.90-0.98$ ) for fruit and 0.90 ( $95 \%$ CI $0.84-0.96$ ) for vegetables (subanalyses found similar relative risks for men and women, and for European and USA populations).

## Current review of the literature

The systematic review identified 15 cohort studies and 34 case-control studies that examined the association between colorectal cancer risk (both incidence and mortality) and the consumption of fruit and vegetables. Details of these studies are given in Tables 9.19 and 9.20. Overall, the evidence supports an inverse relationship between fruit and vegetable intake and colorectal cancer risk (incidence and mortality), although it is not as strong as that for gastric cancer.

The studies investigating colorectal cancer also included a number of studies that looked separately at colon and rectal cancers. For the purposes of this review, we have combined the results of all these outcomes.

The cohort studies were conducted on a limited range of populations with most studies being from the United States (10), the others being
Table 9.19 Summary of cohort studies reporting a measure of association between intake of fruit and vegetables and colorectal

| Russian Federation | (Zaridze et al. 1993) | Males and females | Null | Positive (dried fruit) |

from Europe (3) and Japan (1). It should be noted that three of the study cohorts were common to more than one study.

The majority of studies measured cancer incidence as the outcome, with mortality being used as the study outcome in only four studies. Eight studies investigated both men and women, while three investigated men only and four looked at women only.

Although a number of the studies reported a protective effect of fruit and vegetable consumption on colorectal cancer risk, only three of the 15 showed a statistically significant inverse trend. This is summarized in Table 9.19. A further eight studies did show some inverse association between vegetable consumption and colorectal cancer risk for certain subgroup analyses of fruit, vegetables or colon or rectal cancer separately; three studies showed a statistically insignificant positive association between fruit and vegetable intake and colorectal cancer.

The case-control study populations came from a wider range of countries than those of the cohort studies. They included studies from Argentina, Australia, Belgium, Canada, China, France, Italy, Japan, the Russian Federation, Singapore, Spain, Switzerland, the United States and Uruguay. All studies collected data on both men and women. It should be noted that two of the population cohorts (Australia and New York) were each common to two studies.

Results from 21 out of the 33 populations showed an inverse association with fruit or vegetables, while three found an inverse association only with specific food types (tomato; or spinach, onion and pumpkin; or tomato, pepper and celery). This is summarized in Table 9.20.

It should be noted that although the majority of colorectal cancers are adenocarcinomas, some studies found differences depending on tumour location (proximal vs distal, colon vs rectum). This suggests that pooling of results from different anatomical sites and cell types in many of the cohort and case-control studies may have obscured a true relationship for subgroups.

## Confounding and interaction

All studies adjusted for the effect of sex and age. Other confounders taken into account in the statistical analyses included total energy, meat, fat and protein intakes, BMI, smoking, alcohol consumption, physical activity, family history, dietary supplements, education and area of residence. By analogy with the evidence of lung and stomach cancer, it is conceivable that an effect might only be anticipated in those with particular genetic states (e.g. fast acetylators) that also consume significant quantities of meat. Many studies have excluded cases with strong family history of colorectal cancer or with conditions such as familial polyposis coli, and inflammatory bowel diseases such as ulcerative colitis or Crohn disease from the final analyses.

## Summary

On their own, the prospective epidemiological studies have yet to produce conclusive evidence to support an association of colorectal cancer with fruit and vegetable intake. However, the hypothesis is still worthy of further consideration, as there appears to be an inverse relationship in many cohort studies and in two thirds of the case-control studies in a wide range of different populations. The relationships remained after adjustment for confounding.

The uncertainty in the studies of colorectal cancer is relatively unsurprising in view of the complex biological mechanisms involved in its etiology. The incidence can be expected to reflect a complex combination of genetic factors (including factors that affect the colonic mucosa and those that determine whether certain toxins are excreted in bile or urine), diet (both carcinogenic and protective factors) and hormonal status.

## OESOPHAGEAL CANCER

A detailed description of the studies included in the review of the literature follows.

## Previous reviews of the literature

Three recent reviews of the literature (Cheng and Day 1996; Klerk et al. 1998; World Cancer Research Fund and American Institute for Cancer Research 1997) concluded that there is convincing evidence that diets high in fruit and vegetables decrease the risk of oesophageal cancer.

WCRF/AICR reviewed 22 case-control studies (1997). Of these, 18 showed a statistically significant protective association with at least one category of fruit or vegetables. The protective association in the studies remained after controlling for smoking and alcohol consumption. The Dutch review (Klerk et al. 1998) concluded that high vs low consumption of fruit and vegetables (an average difference of $150 \mathrm{~g} /$ day ) is likely to reduce the risk of oesophageal cancer by $40-55 \%$ in men and women.

Finally, the meta-analysis by Norat et al. (2001) pooled the results of 10 studies assessing the effect of fruit intake and 11 studies assessing the effect of vegetable intake on oesophageal cancer (see more details of methods described in the section on stomach cancer). This estimated that an increase in food intake of $100 \mathrm{~g} /$ day is associated with a relative risk for oesophageal cancer of 0.79 ( $95 \%$ CI $0.65-0.95$ ) for fruit; and 0.92 ( $95 \%$ CI $0.85-1.01$ ) for vegetables.

## Current review of the literature

This systematic review identified four cohort and 28 case-control studies investigating the association of fruit and vegetable intake with oesophageal cancer risk (incidence and mortality). Most studies looked
at oesophageal cancer mortality or at the effect of fruit and vegetable consumption on incidence and mortality considered jointly. In this review, we have also considered these outcomes together, assuming that, since oesophageal cancer survival rates are very poor, incidence is closely correlated with mortality.

The four cohort studies considered are from China (2), Japan and Norway. Details of the studies are given in Table 9.21. Both Chinese studies were based on the same population in the Linxian province, which has one of the highest incidence rates of oesophageal cancer in the world. The study population is part of a Nutrition Intervention Trial.

Three of the studies showed a statistically non-significant inverse trend with fruit and vegetable intake. One Chinese study found an inverse relationship with fresh vegetable consumption (Yu et al. 1993), while the other found an inverse relationship between the intake of both fruit and vegetables and oesophageal cancer incidence (Guo et al. 1994). The most recent study of Norwegian men also found a non-significant inverse relationship between fruit and vegetable intake and oesophageal cancer incidence, but this was based on only 22 cancer events.

Case-control studies provide the majority of evidence for the association of fruit and vegetable consumption and oesophageal cancer risk. The 28 case-control studies identified are summarized in Table 9.22.

The studies came from a wide range of populations worldwide including China (4), Hong Kong Special Administrative Region of China (Hong Kong SAR) (2), India (2), Japan (2) the United States (4), Europe (11) and South America (3). Most of these studies investigated populations of men and women, but five investigated only men and two studied only women. Not all of the study populations were from populations at a high risk of oesophageal cancer.

Of the 28 studies, 20 reported significant inverse associations between oesophageal cancer and fruit and/or vegetable consumption. Interestingly, more of these inverse associations were with fruit rather than vegetables.

Although many studies did not specifically look at the histological type of oesophageal cancer, the majority of the results presented here are likely to be limited to squamous cell cancer. There was one study, in women from the United Kingdom (Cheng et al. 2000), which focused on oesophageal adenocarcinoma. This study found an inverse association of cancer risk with a higher consumption of fruit but not vegetables.

## Confounding

Most studies adjusted for age and sex. Other potential confounders considered in several studies, included smoking, total energy intake, pickled vegetable intake, BMI, marital status, occupational status, educational or socioeconomic status and ethnicity. Supplement intakes, such as vitamins, and intake of hot teas, were also considered in a few studies.
Table 9.2 I Summary of cohort studies reporting a measure of association between intake of fruit and vegetables and

| Country | Study population (reference) | Sex | Age range (years) | Study size | No. of cases | Follow-up (years) | Exposure measure | Association with fruit or vegetable intake |

## Summary

The epidemiology of oesophageal cancer shows wide geographical variation in incidence and mortality rates. Striking differences have been reported not only between regions of the world and countries, but also within smaller geographical areas (Muir and McKinney 1992; Walker et al. 2002). Oesophageal cancer risk also varies with race, ethnicity and sex. Changes in incidence patterns observed in migrant studies appear to indicate that environmental factors, among which diet may be important, play an important role in the etiology of oesophageal cancer.

The main risk factors for oesophageal cancer in Europe were previously thought to be tobacco smoking and alcohol consumption. However, time trends of oesophageal mortality from 1950-1985 in 17 European countries showed that oesophageal cancer had either decreased or increased only slightly (Cheng et al. 1992). This trend differed from that of lung cancer, cirrhosis and alcohol consumption, which had increased substantially during the same period. The results suggest that other populationwide changes in protective risk factors, such as improvements in diet after World War II, had mitigated against the effect of tobacco and alcohol and resulted in a reduction of oesophageal cancer risk. In China, which has a very high incidence of oesophageal cancer, an ecological study of 65 counties showed that oesophageal cancer mortality was significantly associated with fruit consumption, but no correlation was observed with tobacco smoking or alcohol consumption (Guo et al. 1990). There is strong evidence from ecological studies that dietary factors, especially fruit and vegetable consumption, may affect rates of oesophageal cancer.

This review of the literature showed that there are few prospective observational studies of the effect of fruit and vegetable consumption on oesophageal cancer, and that most of these show non-significant inverse associations. Evidence from supplement intervention trials is also inconclusive. Two randomized supplement intervention trials in Linxian, China tested the effect of nutrient/vitamin supplementation in a population with very high rates of oesophageal cancer (Blot et al. 1995). Modest protective effects were seen for mortality in the supplemented group in both trials, but none of the results was statistically significant for oesophageal or gastric cancer. In spite of this, evidence from case-control studies appears to support an inverse relationship between fruit and vegetable consumption and oesophageal cancer risk (incidence and mortality), although this is not as strong as that for stomach cancer.

### 3.8 Estimates of RISK Factor-disease relationships by SUbregion, SEX AND AGE

## Estimates of relative risks

This section describes, for each selected outcome, the studies that were chosen based on the strict selection criteria for meta-analysis outlined in section 3.6, and the final estimates of relative risks derived for CRA.

## Ischaemic heart disease

Details of the cohort studies that most closely met our selection criteria are given in Table 9.23. The EPIC-Norfolk study (Khaw et al. 2001) was included in spite of the fact that it presents results in relation to plasma vitamin C, because plasma vitamin C measurements (available for the whole cohort) were relatively well correlated with fruit and vegetable intake (available from a 7-day food record analysed for a subset of the cohort) and because of the high quality of the methods used to collect and analyse data.

Fruit and vegetable intake in the Nurses' Health and Health Professionals' follow-up studies (NHS/HPFS), EPIC-Norfolk and the Finnish Mobile Clinic studies were treated as continuous variables. The NHS/HPFS studies gave the relative risk in terms of one additional serving per day, which we converted as $80 \mathrm{~g} /$ day (assumed to be one standard serving); the EPIC-Norfolk and Finnish Mobile Clinic studies reported relative risk estimates for 50 g and 1 g increase in intake respectively. Thus, the relative risk estimates were transformed to give final estimates expressed as per $80 \mathrm{~g} /$ day increase.

For the Massachusetts Health Care Panel study (data analysed as quartiles of intakes), the two methods described in section 3.6 were used to estimate the relative risks. With method 1, we estimated the additional $\mathrm{g} / \mathrm{day}$ for which the relative risks given applied. The study gave exposure quartiles with midpoints at $32,88,138$ and $190 \mathrm{~g} /$ day (the last estimated as the lower limit, 164, plus half the previous category interval), and reported relative risks for the two latter categories compared with the first quartile. A difference of 55 g between adjacent quartiles was

Table 9.23 Relative risk estimates for the association between ischaemic heart disease and fruit and vegetable consumption

| Country | Study population (reference) | Sex and age range (years) | Outcome | $R R$ (95\% CI) per $80 \mathrm{~g} /$ day increase in fruit and vegetable intake |
| :---: | :---: | :---: | :---: | :---: |
| Finland | Finnish Mobile Clinic Health Examination study (Knekt et al. 1994) | Males and females (30-69) | Mortality | $\begin{gathered} 0.964 \\ (0.930-0.999) \end{gathered}$ |
| United Kingdom | EPIC-Norfolk (Khaw et al. 2001) | Males and females (45-79) | Mortality | $\begin{gathered} 0.54 \\ (0.40-0.74) \end{gathered}$ |
| USA | NHS/HPFS (Joshipura et al. 200I) | Males and females (34-75) | Myocardial infarction incidence | $\begin{gathered} 0.96 \\ (0.94-0.99) \end{gathered}$ |
| USA | Massachusetts Health Care Panel study (Gaziano et al. 1995) | Males and females (>66) | Mortality | $\begin{gathered} 0.54 \\ (0.35-0.84) \end{gathered}$ |

assumed, which gives exposures of approximately 30, 85, 140 and $195 \mathrm{~g} /$ day. This approximation yielded comparable relative risks per 55 g difference whichever of the two reported relative risks was converted, and the relative risk reported for the 4th vs 1 st quartile was used, which was expressed as a difference in exposure of $3 \times 55=165 \mathrm{~g} / \mathrm{day}$. The method of Greenland and Longnecker (method 2) was then used to estimate the weighted regression slope over the published relative risks, allowing for correlations due to common reference category. Because of its advantages, method 2 was chosen to obtain the final estimates for inclusion in the meta-analysis.

Meta-analysis was used to pool relative risk estimates using the method described in section 3.6. The test of heterogeneity gave a chisquared value of $19.044(d f=3 ; P<0.001)$. The resulting variation between studies suggests that it is inappropriate to pool estimates according to the fixed effects method. Using random effects meta-analysis, the pooled relative risk estimate was 0.903 ( $95 \%$ CI $0.824-0.989$ ) for an $80 \mathrm{~g} /$ day increase in fruit and vegetable consumption. The random effects results are shown in Figure 9.2.

Figure 9.2 Random effects meta-analysis of the association of fruit and vegetable intake with ischaemic heart disease

[^38]The figure shows that there is marked heterogeneity in the best available evidence on the effects of fruit and vegetable consumption on the risk of IHD. The sources of this heterogeneity are currently not understood scientifically, and there is, therefore, no fully satisfactory means for arriving at a summary effect estimate. The random effects model used here provides a pragmatic interim solution to summarizing this evidence, pending better scientific understanding of the underlying relationships. The derived effect size seems plausible in the light of the consistency of the study findings set out in Table 9.13, but it remains subject to substantial uncertainty-only some of that derives from the statistical uncertainty associated with the four studies included in Figure 9.2.

## Ischaemic stroke

Only two cohort studies met the selection criteria for meta-analysis. These are summarized in Table 9.24.

The NHS/HPFS gave the relative risk in terms of one additional serving per day, which we converted as $80 \mathrm{~g} / \mathrm{day}$. As the Zutphen study did not give a single estimate of linear (log) relative risk per consumption, the relative risk estimates were derived using the two methods described earlier for IHD. Since vegetable and fruit consumption were separately analysed, the relative risk for vegetable consumption was used: it seems to us likely that vegetable and fruit consumption would confound each other, so that what is reported as a purely "vegetable" effect includes the effect of fruit eaten by vegetable consumers. Since a diet of only fruit is rare, the vegetable effect reported was assumed to be similar to that which would have been reported for a combined fruit and vegetable diet (although this may underestimate the effect). Method 2, of Greenland and Longnecker (1992), gave an almost identical estimate to Method 1, which used a consumption difference of the 4th vs 1st quartile ( $249.9-128.1=121 \mathrm{~g} / \mathrm{day}$ ) for the 0.82 relative risk (vegetables) as the basis for the estimate. Results based on method 2 are therefore reported here.

Table 9.24 Relative risk estimates for the association between stroke and fruit and vegetable consumption

|  | Study population <br> (reference) | Sex and <br> age range <br> (years) | Outcome | RR (95\% CI) per <br> $80 \mathrm{~g} /$ day increase <br> in fruit and <br> vegetable intake |
| :--- | :--- | :--- | :--- | :---: |
| Country | Zutphen study (Keli <br> et al. 1996) | Males <br> $(50-69)$ | Incidence <br> cerebrovascular <br> accident | 0.87 <br> $(0.49-1.53)$ |
| Netherlands | NHS/HPFS (Joshipura <br> et al. 200I) | Males and <br> females <br> $(34-75)$ | Incidence <br> ischaemic <br> stroke | 0.96 |

Figure 9.3 Fixed effects meta-analysis of the association of fruit and vegetable intake with ischaemic stroke

Key: I, Zupthen study; 2, NHS/HPFS.

Relative risk estimates were combined using fixed-effect metaanalysis, as the random effects could not be estimated. The pooled relative risk estimate was 0.939 ( $95 \%$ CI $0.892-0.989$ ) for an $80 \mathrm{~g} /$ day increase in fruit and vegetable consumption. The results are shown in Figure 9.3.

## Lung cancer

Four studies met our selection criteria for meta-analysis. These are shown in Table 9.25.

Relative risks in the NHS/HPFS and the Finnish Mobile Clinic Health Examination study were available with fruit and vegetable intake treated as a continuous variable. The NHS/HPFS gave the relative risk in terms of one additional serving per day, which we converted as $80 \mathrm{~g} / \mathrm{day}$. The authors of the Finnish Mobile Clinic study provided relative risks per $1 \mathrm{~g} /$ day which were transformed on a log scale to give estimates expressed as an $80 \mathrm{~g} /$ day increase (as discussed earlier in this section).

For the Netherlands Cohort study and the National Health Interview study, data had been analysed as quintiles and quartiles of intake respectively. The method of Greenland and Longnecker (1992) was used to

Table 9.25 Relative risk estimates for the association between lung cancer and fruit and vegetable consumption

|  |  |  | RR (95\% CI) per <br> 80 g/day increase <br> in fruit and |
| :--- | :--- | :--- | :--- | :--- |
| Country | Study population (reference) |  |  |$\quad$| Sex and |
| :--- |
| age range (years) |$\quad$ Outcome | vegetable intake |
| :--- | :--- |

estimate the weighted regression slope over the published relative risks. This gave estimates of relative risks as a continuous variable.

As there was no evidence of heterogeneity (chi-squared value of 3.553, $d f=3, P=0.314$ ), the results from fixed effect meta-analysis were used (estimates were very similar to those obtained with the random effects methods). The pooled relative risk estimate was 0.926 ( $0.886-0.968$ ) for an $80 \mathrm{~g} /$ day increase in fruit and vegetable consumption. The forest plot of the results is shown in Figure 9.4.

These results are consistent with those found in the only other pooled analysis for an association between lung cancer and fruit and vegetable consumption (S.A. Smith-Warner et al. personal communication, 2002). In this study, they found strong, inverse associations in the age-adjusted analyses, and analyses adjusted for education, BMI, alcohol intake and energy intake for total fruit, total vegetable, and total fruit and vegetable intakes. Associations were similar among never, past, and current smokers.

Smith-Warner et al. estimated that the pooled results for total fruit and vegetable intake gave a slightly lower reduction in lung cancer risk than the meta-analysis results for this project. Due to the potential for residual confounding, in our analysis we have decided to use the more conservative estimate of pooled relative risk which is equivalent to 0.96 (0.93-0.99) per $80 \mathrm{~g} /$ day increase in fruit and vegetable intake (S.A. Smith-Warner et al. personal communication, 2002). However, we should note that because of the limitations in our ability to accurately specify fruit and vegetable exposure, we might be underestimating any effect.

## Gastric cancer

Only one study, the Netherlands Cohort study on diet and cancer, met our selection criteria for meta-analysis. This is shown in Table 9.26.

Figure 9.4 Fixed effects meta-analysis of the association of fruit and vegetable intake with lung cancer

Key: I, The Netherlands Cohort study; 2, National Health Interview study; 3, NHS/HPFS; 4, Finnish Mobile Clinic Health Examination study.

Table 9.26 Relative risk estimate for the association between gastric cancer and fruit and vegetable consumption

|  | Sex and <br> age range (years) | Outcome | RR (95\% CI) per <br> $80 \mathrm{~g} /$ day increase in fruit <br> and vegetable intake |
| :--- | :--- | :--- | :---: |
| Study population (reference) | Males and females <br> $(55-69)$ | Incidence | 0.94 (0.86-I.03) |
| The Netherlands Cohort <br> study (Botterweck et al. 1998) |  |  |  |

The relative risks obtained from the Netherlands Cohort study are consistent with the effect estimates obtained from most case-control studies reviewed, but they are more conservative than the estimates of the meta-analysis from Norat et al. (2001).

Data from the Netherlands Cohort study had been analysed as quintiles of intake of fruit and vegetables. The method of Greenland and Longnecker (1992) was used to estimate the weighted regression slope over the published relative risks to estimate relative risks as a continuous variable for an $80 \mathrm{~g} /$ day increase in total fruit and vegetable consumption. This gave a final relative risk estimate for gastric cancer
incidence and mortality for the CRA project of 0.94 (0.86-1.03) for an $80 \mathrm{~g} /$ day increase in fruit and vegetable consumption.

## Colorectal cancer

Three studies met our selection criteria for meta-analysis. These are shown in Table 9.27.

Relative risk in the NHS/HPFS was available with fruit and vegetable intake treated as a continuous variable. The NHS/HPFS gave the relative risk in terms of one additional serving per day, which was converted as $80 \mathrm{~g} / \mathrm{day}$.

For the Netherlands Cohort study and the Swedish Mammography study, data had been analysed as quintiles and quartiles of intake respectively. The method of Greenland and Longnecker (1992) was used to estimate the weighted regression slope over the published relative risks to give relative risks as a continuous variable.

The NHS/HPFS and the Netherlands Cohort study had presented results separately for colon and rectal cancers. The Netherlands Cohort study had also analysed data for men and women separately. These subgroup analyses were combined in the meta-analysis as if they were separate studies. The test for heterogeneity gave a chi-squared value of 8.849 $(d f=6 ; P=0.182)$. As there was no evidence of heterogeneity, the fixed effects results were used (these were very similar to the results obtained with the random effects method). The pooled relative risk estimate was 0.997 (0.973-1.021) for an $80 \mathrm{~g} /$ day increase in fruit and vegetable consumption. The results are shown in Figure 9.5.

The Swedish Mammography study showed that the inverse association was stronger, and the dose-response more evident, among individuals who consumed the lowest amounts of fruit and vegetables. In a subgroup analysis of the population in the lowest quartile of fruit and vegetable intake, the relative risk was $0.77(0.67-0.97)$ for an increase

Table 9.27 Relative risk estimates for the association between colorectal cancer and fruit and vegetable consumption

Figure 9.5 Fixed effects meta-analysis of the association of fruit and vegetable intake with colorectal cancer

Key: I, The Netherlands Cohort study (males, colon cancer); 2, The Netherlands Cohort study (women, colon cancer); 3, The Netherlands Cohort study (males, rectal cancer); 4, The Netherlands Cohort study (females, rectal cancer); 5, Swedish Mammography study (colorectal cancer); 6, NHS/HPFS (males and females, colon cancer); 7, NHS/HPFS (males and females, rectal cancer).
of one serving per day (Terry et al. 2001). It may be that individuals who consume very low amounts of fruit and vegetables have the greatest risk of colorectal cancer. This is consistent with the presence of a plateau effect and highlights the need to study populations with a wide range of dietary exposures. This finding was not replicated in the NHS/HPFS (Michels et al. 2000), although it should be noted that this study had a high reference exposure category and might not have been able to examine very low intake of fruit and vegetables as in the Swedish study.

## Oesophageal cancer

None of the cohort studies of oesophageal cancer in the systematic review met our selection criteria. Studies were either of high-risk populations, had a small number of events, had a relatively short follow-up time or did not cover total fruit and vegetable intake. Very few of the case-control studies had calculated risk for total fruit and vegetable consumption, and none had estimated relative risks for quantified levels of fruit and vegetable consumption that would allow estimation of a continuous variable. Thus, it was decided to use the results of the meta-
analysis from Norat et al. (2001) to derive the final RR estimates. This meta-analysis calculated risk estimates for fruit and vegetables separately per $100 \mathrm{~g} /$ day intake. The pooled relative risks associated with an increase of consumption of $80 \mathrm{~g} /$ day were calculated. These were 0.828 (0.708-0.960) for fruit, and $0.935(0.878-1.008)$ for vegetables. The results suggested risk reductions of between $17.2 \%$ and $6.5 \%$ per $80 \mathrm{~g} /$ day increase in fruit intake and vegetable intake, respectively. For this study, the most conservative relative risks were used, that is, those for vegetables only, 0.935 ( $95 \%$ CI $0.878-1.008$ ).

## Summary of the estimates of relative risks

The relative risk estimates and $95 \%$ confidence intervals are summarized in Table 9.28. Estimates are expressed as the change in relative risk associated with an $80-\mathrm{g}$ increase in daily fruit and vegetable intake.

As discussed earlier, the relative risks are applied to all subregions and to both men and women. Assuming age attenuation at the extremes of age, these relative risks apply for individuals aged 15-69 years. For older adults, the relative risks were reduced by a quarter for ages 70-79 years, and by half for the age group $\geq 80$ years. A relative risk of 1 was applied for those aged $<15$ years.

## Estimates of risk reversibility

There is very little published evidence of risk reversibility for an increased fruit and vegetable intake, mainly due to the difficulty of conducting dietary intervention trials. Hence, the period of the latency between increased fruit and vegetable intake and risk reduction are difficult to predict.

## Cardiovascular diseases

There is some limited evidence from randomized-controlled trials, which suggests that the effect of fruit and vegetables is not immediate for IHD. As was described in section 3.1, the DART study and the Lyon Diet Heart study examined the effect of dietary changes on the secondary prevention of myocardial infarction. The DART study showed no effect on mortality after two years, in the fat advice arm of the trial (advice to reduce fat intake and increase polyunsaturated to saturated fat ratio vs no advice) which was associated with an increased fruit and vegetable intake of about $50 \mathrm{~g} /$ day. However, the Lyon Diet Heart study showed that a Mediterranean-style diet had a marked protective effect on the rate of recurrence of myocardial infarction after 27 months, with an effect still maintained after four years of follow-up. The main disadvantage of these trials was that the interventions encompassed several dietary changes. As a result, it is not possible to estimate the specific influence of increasing fruit and vegetables intake.

Evidence for the specific benefits of an increase in fruit and vegetable intake on cardiovascular health comes from the IEIS and the DASH trial.
Table 9.28 Summary of relative risks ( $95 \% \mathrm{Cl}$ ), for selected diseases with increased fruit and vegetable consumption by

| Outcome | Age group (years) |  |  |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |

| Note: Unit of change in risk is change per $80 \mathrm{~g} /$ day increase in fruit and vegetable intake. |  |  |  |  |  |  |  |  |

As was described in section 3.1, the IEIS showed that after only one year, cardiac events and mortality were reduced by $40 \%$ and $45 \%$, respectively, in a group of men who had previously suffered an acute myocardial infarction and who followed a low-fat fruit and vegetable-rich diet compared with men on a standard low-fat diet (Singh et al. 1993a). The DASH trial showed that hypertensive individuals achieved a reduction in their blood pressure after eight weeks of dietary changes (Conlin et al. 2000; Obarzanek et al. 2001). Both a diet rich in fruit and vegetables and a combination diet rich in fruit and vegetables and low in saturated fat, fat and cholesterol reduced systolic and diastolic blood pressure. After eight weeks, $70 \%$ of the participants on a combination diet rich in fruit and vegetables and low in saturated fat, fat and cholesterol, had a normal blood pressure, with $45 \%$ of those on a diet rich in fruit and vegetables, and $23 \%$ of those on a control diet. The true long-term effect of such dietary changes needs to be assessed using studies of longer duration.

Further evidence for risk reversibility of cardiovascular disease comes from time series analyses in countries of central and eastern Europe. One natural experiment in terms of rapid dietary change occurred with the reunification of Germany in 1989. After reunification, fruit and vegetable availability increased markedly, doubling between 1989 and 1992 (J.W. Powles, personal communication, 2001). But although the previous decline in vascular disease mortality accelerated, the change of trend was not noticeably greater than that in Poland and the Czech and Slovak republics where the increase in fruit and vegetable consumption was almost certainly less marked. However, the results of an ecological study performed in Poland suggested that the observed increase in supply of fresh fruit and vegetables and changes in the type of dietary fat between 1986-1990 and 1994 may have had a short-term positive effect on mortality risk (Zatonski et al. 1998). This study investigated the reasons for the decline in deaths attributed to IHD in Poland since 1991 after two decades of rising rates. For most of the potentially explanatory variables studied (i.e. alcohol consumption, cigarette smoking, socioeconomic indices and medical services) there were no corresponding changes in trend. The authors concluded that dietary changes could provide the best explanation to the reduced IHD mortality rates, with an effect noticeable within four years. While these findings cannot be dismissed, due to the limitations of ecological studies, these exploratory analyses would need to be confirmed with stronger study designs.

## Cancer

The evidence for cancer outcomes is more limited and comes from one major source. The NHS/HPFS studies have both collected dietary intake data repeatedly during a long follow-up period. This enables the examination of the temporal aspects of diet-cancer associations, although this has not yet been published for all the cancer outcomes covered in this
report. For lung cancer risk, the findings support a relatively long latency period for carotenoids (used as a proxy for fruit and vegetable intake), consistent with the known natural history of the disease, and suggest that the critical period for exposure to carotenoids to maximize protection may be between four to eight years before diagnosis (Michaud et al. 2000). This may explain why some observational studies and short supplement intervention trials may not have detected a significant association.

## Proposed risk reversibility for the CRA project

Assuming that the future population intake of fruit and vegetables is increased to the proposed counterfactual, we propose the following estimates of risk reduction:

- ten per cent reduction in relative risk in four years for IHD and stroke; and
- ten per cent reduction in relative risk in eight years for cancer outcomes.

Due to the current limitations of the evidence, it is assumed that risk reversibility following an increase in fruit and vegetable consumption is age independent and that it does not vary among subregions. As this may not be the case, the estimates should be seen as first approximations. Due to the high level of uncertainty, it is proposed that a $\pm 10 \%$ range of error is included in the calculations of avoidable burden for the CRA project.

### 3.9 Quantitative and qualitative sources of uncertainty in MEASURING THE DIET-DISEASE RELATIONSHIP

There are several sources of uncertainty in risk assessment. Some of these will be described in this section with regard to the study of the relationship between fruit and vegetable intake and health outcomes. It is likely that these underestimate the true level of uncertainty that affected the estimates presented in this report.

Little is known of the relative importance of early and late dietary exposure of fruit and vegetables for the risk of the chronic diseases examined in this report. Results from the Boyd Orr cohort suggest that fruit and vegetable intake in childhood could have a protective effect on the risk of cancer in adulthood (Maynard et al. 2003). However, we do not know whether an increased intake of fruit and vegetables is more important in young or middle age for greatest risk reversibility. Hence, it is not possible to comment on how the time trends of risk reversibility may vary among age groups.

In this project, it was assumed that there was no difference in relative risk across populations. However, it is not possible to verify whether this assumption is true as the study populations covered by the literature review were from limited geographical areas and ethnic groups. The
majority of cohort studies were from China, Japan, the United States and Europe, although there was at least one case-control study from the following countries: Australia, Brazil, China (Hong Kong SAR), India, Mexico, the Republic of Korea, Singapore, Turkey, Uruguay and Venezuela.

Relative risks in the developed world may not provide good estimates of the effect in the less developed world. For example, the impact of increasing fruit and vegetable intake may be stronger in undernourished, micronutrient-poor (e.g. vitamin A deficiency) populations in developing countries. However, this has to be considered in the wider context of nutritional requirements (energy and protein may be more important for survival in some populations) and relative causes of deaths (noncommunicable diseases may not be as important killers as in developed countries).

One possibility refers to the ascertainment of exposure. There remains considerable uncertainty as to which constituents, or combination of constituents, of fruit and vegetables would confer a protective effect. Several components have been suggested, but it is unlikely that any single compound will capture the benefits, which seem to arise from a varied diet rich in fruit and vegetables. The sources of uncertainty described for exposure measurement in section 2.9 also need to be taken into account here. Errors in measurement of dietary intake mean that the strength of true associations, if they exist, is likely to be reduced. In addition, the definition of the exposure as "fruit and vegetables" introduces a substantial amount of non-specificity with the resultant potential attenuation of underlying causal relations. That is, the currently unknown active constituents contained within the category "fruit and vegetables" are likely to have a varying quantitative relationship to the less specific category of fruit and vegetables. This is especially important across food cultures with substantial differences in the make-up of foods that constitute the fruit and vegetable group, but also applies even within cultures because of differences in food composition. At a minimum, this suggests that findings of protective associations between fruit and vegetable consumption and a specific disease within one food culture may not generalize well to another culture where the fruit and vegetables in the diet are constituted by different foods-in which the causally active constituents may be present to substantially differing amounts.

Another major source of uncertainty refers to the fact that confounding is a real possibility in observational studies of the relationship between fruit and vegetable intake and health outcomes. Although the studies considered in this project have attempted to adjust for confounding, measurement error in the assessment of potential confounders and the possibility of residual confounding need to be considered.

## 4. Discussion of estimates of attributable burden

The results of the analysis showed that a lack of dietary fruit and vegetables contributes an important share of the worldwide disease burden. It was estimated that increasing individual fruit and vegetable consumption up to the theoretical-minimum-risk distribution could reduce the worldwide burden of disease for IHD and ischaemic stroke by about $31 \% ~(30 \%$ for men and $31 \%$ for women) and $19 \% ~(18 \%$ for men and $19 \%$ for women), respectively. For cancers of the stomach and oesophagus, the potential reduction in disease attributable to an increase in fruit and vegetable intake was $19 \%$ and $20 \%$, respectively. Attributable risk fractions were lower for lung and colorectal cancers ( $12 \%$ and $2 \%$ ).

There were relatively few sex and age differences in the attributable fractions of disease attributable to low fruit and vegetable consumption, mainly because relative risk estimates were assumed to be constant in all adult men and women. However, larger variations were observed in the estimates of attributable DALYs due to low fruit and vegetable intake, as this is a function of both the attributable fractions and the amount of burden of disease accounted for by each health outcome studied in the various age-sex groups, itself affected by other risk factors. The number of DALYs was generally higher in men (except for stroke). As expected for chronic diseases, it tended to be lower in young adults.

There were some subregional variations in the attributable risk fractions and number of DALYs attributable to low fruit and vegetable intake. These tended to reflect differences in exposure levels and disease patterns among subregions.

The total worldwide mortality attributable to inadequate fruit and vegetable consumption was estimated to be 2.726 million deaths or 26.662 million DALYs in 2000. These results need to be interpreted in the light of the current limitations of the methods used, as described earlier in the chapter (e.g. residual confounding, misclassification of exposure). However, they highlight that increasing fruit and vegetable consumption could play an important role in improving public health worldwide.

## 5. Methods for projection of FUTURE EXPOSURE

An aggregate approach based on subregional trends in fruit and vegetable availability was used to project future exposure levels. The methods used are described below.

### 5.1 Trends in fruit and vegetable availability over time

The projection of future fruit and vegetable consumption for the years 2000 to 2030 was based primarily on the observation of subregional
trends in fruit and vegetable availability. The FAO food balance sheet data (FAO 2001) show that there has been an overall worldwide increase in the availability of fruit and vegetables during the past decades. However, large variations exist, among subregions and countries, in the observed trends and amounts available. These variations are described below.

FAO food balance sheet statistics (1961-1999) for each country were used to calculate three-year average subregional fruit and vegetable availability. These calculations show that there has been a relatively steady increasing trend in availability in AMR-A, AMR-B, EMR-D, EUR-A, SEAR-B, SEAR-D and WPR-B between 1961 and 1999. In contrast, downward trends have been observed since the late 1970s or early 1980s in WPR-A and AFR-E. However, as the trend has been slowing down in WPR-A during the last decade, we also assumed that the downward trend would stop. Based on the observed trends in AFR-D, we also assumed that the downward trend would stop in AFR-E. Large fluctuations were observed in AFR-D between 1961 and 1981, followed by a relatively steady increase in fruit and vegetable availability. In AMR-D, the trend also was downwards between the late 1960s until the early 1990s, but this has been followed by a small recovery. In EMR-B, a steep increase was seen between the early 1970s until the mid-1980s. This was followed by a decrease in fruit and vegetable availability between about 1985 and 1990. Thereafter, the trend has been upward again. Finally, in EUR-B and EUR-C, the general increase in fruit and vegetable availability observed during the 1960 s, 1970 s and early 1980 s was followed by a 10 -year decrease in availability. This coincided with the significant political and economic changes that occurred in the subregion before and after the collapse of the former Soviet Union. Around 1993/1994, the trend then changed and a recovery was observed. The current upward trend is relatively gradual in EUR-C, but relatively steep in EUR-B.

### 5.2 Predicting subregional fruit and vegetable intake то 2030

In order to predict subregional fruit and vegetable intakes by age and sex between 2000 and 2030, a two-step process was used. First, the predicted subregional availability figures were obtained using linear regression analyses with fruit and vegetable availability and time (years) as the dependent and independent variables, respectively. For subregions where a relatively steadily increasing trend was observed (AMR-A, AMR-B, EMR-D, EUR-A, SEAR-B, SEAR-D and WPR-B), FAO data from 1961 onwards were used. For WPR-A and AFR-E, it was conservatively assumed that a plateau was reached during the prediction period. For the other subregions, a case-by-case approach was used based on the trends observed. For AFR-D and AMR-D, 1978 and 1992 were used as respective cut-off points for the regression analyses, as these years rep-
resented a point in time where a steep downward trend was stopped. Both EUR-B and EUR-C have experienced large fluctuations recently, and it is thus very difficult to predict future trends. For EUR-C, 1993 was selected as a cut-off since the downward trend slowed down from that point in time. The conservative increasing trend from 1993 onwards was thus used to predict future fruit and vegetable availability in that subregion. In EUR-B, a steep upward trend was observed from 1993. However, it is assumed that this trend will slow down and thus the average of the trend from 1993 onwards and the trend during the last two decades (1980+) was arbitrarily chosen. A similar approach was used for EMR-B where it is assumed that the observed trend since 1988 is too steep to reflect future projections.

The second step calculated the proportional changes in fruit and vegetable availability between 1997 (arbitrarily selected as representing the time when intake data were obtained) and 2000, 2005, 2010, 2015, 2020, 2025 and 2030. These were then applied to the intake data presented in section 2.8 , assuming the same proportional increase in intakes in both genders and all age groups within each subregion.

The results obtained for AMR-D, EMR-B, EUR-B and EUR-C, which are based on smaller numbers of data points, should be treated with particular caution.

### 5.3 Limitations of the methods

The results obtained for the projected fruit and vegetable intakes need to be treated with caution as the approach used has several limitations. One major limitation is related to the lack of time trend data on fruit and vegetable intake around the world, and the resulting need to base the calculations on food balance sheet data. Availability statistics can be a useful tool to observe trends in food availability in the past. However, predicting availability in the future (outside the range of available data) using linear regression analysis and making the assumption that trends will not change, may lead to false conclusions as current trends may change in the next 30 years for many reasons. For example, had we undertaken this analysis for EUR-C 10 years previously, the results would have been completely different. The values obtained for EMR-B, for example, appear to be too high compared with those obtained for the other subregions. In addition, as food balance sheets reflect food availability and not food intake, it is not possible to know whether the relative changes in availability are explained by variations in intakes or by other changes such as an increase in waste at the household level.

Predicting fruit and vegetable consumption is especially difficult because of the range of factors influencing dietary intakes, including food availability, economic situation, seasons, cultural preferences, fashions and knowledge and potential interactions between these factors. To base future estimates of fruit and vegetable intake on the predicted levels of any one of these factors (e.g. predicted gross national product [GNP] of
a country in 20 years) is not justified, in part due to the lack of information on future trends in these factors themselves. Furthermore, assumptions of such relationships would overlook the multiple determinants of diet. For example, we have seen that intakes vary considerably among countries with similar GNP (e.g. Ireland, Italy and the United Kingdom). Thus, the predictions presented in this chapter simply assume a continuation of complex patterns of social, economic and agricultural development of these countries in recent years.

## Acknowledgements

We would like to thank Dan Altmann, Majid Ezzati and Steve Vander Hoorn for their statistical advice. The Stata program used to implement the method of Greenland and Longnecker was written and tested by Ian White.

We also wish to thank Aileen Robertson for her contributions, and to acknowledge the help of many people worldwide who provided us with data on fruit and vegetable intake, those who helped us identify potential sources of intake data and research evidence, and all those who offered advice on methods (see list below).

We would like to thank M.E. Rio, L. Cappelen, M.C. Perez Somigliana, N.M. de Parada, N. Piazza, B. Houssay, H. Lareyna, S. Closa, K. Baghurst, S. Record, S. De Henauw, S. Petrova, S. Fagt, M. Lahti Koski, G.B.M. Mensink, S. Friel, D. Nitzan Kaluski, R. Goldberg, A. Turrini, Y. Matsumura, N. Yoshiike, T. Sharmanov, J. Rivera Dommarco, L. Johansson, M. Deurenberg-Yap, T-Bee Yian, C. Suok-Kai, J.S. Hampl and B.M. Popkin for providing us with data stratified according to the GBD age-sex categories.

## Notes

1 See preface for an explanation of this term.
2 Estimating the subregional mean

- Estimation of the subregional (pooled) mean:
$\hat{\mu}=\frac{\sum N_{i} \times \bar{x}_{i}}{\sum N_{i}}$ where $i=1, \ldots, k$ sampled countries, $N_{\mathrm{i}}$ is the
population of the $i$ th country and $\bar{x}_{i}$ is the mean of the $i$ th country.
- $95 \%$ confidence interval (CI) for this estimator:

The variance of this estimator can be derived using:

$$
\operatorname{Var}(\hat{\mu})=\left(\frac{1}{\sum N_{i}}\right)^{2} \operatorname{Var}\left(\sum N_{i} \times \bar{x}_{i}\right)
$$

and assuming the means are independent

$$
=\left(\frac{1}{\sum N_{i}}\right)^{2} \sum \operatorname{Var}\left(N_{i} \times \bar{x}_{i}\right)=\left(\frac{1}{\sum N_{i}}\right)^{2} \sum N_{i}^{2} \operatorname{Var}\left(\bar{x}_{i}\right)
$$

Where now:
$\operatorname{Var}\left(\bar{x}_{i}\right)=\frac{s_{i}^{2}}{n_{i}}\left(1-\frac{n_{i}}{N_{i}}\right)$, with $s_{i}$ the standard deviation for the $i$ th country, sample size $n_{i}$.
The term $\left(1-\frac{n_{i}}{N_{i}}\right)$ is the finite population correction.
The standard error of the estimator is the square root of the variance.
The $95 \%$ CI for the subregional (pooled) mean is calculated as:
$=$ Subregional mean $\pm$ (1.96 x standard error of this estimator $)$
Estimating the subregional standard deviation

- Estimation of the subregional (pooled) variance and standard deviation:

$$
\hat{\sigma}^{2}=\frac{\sum N_{i} \times s_{i}^{2}}{\sum N_{i}}=\hat{\sigma}^{2}=\frac{\sum N_{i} \times s_{i}^{2}}{N}
$$

where $\sigma^{2}=$ pooled variance for the subregion, $I=1, \ldots, k$ sampled countries, $N_{\mathrm{i}}$ is the population of the $i$ th country and $s_{i}^{2}$ is the variance (square of SD ) of the $i$ th country; N is the sum of the $\mathrm{N}_{\mathrm{i}}$, in other words the sum of the populations of the sampled countries. This is unbiased because the expected value of a sample country's variance is the subregional variance, that is, $\mathrm{E}\left(s_{i}^{2}\right)=\sigma^{2}$,
then $\mathrm{E}\left(\hat{\sigma}^{2}\right)=\frac{1}{N} \sum N_{i} E\left(s_{i}^{2}\right)=\frac{1}{N} \sigma^{2} \sum N_{i}=\sigma^{2}$

- $95 \%$ CI for this estimator:

The $95 \%$ CI for the subregional (pooled) variance $\left(\hat{\sigma}^{2}\right)$ is approximated using:
Lower CI $=$ Subregional variance $\mathrm{x}(n-1) / \chi^{2}(n-1,0.025)$
Upper CI $=$ Subregional variance $\mathrm{x}(n-1) / \chi^{2}(n-1,0.975)$
where $n=\left(\sum n_{i}\right)$ and $n_{i}$ is the sample size for the $i$ th country: $n$ is thus the total size of the sample taken from the subregion.

# Physical inactivity 

Fiona C. Bull, Timothy P. Armstrong, Tracy Dixon, Sandra Ham, Andrea Neiman and Michael Pratt

## Summary

Physical inactivity is recognized as an important risk factor for multiple causes of death and chronic morbidity and disability.

Physical activity was chosen rather than physical fitness as the measure of exposure because it is through increases in the behaviour (physical activity) that health benefits accrue and improvements in cardiorespiratory fitness can be achieved. Moreover, there were insufficient data available worldwide to consider fitness as the exposure. Exposure was assessed as a trichotomous variable to avoid limiting the assessment of total burden to only that associated with the highest risk, namely the most inactive (a dichotomous approach). However due to a lack of data on physical inactivity, use of a more detailed (continuous) exposure variable was not possible nor was the use of a fourth category of "high activity". Therefore, our estimates of burden are likely to underestimate the total attributable burden to inactivity because of limitations with measures of exposure. Level 1 exposure (inactive) was defined as "doing no or very little physical activity at work, at home, for transport or in discretionary time". Level 2 exposure (insufficiently active) was defined as "doing some physical activity but less than 150 minutes of moderateintensity physical activity or 60 minutes of vigorous-intensity physical activity a week accumulated across work, home, transport or discretionary domains".

We found a wide range of survey instruments and methodologies have been used for collecting, analysing and reporting data on physical activity. Most data were available for discretionary-time activity, some data were found on occupational activity and little and no national data were available for transport- and domestic-related activity, respectively. A comprehensive literature search and contact with key agencies and known researchers uncovered over 50 data sets on physical inactivity in adult populations covering 43 countries across 13 subregions. ${ }^{1}$ However,
only 21 data sets covering 32 countries met our inclusion criteria. Hierarchical modelling techniques were used to predict discretionary-time activity using age, sex, geographic region and a measure of tertiary education. Linear regression was used to predict occupational activity and transport-related activity using two World Bank indicators (\% employed in agriculture and car ownership, respectively). We used these estimates to compute the level of total inactivity for 145 countries and aggregated these data to create estimates for 14 subregions.

The final global estimate for total inactivity (level 1 exposure) was $17.1 \%$ and this ranged from $10.3 \%$ in AFR-D to $24.8 \%$ in EUR-C. Across most but not all subregions females were slightly more inactive than males and younger adults were less inactive than older adults (range $9.6-46.8 \%$ across the 12 age-sex categories). The final global estimate for insufficient activity (level 2 exposure) was $40.6 \%$ and this ranged from $31.7 \%$ in AMR-D to $51.5 \%$ in WPR-A.

The independent causal relationship between physical inactivity and ischaemic heart disease, ischaemic stroke, type II diabetes, colon cancer and breast cancer is well established; we provided new estimates of the magnitude of risk associated with inactivity. A comprehensive search of literature from 1980 onwards identified well over 100 studies assessing the relationship between physical inactivity and the set of health outcomes that met our criteria. Also, several quantitative and qualitative reviews of the association between physical inactivity and ischaemic heart disease and stoke were found but there were no quantitative meta-analyses for breast cancer, colon cancer and type II diabetes. Most of the epidemiological studies meeting our inclusion criteria measured discretionary-time activity, some studies assessed occupational activity but only a few studies incorporated transport-related activity. No study included domestic-related physical activity. Given these data and differences between previous work and our definition of exposure, we completed a series of new meta-analyses for each health outcome. To address concerns regarding measurement error associated with physical activity, an adjustment factor was incorporated into the meta-analyses. All risk estimates were attenuated for ages 70 and over. There is emerging consensus on the protective effects of activity in regards to preventing falls, osteoarthritis and osteoporosis and impaired mental health but these disease end-points did not meet our inclusion criteria.

Globally physical inactivity accounted for $21.5 \%$ of ischaemic heart disease, $11 \%$ of ischaemic stroke, $14 \%$ of diabetes, $16 \%$ of colon cancer and $10 \%$ of breast cancer. The results show small differences between males and females, due in part to differences in level of exposure and to different distribution of events between men and women. In summary, physically inactive lifestyles accounted for $3.3 \%$ of deaths and 19 million disability-adjusted life years (DALYs) worldwide. There were small, nonsignificant differences in the attributable fractions across subregions. Due
to our conservative methods and a number of important limitations, our global estimates are likely to be an underestimate of the true burden attributable to inactive lifestyles.

## 1. Introduction

Physical inactivity is associated with many of the leading causes of death, chronic morbidity and disability. The apparent protective effect of being more active, and consequently less inactive, was identified first through studies of occupational activity over 50 years ago. Subsequent research has investigated different types, duration, frequency and intensity of activity in association with various cardiovascular, musculoskeletal and mental health outcomes. Today, there is a significant amount of literature quantifying and qualifying the role of physical inactivity as a risk factor and worldwide interest and efforts to increase levels of participation.

### 1.1 Choice of the exposure variable - physical activity or PHYSICAL FITNESS

There is substantial epidemiological evidence for the protective effects of both a physically active lifestyle and of various levels of physical fitness. Yet, to date, it is still not possible to determine whether one of these exposure variables is more important than the other (Blair et al. 2001). Thus, in theory, either variable could have been selected as the measure of exposure for this project. The final selection of physical activity over physical fitness was based on several reasons. Firstly, physical fitness is primarily determined by patterns of physical activity, particularly activity undertaken in recent weeks or months (Blair et al. 2001). Secondly, there is a genetic contribution to physical fitness and while of some importance, genetic makeup is likely to account for less variation than the lifestyle behaviour (Bouchard 2001). Thirdly, assessment of physical fitness in large samples of adult populations is rare across the majority of countries and infrequent in those countries in which it has been undertaken. Moreover, studies of fitness often exclude adults with certain chronic conditions. Fourthly, most national and international recommendations specify public health targets in terms of reaching thresholds of physical activity not levels of physical fitness.

It is acknowledged that one advantage of choosing physical fitness as the exposure variable would be the opportunity to use an objective, physical measure such as maximum oxygen uptake. This would be desirable for several reasons, including correspondence with many epidemiological studies assessing relative risk. Disadvantages to this approach, however, stem from the lack of nationally representative populationbased estimates, which outweigh the benefits. The difficulties associated with measuring behavioural risk factors are well known and the specific
challenges pertaining to measuring physical inactivity are discussed in detail in the following sections.

Therefore, considering the scientific support, the availability of data, and consistency with public health initiatives, physical activity was selected in preference to physical fitness as the measure of exposure. Given that protective benefits come from undertaking physical activity, from here on, the risk factor is specified as physical inactivity. It is, however, impossible to limit the discussion of both conceptual issues and the reporting of data to solely the "absence" of physical activity. Therefore the reader is forewarned that both physical activity and physical inactivity are discussed. In places the term "physical (in)activity" is used to refer to either activity or inactivity.

### 1.2 CONCEPTUAL FRAMEWORK AND DEFINITION OF PHYSICAL ACTIVITY

The definition of the exposure of physical inactivity was determined after consideration of a number of factors. These issues included: what types of activity across what domains would be included/excluded; what cutpoints between inactive and active would provide the greatest availability of data and opportunity for comparability across data sets and countries; and what cut-points would be consistent with established and emerging scientific evidence. Currently these issues are under considerable debate within the scientific community and there are no definitive answers. Thus, it is in advance of any consensus that a framework and workable definition of physical inactivity as an exposure is presented.

Traditionally, physical activity research has been interested in exercise defined as "planned, structured and repetitive bodily movement done to improve or maintain one or more components of physical fitness"(Caspersen and Stephens 1994). This interest focused attention towards certain types of exercise, mostly vigorous-intensity activities that were undertaken usually outside of work in recreational or discretionary time. In general terms it was acknowledged that some occupational or work-related activities could reach the threshold of vigorous-intensity and thus could potentially qualify as exercise and be beneficial to health. However, because technology and industrial development were causing a rapid decline in these occupations, particularly in developed countries, considerably less interest was invested in this direction. Moreover the opportunity to intervene was more promising outside the workplace. In essence, for those interested, particularly in developed countries, the focus was on exercise and the domain of "leisure-time". Many of the measurement instruments used today reflect this perspective.

A shift away from solely focusing on exercise started after the results from several large prospective cohort studies were published in the late 1980s and early 1990s. These studies were significant because they identified the protective effects of less intense physical activity (Blair and Jackson 2001; Blair et al. 1989, 1992, 2001). By 1996 these findings
were endorsed by several leading institutions and scientific organizations (Pate et al. 1995) and formed the primary focus of the U.S. Surgeon General's Report on Physical Activity and Health (U.S. Department of Health and Human Services 1996). Combined, the evidence and the widespread endorsement shifted the paradigm towards the benefits of moderate-intensity activity such that efforts more recently have been directed towards increasing the amount of moderate-intensity activity undertaken by all adults and children. Such activities include brisk walking ( $>3 \mathrm{mph}$ ), recreational cycling and swimming.

Some have viewed this shift as premature and raised concerns about the detrimental impact on the promotion of the known additional benefits that come from enhanced physical fitness. Furthermore, the exact nature and possible differences between the dose-response relationship between physical fitness and physical activity with various disease outcomes is still under intense debate (Bouchard 2001; Kesaniemi et al. 2001; Macera and Powell 2001). Meanwhile, the shift in focus has raised questions on the definition of "moderate-intensity", on what activities constituent moderate-intensity and on how to measure the prevalence of this broader range of activities within populations. Critically, it opened up the debate on whether activities undertaken in domains of life other than leisure-time can or should be considered beneficial and thus "counted".

The answers to these important questions are often populationspecific because different types of physical activities are undertaken between and within communities that differ across social, economic, geographical and religious aspects of life. Moreover, the importance of, or necessity for, physical activity in different domains of life differs between cultures. It is these differences and the complexity of measuring physical activity that have hindered the development of any international consensus on definitions and common instruments for assessing physical inactivity. Growing concern over these issues has led to several recent initiatives and considerable progress has been made toward developing a common measurement instrument for use in the future. The International Physical Activity Questionnaire (IPAQ) is a new instrument assessing total physical activity and sedentary behaviour (time spent sitting) developed by a group of international experts and tested in collaboration with researchers from 12 countries across six continents. IPAQ has demonstrated good-very good reliability and moderate criterion validity (Craig et al. 2003). Further details are available at http://www.ipaq.ki.se.

For the purpose of this project, it was acknowledged that physical (in)activity can occur across four domains: work, domestic, transport and discretionary time (see Figure 10.1). Each domain represents a sphere of daily life that is common to most populations regardless of culture or economic development and within each domain it is possible to be more or less active. The opportunity for, and the level of, physical (in)activity in each domain for any national population is dependent on

Figure 10.I Generic framework for four domains of physical (in)activity

| Work domain | Transport <br> domain | Domestic domain | Discretionary- <br> time domain |
| :---: | :---: | :---: | :---: |

Figure I 0.2 Relative importance of domains of physical (in)activity in two hypothetical countries

In country A, the work, domestic and transport domains contribute very little opportunity to be active. For example, this country may have well-established and complete coverage of water and electricity supply to homes and dwellings thus reducing the demands to be physically active in the domestic domain. Extensive car ownership with poor public transportation systems may have reduced the opportunity and need for activity in the transport domain. Work may have become more sedentary due to technological innovation. Thus the discretionary (leisure) domain represents the predominate domain where the greatest opportunity to be active exists. This may be typical of a developed country.

In country B, the work, domestic and transport domains contribute the most opportunity or most necessity to be active. For example, this may represent a country that has a high proportion of the adult population employed in agriculture or heavy industry both of which may require large amounts of vigorous physical exertion. Domestic activities may still involve carrying water and/or other food preparation techniques that require moderate- or vigorous-intensity physical activity. Transportation may be dominated by walking or cycling with minimal public transport alternatives and low car ownership. Relative to the previous domains, the discretionary domain may be much less important in terms of providing opportunity or need to be active for the population of this country. This may be typical of a developing country.
economic, technological, social, cultural and religious factors interacting at the individual, community and national level. Moreover, the relative importance of each domain, in terms of either representing an opportunity or necessity to be (in)active, will vary between and within countries over time. A generic model of this framework is shown in Figure 10.1 and two hypothetical countries ( a and b ) are shown in Figure 10.2, each with a brief description.

Using four domains as a framework for the definition of exposure is in contrast to many previous approaches to defining and measuring physical (in)activity, which made the task of searching for and interpreting global data on physical (in)activity more complex. National data on physical activity are not readily available in many parts of the world. There is even less data available across the four domains of work, domestic, transport and discretionary-time activity. Despite this limitation, the framework was selected because it presents the exposure variable in a way that has relevance to all countries around the globe. The framework
can be applied both now and in the foreseeable future, when many countries and large numbers of people are expected to experience major transitions in economic, social and health terms (Chockalingam 2000; Reddy and Yusuf 1998). The underpinning assumptions of our framework include: that physical activity can take place in different domains; that some of this activity is of sufficient intensity and duration to provide protective effects from certain diseases; and that the pattern of physical activity in each domain is very likely to vary across countries. The measurement issues related to each domain are discussed below.

### 1.3 Measurement issues

## INSTRUMENTS

There is currently no universal or even commonly used measure or instrument for physical (in)activity. This poses a serious limitation on efforts to compare levels of exposure across populations, a problem frequently cited in the literature and by others attempting international comparisons (Caspersen and Stephens 1994; IARC 2002).

Physical (in)activity is typically assessed using a series of questions as part of a self-administered or interviewer-administered questionnaire. The wording of the questions, the examples used (if any) and the response format can and do vary. A recent compendium of instruments illustrates the diversity of approaches, many of which are more suitable to the research environment rather than public health surveillance systems (Kriska and Caspersen 1997).

We undertook a review of instruments currently used to gather data at a national or large-scale population level and found that, in general, there are five different formats for questions assessing discretionary-time and work-related activities. These range from items asking for a yes/no response regarding participation in listed activities (format 1) to detailed responses about frequency, duration and type of activity performed (format 5). The formats for questions assessing physical (in)activity in these two domains are outlined in Table 10.1, and the limitations are briefly mentioned below. Few instruments were found that assessed transport-related and domestic activity.

## MEASURES OF DISCRETIONARY-TIME ACTIVITY

Instruments vary in both their intention and ability to capture details on different aspects of discretionary-time physical activities, namely: the specific type of activity (e.g. swimming, tennis, gardening, cycling); frequency (how many times in a specified time frame); duration (usually in minutes); and intensity (e.g. light, moderate, vigorous). Moreover, they use a variety of referent time frames (e.g. last week, last month, usual week, past year).

Format 1 and format 2 (Table 10.1) are similar in assessing frequency and duration of specific types of activity (either prompted or

Table 10.I Summary of five formats of questions assessing physical (in)activity

| Format | Question/response format | Example |
| :--- | :--- | :---: |
| Discretionary (leisure) time |  |  |
| I | Question presents a list of sports/activities. Response | Europe (Institute of |
|  | options are usually Yes/No. If yes, then frequency and | European Food |
| duration (minutes) are usually assessed. Reference time | Studies 200I) |  |
| frame vary from one week to 12 months | Brazil (Datafohla I997) |  |
|  |  | New Zealand (Hillary |
|  |  | Commission I998) |
|  |  | Canada (C. Craig, |
|  |  | unpublished data, |
|  |  | 200I) |
|  |  | USA (CDC I998) | undertaken but no lists are shown/provided. Selected examples may or may not have been provided. If yes, type, frequency and duration (minutes) are usually assessed. Intensity of activity may be recorded also

3

4 All activities over a specific time frame are recorded (e.g. last 24 hours or last 7 days). Responses include duration (minutes) and can be recorded by intensity and/or by domain

5 A series of questions assess participation in categories of activities usually defined by intensity (e.g. moderate-intensity or vigorous intensity). Examples usually provided. Response is usually Yes/No and if yes, frequency and duration (minutes) recorded. Walking as a specific activity can be asked either as a separate question specifying which types of walking to include (all walking, not at work, for transport) or walking is given as an example within the category of moderate-intensity activity

## Work-related

I Question asks respondents to indicate which description best describes their work "mostly" or "usually".
Response categories are often: I) primarily sitting/standing; 2) a lot of walking; 3) hard physical (sweat) labour

| 2 | Question asks respondents to indicate how much time spent doing specific categories of activity (e.g. sitting/standing, walking, hard physical labour). Response scale may vary and can include either hours per day or proportion of time at work | Canada (C. Craig, unpublished data, 2001) <br> Europe (Institute of European Food Studies 2001) |
| 3 | Singular or multiple questions assess participation in categories of work activities defined by intensity (e.g. light or very light, moderate, heavy or very heavy). Examples of tasks or occupations may be provided for each category. Hours or portions of time may or may not be provided | China (North Carolina Population Center 200 Ib) <br> Estonia, Latvia, Lithuania (Pomerleau et al. 2000) |
| 4 | Questions assess frequency and sometimes duration of specific tasks undertaken within a reference time period (e.g. 2-12 months) are recorded. Respondents are prompted with a list of activities | Japan (lwai et al. 2000) |
| 5 | Occupational activity is assessed by classification of type of employment (e.g. brick layer, nurse) or occupation (e.g. professional, blue collar) | Not used by any study included in this chapter |

unprompted). Format 5 assesses categories of activities defined by intensity; the number and type of examples provided can vary. Additional criteria on minimum duration may also be specified. The diary or day-by-day recall methods are grouped together as format 4. However, format 3 is the most distinct set of instruments focusing on the level of activity, rather than its type or purpose. As a group they represent instruments that present categories or descriptions and use various response options, such as: pick the best description, or a Likert scale assessing frequency or duration, or scales such as 1-3 times/week, 4-6 times/week, 1-2 times/month.

Within each of the five formats, questions can be structured to assess level of activity in the discretionary-time domain only or they can address multiple domains. The latter, of course, makes it difficult to compare results across instruments. In the former, respondents are usually instructed to limit the activities they consider. Exactly how each instrument partially or totally includes/excludes different activities can however vary, particularly in regard to the following activities: walking; gardening; domestic/yard tasks. In addition, the majority of instruments focus on assessing participation in endurance/aerobic activities, probably due to the extensive literature supporting the links to health. However, activities that build muscular strength and increase flexibility are also important and warrant further attention.

Currently there is insufficient evidence to classify any of the instruments as right or wrong, but they are clearly different and there is good evidence that different instruments will produce different estimates of particular behaviours (Pratt et al. 1999). Much research has been undertaken testing different measures of physical activity to assess their reliability and validity (Jacobs et al. 1993). The more frequently used instruments (such as the Minnesota Activity Questionnaire, Seven Day Activity Recall) have been tested for reliability and validity in more studies across diverse populations (Kriska and Caspersen 1997). However, the questions used to gather population health data are often not established instruments and often lack formal testing.

## Measures of work-RELATED ACTIVITY

In recent times work-related physical activity has received less attention than discretionary-time activity. Therefore, there are sparse data on patterns of activity at work and much speculation on the accuracy of recall of work activities, especially potential discrepancies between recall and actual intensity and duration of activity (Jacobs et al. 1993; Leenders et al. 2001). In particular, there is concern about the extent of overreporting because individuals may over-estimate intensity and/or duration of work-based activities.

The most frequently used approach to assessment in this domain is to ask about three types of activities chosen because they are common in many occupations (formats 1, 2 and 3 in Table 10.1). More specific assessment of work activity can be obtained using a detailed recall (diary) or prompted recall with a list of activities (format 4). Historically, job occupation has been used as a proxy measure for work-related physical (in)activity (format 5) but as technology and work practice differs between countries and over time this is deemed to be the least favoured approach. To date, there is little evidence on the reliability and validity of most of these instruments or approaches.

## MEASURES OF TRANSPORT-RELATED AND DOMESTIC ACTIVITY

Measurement of transport-related and domestic physical activities is the least well-developed area. There are few specific questions or instruments available and some activities in these domains are captured as part of questions aimed more at the discretionary or work-related domains. This confusion makes quantifying the prevalence of physical (in)activity in the transport and domestic domains very difficult.

Most of the available data on transport-related activity are from sources within the discipline of transportation. Usually these data are limited to trip origin and destination, distance, duration and mode (e.g. cycling, walking). How well they capture walking and cycling as part of multi-modal travel can vary. Also transportation surveys rarely capture the perceived intensity of the activity although a computed measure could be obtained if distance and duration were both assessed. Data on
patterns of transport are most often presented as modal split with total number of trips as the denominator; other metrics include miles of travel. Data in these formats are not readily integrated or compared with data from population health surveys on physical activity. Moreover, it is usually only in research projects that data on transport-related activities and physical activities in other domains are collected on the same individuals.

Assessment of domestic activities as a distinct domain is uncommon. If these activities are considered at all, they are usually included as examples within the structure of other questions. For example, washing floors or vacuuming can be given as examples of moderately-intense activities. However, within the field of diet and nutrition some researchers very carefully assess energy intake and energy expenditure. But for these purposes they often assess total energy expenditure using doubly-labelled water $\left(\mathrm{H}_{2} \mathrm{O}_{2}\right)$, direct observation or very detailed diary methods. There is currently no suitable, valid and reliable instrument for use in assessing activity in the domestic domain. It is, therefore, evident that further instrument development is needed to advance the assessment of physical (in)activity in both transport and domestic domains.

## Further issues related to measurement methodology

In addition to the use of a variety of instruments, the method of data collection can vary. Self-report instruments continue to be the most widely used method for assessing physical activity in adults (Sallis and Saelens 2000), particularly in developed countries. In these countries widespread coverage of telecommunications has led to increased use of telephone-based surveillance systems (e.g. the Behavioral Risk Factor Surveillance System in the United States of America). In contrast, household surveys remain more common in other regions (e.g. Central and South America, Asia, Africa). There is no scientific evidence to support one methodology over the other in terms of accuracy of data on physical activity. But it is possible that each method may obtain different estimates of the behaviour. If the magnitude and direction of this difference were known for different populations it would be possible to include some statistical adjustment. However, in the absence of this information the inclusion of data collected using different interview methods will be a limitation to our estimates.

Patterns of physical activity are known to vary across different climatic seasons (Pratt et al. 1999). Ideally national estimates would be based on data collected across all seasons (a 12 -month period) or data collection would be limited to a specified season. Cross-country and global comparisons could then be conducted either using only data collected in comparable seasons or only data collected over all seasons. Needless to say, with the overall dearth of data on physical (in)activity it was not possible to impose seasonality criteria within this project and this feature of the data will be another limitation to our final estimates.

### 1.4 Quantifying levels of exposure

Once data on physical (in)activity have been collected using any one of the approaches described above, the data can be treated as either a continuous or categorical variable. There are examples of both approaches with national data from around the world. Both approaches were considered for this project but due to the availability and comparability of data we chose to treat physical inactivity as a trichotomous categorical variable. A brief description of both approaches is provided below.

## Treating physical (in)activity as a continuous variable

Minutes of activity can be presented as a continuous variable either as mean minutes per specified time frame (e.g. per week or per day) or it can be used to derive an estimate of energy expenditure expressed as metabolic cost (metabolic equivalent, MET) or kilocalories/kilojoules ( $\mathrm{kcal} / \mathrm{kJ})$. One MET represents the metabolic rate of an individual at rest and is set as $3.5 \mathrm{ml} \mathrm{O} 2 / \mathrm{kg}$ per minute or approximately $1 \mathrm{kcal} / \mathrm{kg}$ per hour (Kriska and Caspersen 1997). With this approach, analysts use available lists of the energy requirements of specific activities (Ainsworth et al. 2000) or standard MET values for categories of activity. For example, the following MET values are frequently, but not consistently, applied to the following categories: vigorous-intensity activities $=>6$ METs; moderate-intensity activities $=3-6 \mathrm{METs}$ ( $=4.5$ ); walking $=3$ METs (Ainsworth et al. 2000). Energy requirements of a large number of tasks across all four domains are available (Ainsworth et al. 2000).

The continuous measures were not selected as the basis for the definition of the exposure, nor were data in these formats available for use in any other way for two reasons. Firstly, these estimates were derived from different instruments, and each analysis used different criteria to compute their estimates. Thus, large variability prohibited comparability despite the seemingly similar continuous measures of risk. Secondly, data obtained as mean minutes, mean kcals or mean MET minutes of activity could not be used to compute the distribution of exposure because the relationship between these values and the pattern of inactivity in a population is not known. In contrast, the relationship between mean body mass index (BMI) and the prevalence of obesity in populations has been explored.

## Treating physical (in)activity as a categorical variable

A current trend in analysing population data on physical (in)activity is to collapse the continuous data on minutes of activity into a categorical variable and report the prevalence estimates of each category. This is undertaken for each specific type of activity (e.g. walking, sports, lifting loads, climbing stairs) or more usually, the total amount of time spent doing physical activities assigned to different categories (e.g. total minutes of moderate-intensity or vigorous-intensity activity or heavy
physical labour). The total of all activity can be calculated by summing all minutes of each activity or each category. However, close inspection reveals that these general approaches can include or exclude some specific physical activities or some domains depending on the investigators' purview. For example, gardening activities may be asked about but not included in calculations of activity (Armstrong et al. 2000) or workrelated activity may be assessed but excluded or else reported separately from discretionary-time activity (Pomerleau et al. 2000). These specific analytic details necessitate very careful attention before comparisons between data sets can be attempted.

It has also become quite common among those dealing with national or regional surveillance data to present categorical data and to select the categories that correspond with various national public health guidelines or goals. A recent development has been the reporting of data as a measure of "recommended" or "sufficient" levels of activity in accordance with the U.S. Surgeon Generals' Report on Physical Activity and Health (U.S. Department of Health and Human Services 1996). This recommendation states that " 30 minutes of moderate-intensity activity on most, if not all days of the week" is recommended for all adults. It is often, but not always interpreted and analysed as 150 minutes of moderate-intensity activity over at least five sessions or day/week. But there is still sufficient variation between the ways in which this recommendation is interpreted to make seemingly simple comparisons somewhat difficult.

### 1.5 Correspondence between measures of exposure used in population surveys and epidemiological research

The majority of epidemiological studies have explored the relationship between activity and disease outcomes by dividing level of activity into two or more groups. This is true whether the exposure was physical activity or physical fitness. The nature of the dose-response relationship has been explored using dichotomous categories (Morris et al. 1980), tertiles (Bijnen et al. 1998), quartiles (Folsom et al. 1985) and quintiles (Singh et al. 1998). Although continuous data are usually preferred because this maximizes the opportunity to detect associations, use of categorical data is warranted when the association may not be linear. Indeed, the nature of the curvilinear or linear relationship between physical activity and disease outcomes is a major focus of current research efforts (Blair et al. 2001; Kesaniemi et al. 2001; Williams 2001). Three possible relationships are illustrated in Figure 10.3. One contemporary view supports the presence of a threshold as shown by curve B in Figure 10.3, particularly for cardiovascular end-points. Curve B indicates that the greatest reduction in risk comes from increases at the lower levels of activity. Experts involved in a recent evidence-based symposium concluded that there is "an inverse and generally linear relationship for the rates of all-cause mortality, total cardiovascular disease, and

Figure 10.3 A schema of three possible relationships between physical inactivity and disease end-points

Increasing level of physical activity
coronary heart disease incidence and mortality and for the incidence of type 2 diabetes mellitus", a position reflected in curve C (Kesaniemi et al. 2001).

While the debate on the exact shape of the relationship is likely to continue, the use of categorical data may be justified given the known difficulties (i.e. error) associated with both the measurement instruments used to assess physical (in)activity and respondent recall of the behaviour. Under these circumstances continuous data may present an artificial level of accuracy and specificity.

It is worth noting one additional difficulty that obscures the level of correspondence between measures and thus the accurate application of relative risk results from epidemiological studies to prevalence estimates in order to calculate population attributable risk and the burden of disease. Namely, the lack of detailed descriptions of the absolute values of activity represented by the investigators' chosen categories. For instance, it is difficult to compare the level of activity in the lowest tertile of activity from study A with study B unless the activity level is defined and reported. Likewise it is almost impossible to make accurate interpretations of tertiles and quartiles without appropriate descriptive statistics for each group. This omission necessitates qualitative judgements when comparing or pooling results across studies and may obscure the strength and nature of the disease-risk factor association.

Notwithstanding, these are important limitations; currently the greatest concordance between measures of physical activity used in epidemiological studies and population surveillance is found at the lower and
upper ends of the physical activity continuum. Application of the relative risk results for the least active group (be it tertile, quartile or quintile) to prevalence estimates for lowest level of activity in whole populations is possible. There is, however, less certainty surrounding the agreement between measures of low-mid levels and mid-upper levels of exposure.

Measurement error associated with assessing exposure to physical inactivity is a major limitation to this project. We addressed this problem in several ways. Our treatment of the exposure as a trichotomous variable avoids presenting a misleading level of accuracy. The definition of the categories corresponds with our greatest level of confidence in the accuracy of our data, particularly at the lower end. Our definitions and estimates of exposure within each domain accommodate the known or suspected direction of measurement error. Finally, as we describe in our review of epidemiology, our pooled meta-analyses included an adjustment for measurement error based on available evidence of reliability of the instruments used in each study.

### 1.6 Definition of exposure

In balancing the need for a conceptual framework with global relevance, concordance with the epidemiological evidence, current public health recommendations, as well as the limited availability of national data, the following definitions of a three level exposure of physical inactivity were developed:

## Exposed

Level 1 Inactive:
defined as doing no or very little physical activity at work, at home, for transport or during discretionary time.

Level 2 Insufficiently active:
defined as doing some physical activity but less than 150 minutes of moderate-intensity physical activity or 60 minutes of vigorous-intensity physical activity a week accumulated across work, home, transport or discretionary domains.

## Unexposed

Level 3 Sufficiently active:
defined as at least 150 minutes of moderate-intensity physical activity or 60 minutes of vigorous-intensity physical activity a week accumulated across work, home, transport or discretionary domains, which approximately corresponds to current recommendations in many countries.

In the work domain, inactive was defined as not doing any "hard" or "vigorous" physical activities at work. Where needed, we classified those that reported "mostly walking" or "mostly standing" or any equivalent category, as inactive. The effect of our definition is to potentially inflate
the proportion classified as inactive at work because some adults may perform these tasks during their work in combinations of duration and intensity sufficient to gain some health benefits. However this is perhaps counterbalanced by at least some likely misclassification of adults as active due to "heavy" activity. In the absence of data with sufficient detail and no prior evidence on which to base our classification, our definition reflects the limitations of measurement in this domain.

Inactive in the transport domain was defined as no walking or cycling trips. Therefore, a single walk or cycle trip was sufficient for an adult to be classified as active in this domain. With few data on trips per person and no data on trip intensity or duration we accepted all walking and cycling trips as activity that could provide some health benefits. In contrast to the work domain this definition is lenient and the likely effect is to overestimate transport-related activity. However, unlike walking at work, which may be performed in short bouts and undertaken intermittently, transport-related activity may be of longer duration and undertaken at moderate-intensity. Inactive in the domestic domain was defined as no moderate- or vigorous-intensity domestic-related activity. However, with no national data worldwide we were unable to include this domain of activity in our assessment.

Insufficient activity was assessed by distinguishing between those adults who met the threshold of at least 150 minutes of moderateintensity physical activity accumulated from one or more domains from those adults who did not. Given the lack of national data using the same or equivalent definition, we used the limited available data to develop an algorithm to estimate the prevalence of this level of exposure in each country. Full details of our methods for assessing inactive (level 1) and insufficiently active (level 2) are described in section 2.

### 1.7 Age groups included-Adults but not children

Very few data were available on levels of (in)activity in children and adolescents. Moreover, the literature on children also includes a diversity of instruments and measurement methodologies (Sallis and Saelens 2000). Therefore, due to the magnitude of the task and the project timelines, the scope of this project was limited to quantifying exposure in the adult population only. Furthermore, there is limited epidemiological evidence demonstrating the level of current risk associated with inactivity and the selected health outcomes in populations aged $<18$ years.

### 1.8 Theoretical-minimum-Risk exposure distribution

For physical inactivity the theoretical-minimum-risk exposure distribution could be set as equal to the estimated proportion of the total population that would be physically unable to meet the basic requirement of "at least some activity" in at least one domain. Data from Australia $(2 \%)$ and the United States (4-6\%) indicate that total disability (as defined by each country) is well below $10 \%$ of the population but it is
unknown as to what proportion of this sub-population would be unable to do at least some physical activity.

Conceptually the theoretical-minimum-risk exposure is that level of activity which could theoretically occur if we could remove all individual, social and environmental causes of inactivity. Under such a scenario it is possible to consider a minimum that reflects all but the congenital causes of inactivity. As these are few, if any, and are likely to affect less that $1 \%$ of the whole population, we have chosen to set a theoretical minima as zero-a value that is comparable to other risk factors.

## 2. Estimating the prevalence of exposure

There were large gaps in the availability of nationally representative data on physical inactivity within some subregions and no data for several subregions. This was true across all four domains of activity included in the definition of exposure and both levels of exposure. To address this problem multivariate and linear regression analyses were conducted to create predicted values for missing data.

### 2.1 Search strategy

An extensive search was undertaken to identify studies reporting prevalence of inactivity for male and female adults (aged $\geq 15$ years) worldwide. A particular effort was made to identify data in developing regions to avoid the need to derive estimates for these countries solely on data from developed countries.

Data were sought on physical inactivity across four domains, namely, discretionary time, work-related, transport-related and domestic. The initial search identified several studies in which population-based estimates of physical (in)activity were reported as a risk factor for specific diseases. Based upon these findings, a second search was conducted to include as keywords those diseases where physical inactivity has been shown to have a relationship, in both prevention and as a risk factor. For example, diabetes, cardiovascular disease, obesity and cancer were keywords used in the second search. Papers reporting data on physical inactivity in one or more domains were accepted for consideration. However, our search most frequently identified estimates for discretionary-time activity and rarely data on occupational, transportation or domestic (household) physical activity. Therefore separate searches for occupational and/or work, transportation and domestic domains were performed. For all searches, country names were included when global, international and/or world keywords were not used.

Publications reporting data collected between 1996 and 2000 were sought because the primary goal was to estimate prevalence of inactivity in the year 2000 .

## ELECTRONIC LITERATURE SEARCH

Medline, HealthStar and Chronic Disease Prevention searches were systematically conducted for studies published between 1996 and 2001 and limited to English (both United Kingdom and American English spellings) and Spanish languages. Additionally, multiple queries for each keyword were used. For example diabetes AND physical activity AND country X.

The following keywords were used:

- exercise, physical fitness, physical exercise, physical (in)activity, sedentary, energy expenditure;
- chronic disease prevention, diabetes, cancer, cardiovascular disease, hypertension, obesity;
- international, global, world, developing countries, country names;
- monograph, statistics, survey(s), prevalence;
- transportation (and physical activity/energy expenditure);
- occupation (and physical activity/energy expenditure and activity); and
- domestic (and physical activity/energy expenditure and activity).

## Electronic Listserve

A request for assistance in locating "gray" or fugitive literature (e.g. government and non-government agency reports) as well as unpublished data was posted on a cardiovascular listserve (procor-dialogue@ healthnet.org).

## Government and non-government agencies

World Health Organization (WHO) Headquarters, WHO Regional Offices, WHO collaborating centres and partner organizations worldwide were contacted to assist in identifying authors, researchers, organizations and institutions in obtaining national data on prevalence of physical activity, either at the country, regional or municipal level.

Authors of relevant papers, ReLEVANT ACADEMIC INSTITUTIONS AND EXPERTS IN THE FIELD
Direct contacts were made with national governments, private and public institutions and individual authors to enquire whether unpublished or published data were available in English or other languages.

### 2.2 CRITERIA FOR CONSIDERING SOURCES AND STUDY INCLUSION

 All identified studies were reviewed and included if they fulfilled the following criteria.Time frame-data were obtained between 1996 and 2001. However, if there were no other data available for the country/region, studies reporting data collected after 1990 were considered.

Sample-studies reporting data from large, randomly selected, nationally representative samples with a wide age range were preferred. However, given this was not available in the majority of countries, studies with smaller samples, regional representative samples or narrow age ranges were considered.

Measure of exposure-the proportion of the population exposed (inactive) in one or more domains (discretionary time, occupational, domestic, transport-related) was required. In cases where data were presented as mean minutes, METs, total energy expenditure (kcals) or in any other way, the authors were contacted and asked to provide the data expressed as a proportion of the sample population. Where possible authors were asked to use our definition of exposure (overall inactivity) and/or the definition of inactivity relevant to each domain. If these data were obtained, they were considered for inclusion.

Measurement instrument—studies reported (or later provided) the instrument used to assess physical activity. As no standard measure of physical activity exists each instrument or set of questions was reviewed in this work. Those studies using previously published instruments assessing physical activity in one or more domain were accepted. Studies using questions unknown to the authors were assessed for face validity. A study was included only if it was deemed that the question(s) would provide reasonably comparable estimates.

Data collection-studies were included if data were collected by telephone survey, face-to face interview or during a physical examination.

### 2.3 Methods for selecting estimates where more than one DATA SOURCE EXISTED

The following criteria were used to select data sources in cases where more than one source was available for a country or group of countries:

- the most recent data source-in some cases this meant the data were not yet in the public domain and specific analyses were undertaken for this project;
- nationally representative data or the study that allowed the best approximation of a national sample considering the studies representativeness and coverage of the desirable age range;
- a single study with common methods and representative population data from many countries was preferred over equal quality studies from individual countries; and
- the study providing the most comparable measure of physical inactivity as defined in this study.

### 2.4 Description of studies, including METHODOLOGICAL QUALITIES

Overall our search identified over 50 studies containing measures of physical (in)activity in one or more domain. These data covered 43 countries and 13 subregions. However, not all studies met the inclusion criteria and for some studies we were unable to obtain data in the desired format within the study time frame. Thus, our final analyses were conducted using 17 data sets for discretionary-time activity, two data sets for work-related activity and five data sets for transport-related physical activity representing 34 countries across 10 subregions. Figure 10.4 illustrates data coverage by country showing those countries that had data that met our inclusion criteria. Table 10.2 shows the proportion of the adult population for which we had data for each subregion (calculated by 12 age and sex categories).

Figure 10.4 Exposure data coverage by country ${ }^{\text {a }}$

Table I0.2 Proportion of the adult population for which there were data on physical inactivity, by subregion

| Subregion | Population in subregion (000s) | \% population within <br> subregion covered with data |
| :---: | :---: | :---: |
| AFR D | 164917 | 0 |
| E | 192766 | 15 |
| AMR A | 255419 | 96 |
| B | 297674 | 48 |
| D | 44658 | 34 |
| EMR | 86854 | 7 |
|  | D | 204038 |
| EUR | 342220 | 21 |
|  | B | 161213 |

Table 10.3 provides an overview of the studies reviewed with details on the data source, sample characteristics and the domains of physical activity assessed by country and subregion. Overall, over $90 \%$ of the data sources comprised nationally representative samples and all data were collected using a random sampling methodology. Sample sizes ranged from 226 in Ethiopia (Alemu and Lindtjorn 1995) to 16000 in China (Du et al. 2002) with the majority of studies including between 2000 and 4000 subjects. Most data were collected as part of either national surveys or ongoing monitoring systems or as part of a research project. There is one example of data from a commercial marketing company (Instituto Gallup De La Argentina 2001) and one example of a large multi-country study (Martinez-Gonzalez et al. 2000). The foci of research studies were most often cardiovascular disease, hypertension or diabetes. All data were collected after 1990.

The majority of data were collected using a questionnaire assessing multiple lifestyle risk factors although several studies collected data on physical activity only (e.g. Australia). Only a few studies assessed occupational activity as a separate domain and typically these questions assessed prevalence of three types of occupational activity, for example "mostly walking", "mostly standing" or "mostly heavy labour". Very few data were found on transport-related activity. Specific items on trans-port-related activity were included in only one of the health surveys (China) (North Carolina Population Center 2001b) although several other countries included walking or cycling for transport within the context of their physical activity questions. No studies were found reporting national data on physical activity in the domestic domain

alone. Like transport, domestic activities were sometimes included within the context of broader questions, particularly in instruments developed for use in developing countries. Details of the questionnaire, the domains and definition of inactivity for each data set included in the analyses are provided in Tables 10.4-10.6.

Below are brief summaries of the data found and included, described by geographical region.

## AFrica

Finding data on physical activity from countries in the African Region was most difficult.

Several studies were found for various sub-populations in South Africa (Levitt et al. 1993, 1999; Sparling et al. 1994; Steyn et al. 1985, 1991). But these were regional studies with modest sample sizes. In the absence of a single study with a nationally representative sample, published data from the larger, more recent risk factor study in a black population (known as the Black Risk Study, BRISK) (Steyn et al. 1991) were selected to represent the black South African population. Estimates of inactivity among the white South African population were imputed from American data after a qualitative assessment (Lambert 2001) of the similarities in urban lifestyles. Given national estimates from the United States include white and non-white populations, the extrapolation to white south Africans may slightly underestimate levels of activity. This approach adds greater uncertainty to the estimates for this region and this is addressed in later sections.

Data from two small studies, one in rural Ethiopia (Alemu and Lindtjorn 1995) and the other in the United Republic of Tanzania (Aspray et al. 2000), provided a useful post hoc validity check on our final estimates of discretionary-time inactivity. Both studies assessed physical activity across multiple domains that could not be disaggregated.

No data were found to represent those countries in the AFR-D subregion. Two studies reported data from Nigeria (Ezenwaka et al. 1997; Forrest et al. 2001) and one study submitted for publication from Cameroon (Sobngwi et al. 2002) were identified but all three studies reported physical activity using different summary scores and/or units. At the time of our analyses the results from reanalysis were not available.

## Americas

Data on discretionary-time physical inactivity and work-related activity from the United States and Canada were identified for the AMR-A subregion. Both countries have established surveillance systems collecting nationally representative data on patterns of physical activity (C. Craig, unpublished data, 2001; S. Ham, unpublished data, 2001a; Macera et al. 2001). Data on transport-related activity for the United States were
available from the National Personal Transportation Survey (Federal Highway Administration Research and Technical Support Center 1997) and data for Canada were found in a cross national comparison report (Pucher and Dijkstra 2000). No data were found for Cuba, the third country in this subregion.

For the AMR-B subregion national data on physical activity were found for Argentina, Brazil and Chile. In Brazil multiple data sets were found for different cities including Porto Alegre (Duncan et al. 1993) and São Paulo (Andrade et al. 2001). However data from the most recent, largest, most representative study, with sampling from 98 cities across Brazil was selected (Datafohla 1997). Data for Argentina were obtained from a recent national Gallup Poll that included one item on physical activity (Instituto Gallup De La Argentina 2001). Data for Chile were obtained from a recent published study conducted in a metropolitan area of Valparaiso. (Jadue et al. 1999) Two studies from Peru with data on work and discretionary-time activity were identified for AMRD (E. Jacoby, unpublished data, 2000). Only the data on discretionarytime activity were available for inclusion.

## Eastern Mediterranean

Only two studies were found reporting data for physical activity EMRB and EMR-D and neither study provided national estimates. One study from Saudi Arabia reported estimates for only discretionary-time inactivity in male adults (al-Refaee and al-Hazzaa 2001). While these data are limited in both domain and are for males only, the questions were deemed comparable and due to the lack of any alternative data they were included for EMR-B. The second study reported data on physical activity from a large sample of adults in a region of Egypt (the city of Cairo and surrounding villages) (Herman et al. 1995). The measure of inactivity assessed discretionary-time, transport and work-related activity in combination. Because it was not possible to disaggregate these components these data were used only as a post hoc check of the final predictive model.

## EUROPE

Although several individual European countries have collected data on various domains of physical activity in recent years (Hassmen et al. 2000; MacAuley et al. 1996, 1998) we selected a recent, large, multi-country study ( $n=15239$ ) assessing both discretionary-time and work-related physical activities (Institute of European Food Studies 2001). The study was selected for inclusion because it collected national representative samples from 15 countries and data were collected within a defined period of time using the same measurement instrument. The Physical and Nutrition European Union data set (known as PAN EU) provided $87 \%$ coverage of EUR-A; however these data were collected by commercial marketing companies in each country and there were no available data
on the response fraction. This concern increases uncertainty around these estimates but the data were deemed more comparable than using a larger number of country-specific estimates, collected using a variety of instruments and providing less coverage of the EUR subregions.

Data on transport-related activity are likely to exist for many European countries at either a national or regional level, often in departments of transportation or planning databases. However, these data remain difficult to locate and require translation. In lieu of obtaining these data directly we used a recent report that provided national estimates of walking and cycling for several European countries and Canada (Pucher and Dijkstra 2000).

No data were found for EUR-B. Data from the MONICA project that included two sites in Poland were considered, but were not nationally representative and were therefore excluded.

One study reported data from three countries in EUR-C, namely Estonia, Latvia and Lithuania (Pomerleau et al. 2000). Two sources were identified for data on physical activity in the Russian Federation. An unpublished research study investigated patterns of activity in an adult population in Moscow (Zabina et al. 2002) and a publication using data from the Russian Longitudinal Monitoring Survey (RLMS) (North Carolina Population Center 2001a). We were unable to complete analyses of the most recent RLMS data (1998/2000) and therefore selected the published estimates from survey six in 1995 and we were provided with additional unpublished analyses from this data set (Cockerham and Sneed 2001). Combined the two sources of data provide $63 \%$ coverage of EUR-C. No data were found on transport-related activity for EUR-C.

## South-East Asia

Our search found only a few studies with data on patterns of physical activity in India (Gupta et al. 1994; Singh et al. 1998) and one study with data from Bangladesh (Hypertension Study Group 2001). Other contacts through international agencies and electronic listserve identified several studies with unpublished data although none of these included nationally representative samples (Misra et al. 2001; K. Reddy, unpublished data, 2001). One study investigated an urban slum population (A. Misra, unpublished data, 2001) and another a population selected from an industrial workforce (K. Reddy, unpublished data, 2001). Both studies provided us with additional unpublished analyses, and we attempted to create a weighted (by urban and rural) national estimate. However, the results from these studies showed no clear pattern and we had low confidence in our estimate. Therefore, these data were not used in the final analyses. The small, published study with a population of older adults from rural and urban towns in Bangladesh and India was considered for SEAR-D. However, on close inspection these data were considered insufficient for inclusion.

## Western Pacific

Australia and New Zealand both have established health and population surveillance systems and from time to time conduct national surveys specifically aimed at assessing patterns of physical activity. Data from these specific surveys were selected for our analyses (Armstrong et al. 2000; Hillary Commission 1998). No national data on transportation activity were found for this region, thus we substituted data on cycling and walking for transport from a combination of two reports from Australia; one included a large survey with a representative sample of the population in Western Australia (Bull et al. 2000) and the other included data from a transportation project also undertaken in Western Australia (Travel Demand Management 1999).

Two studies published in English were found reporting data on dis-cretionary-time physical activity in Japan (Arai and Hisamichi 1998; Kono et al. 1999) and translation of data from another source was also provided (N. Murase, unpublished data, 2001). However, we chose to include data from the larger Japanese Lifestyle Monitoring Study (Iwai et al. 2000) even though only discretionary-time physical activity was assessed in a middle-aged adult population (40-60 years). A small study in Singapore with data from women only was also found but after considering the instrument and definition of inactivity it was excluded.

Subregion WPR-B is represented by data found from China. Nine published studies were identified (Bell 2001; Hong et al. 1994; Hu et al. 1997, 2002; Matthews et al. 2001; Paeratakul et al. 1998; Pan et al. 1997; Yu and Nissinen 2000; Yu et al. 2000) but excluded in preference for recent data from the China Health and Nutrition Survey (CHNS) (North Carolina Population Center 2001b). Micro data were available online (http://www.cpc.unc.edu/) and we conducted additional analyses on physical activity across different domains (Ham 2001c). Additional data from the State Sport General Administration of China were also found and these suggested notably higher estimates of discretionarytime activity compared with CHNS. After a careful review of the two questionnaires and input from experts familiar with China, the average of the two studies was used to estimate the prevalence of inactivity in China (Wang 2002). These data provided $85 \%$ coverage of WPR-B.

### 2.5 COMPARABILITY OF INSTRUMENTS ASSESSING PHYSICAL activity and estimates of exposure among INCLUDED STUDIES

Tables $10.4,10.5$ and 10.6 provide a summary of the data sets used to assess physical (in)activity in discretionary-time, work and transport domains, respectively. For each data source a brief description of the question and the definition of inactive is provided. Below is a summary on the comparability of the final selection of studies in each domain.
Table 10.4 Summary of questions used to assess discretionary-time physical (in)activity

| Subregion | Country | Reliability | Validation | Study title/instrument (reference) | Discretionary-time (in)activity |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  |  |  |  |  | Method of assessment | Definition of inactive |
| AFR-E | Ethiopia | Not available | Not available | Borana Health and Nutrition Study (Alemu and Lindtjorn 1995) | Seven-day recall via a series of close-ended questions. Participants were interviewed for 7 consecutive days every three months for one year. Activities coded as sleep (I MET), light (I.5 METs), moderate (4METs), hard (6METs), very hard (IOMETs) | Reported mean day EE in kcals/day and kcals/kg per day. (Reanalysis for this work defined inactive as no hard or very hard activities over a 7-day period) |
|  | South Africa | Not available | Not available | BRISK study (Steyn et al. 1991) | Question: After working hours do you get any regular (more than twice/week) exercise? If yes, is it light or strenuous? | No exercise outside of working hours |
| AMR-A | Canada | Not available | Not available | 1998 Physical Activity Monitor (C. Craig, unpublished data, 2001) | Prompted recall of participation in approximately 25 different activities over last 12 months. For each activity reported, number of times in last 12 months and average duration/occasion were recorded | Energy expenditure equal to or less than 0.5 KKD (kcals/kg per day) |
|  | USA | $\begin{aligned} & \text { Карра = } \\ & 0.57-0.77 \end{aligned}$ | Not available | National Physical Activity Survey 1999-2000 (Ham 2001a) | Question: In last month, have you participated in any physical activities or exercises such as brisk walking, bicycling, vacuuming, gardening, or anything else that causes small increases in breathing or heart rate? If yes, type, distance, usual minutes and frequency are recorded | No activities reported |

| AMR-B | Argentina Brazil | No No | No No | August Omnibus Wave-Gallup Poll (Instituto Gallup De La Argentina 2001) Brazil - 98 Cities Project (Datafohla 1997) | Question: Do you regularly practice some type of physical activity? If yes, what (choice of 8 activities or "other")? <br> Prompted recall of participation in 15 sports and activities (+ "other"). If yes, frequency during last month and pattern of participation over last 10 years was recorded | No practice of regular physical activity <br> No activities reported |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | Chile | Pearson correlation for leisure index 0.74-0.83 | Pearson correlation $r=0.83$ (VO2 Peak) 0.44-0.56 <br> (EE from 3day diary) | Baecke Questionnaire of Habitual Physical Activity (Jadue et al. 1999) | Participation in sports assessed in two ways. One question asked Do you play sports? If yes, type, frequency, duration recorded. Second question asked During leisure time I play sports? Response is on 5 -point Likert scale (never-very often) | Persons who "never" do exercise (sports) regularly in their free (leisure) time |
| AMR-D | Peru | Not available | Not available | National Living Standards Measurement Survey (Cortez et al. 2002) | Question: In the last month, did you practice any sport such as soccer, volleyball, jogging or walking, among others? If yes, How many times during the last month did you participate in these activities? | No practice of physical activity in leisure time in last month |
| EMR-B | Saudi Arabia | Not available | Not available | Research project using original questions (al-Refaee and al-Hazzaa 2001) | Question: Do you currently do any type of physical activity in a typical week? If yes, Is it regular? How many days? For how long? What kind? | No current physical activity at all (no walking, jogging, swimming, gardening, yard work or any sporting activity) |
| EMR-D | Egypt | Not available | Not available | Research project using original survey (Herman et al. 1995) | One question assessed activity "outside the job" (including transportation to and from work, sporting activities, and other leisure time physical activity). Response was on a 4-point scale | No physical activity weekly |

Table 10.5 Summary of questions used to assess work-related physical (in)activity

|  |  |  |  |  | Occupational activity |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Subregion | Country | Reliability | Validation | Study title (reference) | Method of assessment | Definition of active |
| AFR-E | South Africa | Not available | Not available | BRISK study (Steyn et al. 1991) | Question: Does your work involve mostly: I) primarily sitting/standing; 2) a lot of walking; 3) hard physical (sweat) work? | Category 3: hard physical (sweat) work |
| AMR-A | Canada | Not available | Not available | 1998 Physical Activity Monitor (C. Craig, unpublished data, 2001) | One question assessed activities undertaken at home or at work like lifting boxes, carrying objects, climbing stairs or walking as part of your job or chores. Frequency was recorded. Response scale was: I) almost all the time; 2) almost three-quarters; 3) almost half of the time; 4) about a quarter and/or almost none of the time | Category I: almost all the time |
| AMR-A | USA | Not available | Not available | National Physical Activity Survey 1999-2000 (Ham 2001b; Macera et al. 2001) | Question: When you are at work which of the following best describes you: Mostly sitting or standing? Mostly walking? Mostly heavy labour? | Middle and upper category: mild physical exertion and heavy physical exertion |
| EUR-A | European Union ${ }^{\text {a }}$ | Not available | Not available | Pan-EU survey (Institute of European Food Studies 2001) | One question assessed typical day's activity (either at work, college, in the office or at home). Categories of responses: I) sitting down at work; 2) standing or walking around; 3) more physical work than any of the above. Approximate number of hours/day recorded | Category 3: more physical work than sitting down, or standing or walking around for 3-6 hours |

| EUR-C | Estonia, Latvia, Lithuania | Not available | Not available | Research project using original survey (Pomerleau et al. 2000) | Question not specified but responses coded as low; moderate (mixed sedentary and standing work); high (work requires a lot of walking, lifting, carrying-examples given include heavy housework); and very high (heavy manual work and example occupations given) | Categories: high (work requiring a lot of walking, lifting or carrying) or very high |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| WPR-A | Japan | Not available | Not available | Japan Lifestyle Monitoring Study (Iwai et al. 2000) | Frequency and average duration of various types of labour and other activities on the job, including household activities, for every two months within the last 12 months were queried. Responses were classified into 4 categories according to intensity: sedentary (I.5 METs), standing/walking (2.5 METs), moderately strenuous work (4.5 METs), strenuous work (7.5 METs). A total work activity score was calculated. Lists of activities for 5 major types of businesses were used as prompts | Strenuous work ${ }^{\text {b }}$ |
| WPR-B | China | Not available | Not available | China Health and Nutrition Survey 2001 (Ham 2001c) | Time spent in three categories of activities during a work day assessed. ## DISCRETIONARY-TIME (IN)ACTIVITY

The 17 studies providing data for 33 countries that were included in this report used 17 different measures to assess physical activity in discretionary time (Table 10.4). Seven studies assessed participation using an instrument comprising a list of specific activities (i.e. a prompted approach $n=6$ ) or by asking the respondent about "any activities" and recording the type (i.e. unprompted approach $n=1$ ). Both approaches assessed frequency and duration (as detailed in Table 10.1 and ascribed questionnaire format 1 and 2 , respectively).

Nine studies used either a single question or a small number of questions with either open or closed response format (Table 10.1, format 3). These instruments comprised the most diverse set of questions and rarely were the reliability or validity properties of the instruments reported. Only one study used an instrument that captured time spent doing categories of activities (format 5), where categories were defined by the intensity of activity (e.g. moderate-intensity and vigorous-intensity). Only one study used a detailed recall over the past seven days (format 4).

Despite these 17 questionnaires appearing quite different, closer inspection revealed considerable similarity in what each measure attempted to assess. Moreover, the definitions of inactive (level 1 exposure) were very comparable. Three quarters of the studies $(n=14)$ used "no", "none", "never" or "zero" as part of their quantification of inactive. In one study (C. Craig, unpublished data, 2001) inactive was defined on a continuous scale (as less than $3 \mathrm{kcals} / \mathrm{kg}$ per day). Three studies used the lowest category of activity as described in their question (Cockerham and Sneed 2001; Craig 2001; Pomerleau et al. 2000).

The degree of similarity across the definitions of inactive was sufficient for these data to be included in our analyses. However, it is recognized that this comparison is not perfect. Walking and gardening were included in some studies and not others; nor were these activities always defined the same way. Furthermore, the reference time frame and definition of "regular" used in questions were not always consistent. These differences remain limitations to the comparison of data on physical activity.

## WORK-RELATED (IN)ACTIVITY

Table 10.5 provides a summary of the questions used to assess workrelated physical (in)activity in each study for which we had at least some data for consideration. Three of the seven instruments were used in formats 1 or 2 and asked about three types of work activities, namely walking, standing and hard (or heavy) physical work/labour (e.g. EU, South Africa, the United States). Three studies used an instrument (format 3) assessing different categories of intensity (e.g. light, moderate and heavy) and this was deemed comparable to format 1 and 2 instru-
ments. The remaining instrument captured frequency of different types of work-related activity (Iwai et al. 2000).

While there were clear differences in the format of the instruments used to assess this domain, the more significant problem was that "nonwork" activities were also included in the wording of items and thus the physical activity prevalence estimates. For instance, Canada included "chores", and this may have been interpreted as household (domestic tasks) and Japan specifically cited "household activities". The wording and consequently broader scope of the questions severely limited the comparability of these measures of work-related physical activity-so much so that we concluded that only the questions used in the studies from the United States and China were sufficiently similar to allow comparison and thus only these data were used in subsequent analyses.

## TRANSPORT-RELATED (IN)ACTIVITY

Our search for data on transport-related physical activity, and more specifically patterns of cycling and walking to get to and from places, found very few national data sets. It is acknowledged that many countries collect these data as part of national or regional transportation planning and evaluation activities. However, it was beyond the scope of this project to complete an exhaustive search of these sources. Table 10.6 presents details of the six sources used in this study covering 15 countries.

Transportation data can be collected either by prompted recall during a telephone interview or from diaries completed daily over a specific time frame (usually 3-7 days). Trip origin and destination are usually recorded as well as trip mode and duration. This approach is common in developed countries and examples include the National Personal Transportation Survey in the United States (Federal Highway Administration Research and Technical Support Center 1997) and similar instruments used in several European countries (Pucher and Dijkstra 2000) and Australia (Travel Demand Management 1999). In contrast the Health and Nutrition Survey in China included very specific questions to capture the number of walk or cycle trips to a range of specific destinations.

Integrating measures of transport-related physical activity into the assessment of total physical (in)activity is at a very early stage. For this project we were limited to sources of data from three transportation surveys and one health survey. It is acknowledged that other studies previously mentioned and included under other domains may have captured all or some walking trips, either by using a distinct question or by specifying walking as an example of moderate-intensity activity (Armstrong et al. 2000). The same possibility exists for some cycling trips. However, in these cases it was not possible to disaggregate the activity into separate domains. Clearly further development of a standard set of questions for transport-related physical activity is required.

With the exception of China and the United States, all the studies used for this project presented data as "percent of trips" not as a proportion of people undertaking trips. In lieu of obtaining data in the latter format we analysed data from the United States to help derive an estimate from per cent of trips. This method is described in full detail in later sections.

## DOMESTIC-RELATED (IN)ACTIVITY

No data were obtained on physical (in)activity in the domestic domain. We found several studies that did include questions to assess this domain but the data were not reported. Like transport-related activity, some domestic-related activity may have been captured because of the wording of questions or the examples provided. For instance, "housework" could be specified as a moderate-intensity activity in addition to examples of sports and recreational pursuits. In this situation, it was usually impossible to disaggregate the data and, if used, this data could potentially lead to erroneous estimates.

Due to the lack of sufficient data in this domain it was not possible to estimate the magnitude of domestic physical activity or inactivity. It is recognized that this is an important domain and therefore a significant limitation to our final estimates. Moreover, it is highly likely that there is considerable variation in levels of domestic activity between developing and developed countries, within countries, between males and females and across ages. The magnitude and direction of these differences are not well known. Some data are available from studies investigating energy intake and expenditure but these studies usually investigate very specific populations and provide too few data to generalize.

## Combination measures of (in)activity across domains

Several countries used instruments that assessed physical activity across multiple domains. Often these questions presented a brief description and respondents chose a category (e.g. in Egypt) (Herman et al. 1995). In one case very detailed data were obtained via a seven-day recall instrument and the final analyses combined all activity across all domains (e.g. in Ethiopia) (Alemu and Lindtjorn 1995). Data from these approaches were excluded from our estimates in the specific domains. However, where appropriate these data were used post hoc to assess the fit of our final predicted estimates.

### 2.6 Treatment of data

## DEALING WITH DATA REPORTED FOR DIFFERENT AGE CATEGORIES

Much of the data obtained was not available using the same cut-point for age categories. The first and preferred solution involved contacting the original investigators and requesting data analysed by the relevant age groups. Where this was not possible or where data were no longer
accessible, an indirect method was used to compute age-specific estimates, by assuming uniform distribution of population and exposure in one-year increments of each age category.

Where data were available for only some of the age groups included in the lower and upper age categories used in this report (e.g. 15-29 years, 60-69 years, 70-79 years) the obtained prevalence estimate was applied to all years in the category. For example if data were available for only those aged $60-65$ years it was applied to our 60-69 year category, and also extrapolated to older age groups such as $70-79$ or $\geq 80$ years. The effect of this is to slightly underestimate inactivity in the older years within an age category (inactivity usually increases with age) and slightly overestimate the prevalence of inactivity within the youngest age category.

## DEALING with data from non-Nationally representative samples

Several data sets did not come from nationally representative samples. In these instances, descriptions of the study sample and information on the age, sex, ethnic/racial and rural/urban profile of the country were used to create adjusted weighted national estimates. For example, these steps were undertaken with data from Bangladesh and India, which were samples from older adults in urban and rural towns, and also for transport data from Australia that were weighted to form a national estimate.

Dealing with missing data by Sex, age and subregion
Table 10.7 provides a summary of the amount of data identified for each of the 14 subregions according to six age groups and both sexes. Of these 168 cells, $44 \%$ were missing data. For the 14 subregions, the missing cells ranged from $0 \%$ (AMR-A and WPR-B) to $100 \%$ (SEAR-B). Across subregions, missing data cells ranged from $32 \%$ for the four age groups spanning 15-69 years, and increased to $57 \%$ and $79 \%$ for the $70-79$ and $\geq 80$ age groups, respectively. These incomplete subregional by age and sex data cells presented two tasks:

- obtaining estimates for missing age and sex categories; and
- obtaining estimates for countries/subregions where no data source exists.

One approach to solving these two issues was to select the most comparable data set available and apply these values to missing cells. For example, data from EUR-C could be substituted for EUR-B, or WPR-B (which includes China) could be used to derive estimates for SEAR-B and SEAR-D. Similarly missing data for older adults in Europe could be derived from known data from the Americas. While plausible, this approach is weak because any limitations in the data for one subregion will be extended to the other. Moreover, it makes no attempt to better represent the likely differences that exist between countries.

Table 10.7 Summary of data available by subregion, sex and age ${ }^{\text {a }}$

| Subregion | Countries with data | Sex | Age group (years) |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  |  |  | 15-29 | 30-44 | 45-59 | 60-69 | 70-79 | $\geq 80$ |

An alternative approach was to develop a statistical model to predict national estimates of physical inactivity. Known correlates of inactivity at the individual level could be explored for their predictive value at the national level (e.g. level of education). In addition, a range of other parameters, possibly related to inactivity, such as indicators of economic development (e.g. per capita gross national product [GNP]), could be investigated. Using this "ecological" approach represents the first stage of the epidemiological approach to identifying and understanding the determinants of physical inactivity. Such a model was used to predict
values for countries with missing data and values for missing age/sex cells in countries with only some data. This approach has the advantage of using all available, comparable data on physical inactivity to develop a statistical relationship with other indicators for which there are data available worldwide. We also had to decide whether to create a single model to predict the sum total of inactivity (i.e. inactivity across all four domains as stated in the definition of exposure) or four separate models-one for each domain. The latter approach was selected because of the complexities of the behaviour and the likelihood that different parameters may explain levels of inactivity in different domains.

### 2.7 Estimating prevalence of level i exposure (inactive) USING REGRESSION ANALYSIS

Multivariate and linear regression analyses were used to create predictive models for discretionary-time, work-related and transport-related levels of inactivity. All data obtained from the worldwide search that met our inclusion criteria were considered for inclusion in this process. Only data that clearly represented a single domain were included in the domain-specific modelling exercise. Domestic physical inactivity could not be modelled due to insufficient data. Estimates from countries with measures of physical (in)activity that comprised multiple domains were used post hoc to assess the fit of predicted estimates of overall inactivity across all domains. Only one source of data per country was used.

From a practical stance it was necessary to treat all data within a domain as either values of exposed (namely \% inactive) or unexposed (\% active). In most cases we found it more convenient to work with a model predicting prevalence of doing some physical activity (unexposed) and in the final step to reverse the direction to inactivity (exposed). The exception was in the discretionary-time domain where the predictive model was developed for inactivity.

The modelling approach of level 1 exposure required six steps:

1. Create a predictive model to estimate discretionary-time physical inactivity, and subtract values from 100 to create estimates of physical activity.
2. Create a predictive model to estimate work-related physical activity.
3. Create a predictive model to estimate transport-related physical activity.
4. Sum the domain-specific estimates of physical activity and adjust for overlap across domains.
5. Scale estimates of physical activity and subtract values from 100 to compute final estimates of level 1 exposure (physically inactive).
6. Aggregate age by sex country-level estimates to create age by sex regional-level estimates.

Within each step estimates for each age (six categories) by sex (male/female) cell were modelled and predicted rather than working with and predicting only single point estimates to represent all persons from each country. Table 10.8 summarizes the potential parameters found from World Bank data (World Bank 1999) that were considered for inclusion in the models of (in)activity in each domain. Many of these potential parameters were highly associated including, for example, GNP and per cent of the population completing tertiary education (hereafter referred to as "\% tertiary education") (correlation matrix not reported). Criteria for parameters were the following:

1. Parameters must be available on a national level for most countries across most regions.
2. Parameters must come from a reliable (reputable) source.
3. Parameters must be from recent sources consistent with our exposure variable.

Within each domain, predicted estimates were limited to the countries for which data on the selected parameters were available from the World Bank ( $n=146$ ). After completion of the first five steps, the final task was to aggregate the age-sex-country specific values to create age by sex

Table 10.8 Summary list of potential parameters considered for modelling level I exposure

| Parameter categories | Potential parameter |
| :--- | :--- |
| Demographic | Country population <br> Regional population <br> Per cent urbanization <br> Typical population density experienced by an individual <br> GNP per capita <br> World Bank classification |
| Economic | Per cent completing tertiary education |
| Socioeconomic | Subregion |
| Geographical | Latitude of the country centroid |
| Climatalogical | Mean annual temperature |

regional estimates. At this point known data replaced predicted values where available. Each of the above steps undertaken to estimate the prevalence of exposure level 1 (inactive) is described in detail below.

Step 1: Estimating discretionary-time physical activity
Data by age and sex from 32 countries provided the basis for estimating the prevalence of discretionary-time physical inactivity (level 1 exposure) for 12 age-sex categories in 146 countries. A mixed model for nested, repeated measures was used to identify a model with predicted values that best approximated the data. Twelve age-sex categories were treated as repeated measures nested within each country.

The general linear mixed model is

$$
\mathrm{Y}=\mathrm{X} \beta+\mathrm{Zu}+\mathrm{e}
$$

where: $Y=$ observed response variables
$\mathrm{X}=$ matrix of known values of covariates
$\beta=$ matrix of unknown fixed-effects parameters
$\mathrm{Z}=$ known design matrix of random effects
$\mathrm{u}=$ matrix of unknown random-effects parameters
$\mathrm{e}=$ error.

The model assumes that the error is independent and identically distributed (iid). A mixed model was chosen as most suitable for these data because we considered the possibility of correlation within countries (e.g. clustering of age by sex prevalences). Within-country estimates are likely to cluster because the level of economic development and culture is likely to determine if any data were available and relatively small differences in use of discretionary-time within a country; in contrast, the differences in measurement instruments and protocols would be greater between countries. In addition, using a mixed model allowed for the consideration of clustering of physical activity patterns by geographic region (our strata variable) and this was deemed desirable for the analysis. Mixed models are robust to two characteristics of our prevalence data, heterogeneous variances within clusters (e.g. countries and regions) and missing and unbalanced data. It is acknowledged that missing data may not be random. The effect of missing data is most likely to increase error in subregions with less coverage and reduce error in subregions with better coverage. We compensated for the limitation due to missing data in our calculations of age by sex by subregion estimates by increasing our $95 \%$ confidence limits (described in detail later).

A simple repeated (up to 12 age by sex cells per country) measures model is

$$
\mathrm{y}_{\mathrm{ij}}=\mu+\alpha_{\mathrm{ij}}+\mathrm{d}_{\mathrm{i}}+\mathrm{e}_{\mathrm{ij}}
$$

where $\mu$ and $\alpha_{\mathrm{ij}}$ are fixed-effects parameters, $\mathrm{d}_{\mathrm{i}} \sim \operatorname{iid} \mathrm{N}\left(0, \sigma^{2}\right)$ is the random-effect parameter, and $\mathrm{e}_{\mathrm{ij}} \sim \operatorname{iid} \mathrm{N}\left(0, \sigma^{2}\right)$.

Several tasks were undertaken before the multivariate modelling. Firstly, the skewed physical inactivity data available from 32 countries were transformed to obtain a more normal distribution. Various transformations were attempted but several countries (e.g. Chile, China, the Russian Federation) which had very high estimates of inactivity (ranging $85-96 \%$ ) prevented any transformation from creating a truly normal distribution. Nonetheless, the square root transformation created a more satisfactory variable with a distribution closest to normal (Figure 10.5).

Secondly, we created a variable regional strata to allow countries with data within a region to have a greater influence on the predicted values of other countries in the same region. Due to the overall lack of data across the 14 subregions, five new regional strata were developed to help our analyses. These strata were defined by considering geographical location, World Bank income classification, social, religious and cultural similarities and the availability of data on exposure. The five strata are shown in Table 10.9.

## Weighting

After some preliminary attempts at modelling discretionary-time physical activity and predicting age by sex by country estimates we introduced a weighting factor for each data set. This step was in addition to using the regional strata parameter, and weighted data to the world popula-

Figure 10.5 Transformed age $x$ sex estimates for discretionary-time physical inactivity data $(n=276)$ from 3I countries

Table I0.9 Country allocation to regional strata parameter for modelling level I exposure

| Regional strata created for model | Countries included |

|  | Oman, Saudi Arabia, United Arab Emirates, Yemen); North |
|  | Africa (Algeria, Egypt, Morocco, Tunisia); and the Russian |
|  | Federation |

tion (aged $\geq 15$ years). A weighted model should produce similar parameter estimates regardless of the number of countries, or which specific countries, were included in the model. This was an important consideration because over half of the data were from China, Europe, North America and the Russian Federation. The intent was to avoid these data dominating the model and thus the final estimates.

In practice, known data from a country were weighted to the total population (by age and sex) of the regional stratum proportional to the country population in which the data were available. The sum total population was the total population (aged $\geq 15$ years) in the 146 countries for which the independent variable ( $\%$ tertiary education) was available.

Over half of all the available data on physical inactivity were from countries in the Western industrialized stratum and within this stratum these data represented $90 \%$ of the population. In the South-East Asia stratum, data were available from China, Japan and Singapore, and China represented $77 \%$ of the stratum's population. Using the weights improved the predicted prevalence estimates by allowing China to contribute to the model approximately 1.3 times its population, while limiting the influence of data from countries in the Western industrialized countries to slightly more than their population of each country ( 1.1 times).

The remaining strata had fewer countries with data and thus smaller proportions of the strata population were represented. In these cases, the countries with data determined the age by sex trends of inactivity while the covariate ( $\%$ tertiary education) influenced the intercept for each individual country. Individual weights are not shown because they varied for each country depending on what age by sex data were available and the age by sex population of the stratum.

## Preliminary models of discretionary-time physical inactivity

All of the parameters listed in Table 10.8 were explored in univariate and multivariate models. As mentioned many of the World Bank indicators were correlated and if used in combination would cause problems of collinearity, or unreliable parameter estimates resulting from correlated covariates. Using $\%$ tertiary education was found to explain almost equal variance as GNP and provided smaller residuals that were more normally distributed. Education was reasonably normally distributed. The single point estimate of education per country was applied equally to the 12 age by sex cells.

Figure 10.6 shows a plot of national estimates of discretionary-time physical inactivity by the indicator \% tertiary education for 31 countries. The figure shows that countries with lower tertiary education have a higher prevalence of discretionary-time inactivity.

In addition to exploring a range of demographic, economic and development indices we tested a model that included a variable rating the "data representativeness". As discussed there is insufficient evidence on which to base judgements about different types of instruments, thus we created a variable that differentiated national sources of data from nonnational (regional or metropolitan). China was coded as national because the sample was representative of 16 provinces. Including the data representativeness parameter did not, however, improve our model; thus it was removed.

## Final model of discretionary-time physical inactivity

The final model parameters were education (defined as \% tertiary education), age, sex, region, a three-way interaction termed age x sex x region and corresponding two-way terms. This parameter allowed trends for age to vary by sex and for each different region and it helped to

Figure I0.6 National estimates of discretionary-time physical inactivity by the indicator \% tertiary education ( $n=31$ countries)

improve the predictive power of our analysis. Available data suggest that the trend for inactivity across age can vary by sex and by region. Education allowed inactivity for each country to be based upon an external measure known to be highly associated with a number of risk factors, including discretionary-time physical inactivity, at the individual level. Other social and economic indicators were tested and some produced good results (e.g. particularly GNP per capita), but the best model fit and distribution of the residuals was obtained using the parameter education.

Applying the simple repeated measures model to estimate discretionary-time activity, we get

$$
y_{i j}=m+a_{i j}+d_{i j}+e_{i j}
$$

where $\quad y_{i j}$ is the response, prevalence estimates for age x sex x country categories;
m and $\mathrm{a}_{\mathrm{ij}}$ are fixed-effects parameters: intercept, age, sex, region, \% tertiary education, interaction parameters;
$\mathrm{d}_{\mathrm{i}}$ is the random-effect parameter, country; and
$\mathrm{e}_{\mathrm{ij}}$ is error.
The final model for predicted discretionary-time physical inactivity using data obtained from the World Bank is represented by:
square $\operatorname{root}($ DISCRETIONARY-TIME PHYSICAL
INACTIVITY $)_{\text {COUNTRY,AGE,SEX }}=\alpha_{i}+\beta_{1}(\mathrm{AGE})+\beta_{2}(\mathrm{SEX})$
$+\beta_{3}(\mathrm{REGION})+\beta_{4}(\mathrm{AGE} \times \mathrm{SEX})+\beta_{5}(\mathrm{AGE} \times \mathrm{REGION})$
$+\beta_{6}(\mathrm{SEX} \times \mathrm{REGION})+\beta_{7}(\mathrm{AGE} \times \mathrm{SEX} \times \mathrm{REGION})$
$+\beta_{8}(\%$ TERTIARY EDUCATION $)+\mathrm{d}_{\text {COUNTRY }}+\mathrm{e}_{\mathrm{COUNTRY,AGE,SEX}}$
where $\mathrm{d}_{\text {COUNTRY }} \sim$ iid $\mathrm{N}\left(0, \sigma_{\mathrm{d}}^{2}\right)$ is the random-effect intercept, and $\mathrm{e}_{\text {COUNTRY,AGE,SEX }} \sim$ iid $\mathrm{N}\left(0, \sigma_{\mathrm{d}}^{2}\right)$ is error.

Figure 10.7 shows a plot of the predicted estimates by actual data for 31 countries. The final model explained $52 \%$ of the within-country variance in the prevalence of physical inactivity. The remaining $48 \%$ of variance is attributed to variables not included in this model. Chile, China and the Russian Federation were identified as potential outliers and models were run including and excluding these data. The final model excluded only the Russian Federation and the predicted prevalence estimates fitted the data better by reducing the standard deviation of the residuals from 5.2 to 4.7 .

Modelling was done using SAS 8.1 with the restricted maximum likelihood (REML) method and unstructured covariance structure. The REML method is a better, more conservative estimation method than least squares. We modelled within-country data as repeated measures and "countries" as a random selection of all possible countries. Various

Figure 10.7 Plot of predicted estimates against actual data for discretionary-time physical inactivity $(n=276)$ from 31 countries

models were compared using education and GNP with manual inclusion/exclusion of possible outlying countries. The best-fit model was assessed by minimizing the standard deviation of the residuals calculated by transforming the predicted empirical best linear unbiased predictors (EBLUPs) as well as by minimizing the -2 residual log-likelihood, Akaike's information criterion (AIC), and Schwarz's information criterion (BIC).

The model gives each country its own random-effect intercept estimate which adjusted the overall model intercepts higher or lower by a small percentage. These random-effect intercepts help the model fit the data better than a fixed-effects model by allowing each country to have a different mean value. A shortcoming in using random-effect intercepts is that the random effects are not used to adjust the intercepts for the 114 countries with no data when calculating predicted values. Therefore, the predicted values may be biased if the random-effects estimates are not randomly distributed with a mean of zero. The random-effects estimates for our model were randomly distributed within strata. Figure 10.8 presents a histogram of the distribution of the model residuals by age and sex category estimates showing a normal distribution.

Figure 10.9 shows the residuals from the final model plotted by dis-cretionary-time physical inactivity. The plot shows an increasing trend toward positive residuals with higher estimates of physical inactivity; this is an expected effect of using skewed response data in a model that assumes normal distribution. The model underestimated high prevalence and overestimated low prevalence although the maximum absolute residual for any age-sex estimate was approximately $15 \%$.

Figure 10.8 Distribution of residuals from final model of discretionarytime physical inactivity $(n=276)$

Figure I0.9 Plot of residuals for predicted age- and sex-specific estimates of discretionary-time physical inactivity $(n=276)$ from 3I countries

Figure I0.10 Distribution of predicted national estimates of discretionary-time physical inactivity for all countries ( $n=146$ )

Figure 10.10 shows the distribution of predicted national estimates of discretionary-time physical inactivity from the final model for all countries (total $n=146$ ). The plot shows about one third of the countries had estimates of discretionary-time physical inactivity around $40 \%$. Just over one third of countries had predicted estimates ranging from 55 to 75 per cent.

Figure 10.II Predicted national estimates of discretionary-time physical activity by the indicator \% tertiary education ( $n=146$ )

The final task in this step was to convert the model output (discre-tionary-time physical inactivity) to estimates of physical activity. This was easily done by subtracting the values from 100. Figure 10.11 shows a plot of the predicted national estimates of discretionary-time activity for each country by the indicator $\%$ tertiary education ( $n=146$ ). Countries with data are more developed with higher levels of tertiary education (shown by squares). The predicted values (circles) show different levels of activity for the same values of education reflecting the influence of our regional strata parameter in the predictive model.

Step 2: Estimating work-Related physical activity
Although several sources of data on work-related physical (in)activity were found for a number of countries (see Table 10.5), after careful inspection and discussion with the authors, few data could be included. Specifically, we found several data sets that appeared to be limited to work-related physical activity that also included some domestic activities listed as "chores". This was true for data from Canada, Estonia, Japan, Latvia, Lithuania and the EU. Because this could inflate the prevalence estimates of work-related activity these data were excluded.

Several other countries addressed work-related activity (e.g. Egypt and Ethiopia) but these data could not be disaggregated from overall measures of physical activity. Therefore only data from China and the United States remained as distinct estimates of work-related physical activity for use in a predictive model. Fortunately these countries represent quite different societies and cultures. Moreover, because we had access to the
micro data sets, age-sex estimates for both China and the United States were computed. Only estimates for heavy physical activity at work (or its equivalent) were included.

Figure 10.12 shows the proportion of adults reporting heavy activity at work by age and sex for both China and the United States. Heavy physical activity at work declines over age and is less likely to be reported by females compared with males in both China and the United States.

A simple linear regression equation was developed using the economic development indicator of \% employed in agriculture (hereafter referred to as "\% agriculture"). This World Bank indicator was selected and used by making the following assumptions:

- the proportion of the population employed in agriculture would reflect the level of work-related activity undertaken in a country; and
- there is a linear relationship between the proportion of the population undertaking physical activity at work and the proportion of the total population employed in agriculture.

Figure 10.13 shows the prevalence of heavy work-related physical activity by the indicator \% agriculture for males and females in China and the United States. More men were active at work than women in both China and the United States but the difference was greater in the United States (absolute difference of $12 \%$ compared with $6 \%$ ).

The final model parameters used to predict prevalence of work-related physical activity were \% employed in agriculture ( $\% \mathrm{AGR}$ ), age, sex and

Figure I0.I2 Prevalence of heavy work-related physical activity by age and sex, for China and the United States

Figure 10.13 Proportion of males and females in China and the United States who undertake heavy physical activity at work, by the indicator \% agriculture

Source: China data obtained from the China Health and Nutrition Survey (Ham 2001c); United States data obtained from the NPAS (Ham 2001a) and \% agriculture indicator obtained from the World Bank (1999).
an interaction term "sex by agriculture". This interaction term allowed estimates for work-related activity to vary between sex and by age as suggested by data from China and the United States (see Figure 10.12). Prevalence estimates for age categories 15-59 years were assumed to be the same because there were no clear trends by age in the data from China and the United States. However, an adjustment was introduced for age categories typically associated with retirement. Estimates for work-related activity for age categories 60-69 years, 70-79 years and $\geq 80$ years were progressively lower than those for $<60$ years to account for the reduced likelihood of heavy physical work and increasing proportion of retired persons in each age group. We calculated the mean difference and reduced estimates by $13 \%$ and $19 \%$ for males and females aged $60-69$ years, respectively; and by $19 \%$ and $26 \%$, and $20 \%$ and $27 \%$ for males and females, aged $70-79$ and $\geq 80$ years, respectively (the reference estimate was $50-59$ years). The magnitude of these adjustments were calculated using the mean of the differences seen between the relevant age groups in China and the United States (Figure 10.12). Additional adjustments for sex differences are described below.

Estimates for females were also adjusted to have lower values than males as suggested by the data from China and the United States (Figure

Figure IO.14 Predicted national estimates of heavy work-related physical activity by the indicator \% agriculture $(n=146)$

10.12) but the magnitude of difference seems to vary (range 6-12\%). Thus, for the 146 countries we were working with, those countries with higher total persons employed in agriculture the difference between men and women was smallest (minimum difference set as China value namely $6 \%)$. In countries with fewer total persons employed in agriculture the difference was greatest (maximum difference set as United States value, namely $12 \%$ ).

The regression equation is represented by

$$
\begin{aligned}
& \% \text { heavy physical activity at work } \\
& \quad=\alpha_{\mathrm{i}}+\beta_{1}(\mathrm{AGE})+\beta_{2}(\mathrm{SEX})+\beta_{3}(\% \mathrm{AGR})+\beta_{4}(\% \mathrm{AGR} \times \mathrm{SEX})
\end{aligned}
$$

Figure 10.14 shows predicted national estimates of heavy physical activity at work by the indicator \% agriculture.

## Step 3: Estimating transport-related physical activity

There were few data available reporting the proportion of the population undertaking transport-related physical activity, specifically cycling and walking. However some data were found reporting the per cent of "total trips" that were undertaken by bike or by foot, although even these data were not readily available from national samples.

Data used for modelling transport-related activity came from 13 countries, namely Australia (Travel Demand Management 1999), China (North Carolina Population Center 2001b), the United States (Federal Highway Administration Research and Technical Support Center 1997) and Canada and nine European countries whose data were obtained in
a report comparing trends between North America and Europe (Pucher and Dijkstra 2000). Only the data from China and the United States were available with the variable "persons" rather than "trips" as the denominator. All trip data had to be converted using available information and some adjustments. We wanted to avoid assuming that a separate individual undertook each trip (e.g. 150 trips $=150$ persons) because this is highly unlikely. It is more likely that a smaller proportion of the population walks or cycles and that they account for the majority of the trips (e.g. 150 trips might equal 50 persons). To explore this further we conducted new analyses using the nationwide personal transportation survey (NPTS) database (Ham 2001b) and found that $5 \%$ of all trips were cycling and walking and that they were undertaken by just $10 \%$ of the sample population. This gives a ratio of trips to persons of 1:2. This ratio was adjusted for use with data from Australia $(1: 1.5)$ and European countries ( $1: 1.25$ ) based on the conservative assumption that more individuals undertake more trips in these countries compared with the United States.

Figure 10.15 shows the prevalence of active transport (walk and cycle trips) undertaken by males and females in China and the United States. There was little difference between men and women in both China and the United States but considerable difference between the two countries. However, one notable difference is car ownership. This parameter was explored as a potential predictor of activity in this domain.

Figure $\mathbf{1 0 . 1 5}$ Proportion of adults undertaking transport-related physical activity (cycling or walking) by age and sex, in China and the United States

A simple linear regression equation was developed using the economic development indicator of cars per thousand population (see Figure 10.16). The underlying assumption is that the prevalence of cycling and walking declines as car ownership increases.

The final regression equation is represented by

$$
\begin{aligned}
& \text { TRANSPORT-RELATED PHYSICAL ACTIVITY }=\alpha_{i}+\beta_{1}(\text { CARS }) \\
& =\text { TRANSPORT-RELATED PHYSICAL ACTIVITY } \\
& =73.69-(0.063 . \text { CARS })
\end{aligned}
$$

Figure 10.17 shows the predicted estimates (shown in circles) as well as actual country estimates (shown in squares) for transport-related physical activity data.

China had the lowest ownership of cars and the highest proportion of the population walking and cycling for transport. In contrast, the European countries had much higher car ownership and lower levels of active transport. Australia, Canada, New Zealand and the United States do not fit this model well. They have high estimates of car ownership, with values similar to European countries, but notably lower levels of active transport. This may be due to the degree to which these geographically large countries have developed public transportation infrastructure and the quality of these systems. It is also possible that the mean distance to work (or other destinations) is greater reflecting "sprawling" communities or particular land use patterns that may differ

Figure 10.16 Age-sex estimates of transport-related physical activity for 13 countries, by the indicator cars per thousand population ( $n=156$ )

Figure 10.17 Predicted estimates and actual country data for transportrelated physical activity (cycling and walking) by the indicator cars per thousand population ( $n=146$ countries)

between Australia, Europe and the United States. It is likely that a more sophisticated multivariate model, including average miles driven, would better describe and predict active transport. However in the absence of available data on these other possible parameters we limited our model to cars per thousand population.

Four countries had transport data by age and sex, but the pattern differed for each country (China, Germany, the Netherlands and the United States), therefore a model ignoring age and sex was developed. Australia and the United States were identified as outliers and excluded from the linear regression. In subsequent steps of the analyses the actual values for these countries, as well as from China, were used.

## Step 4: Summation of domain estimates and adjustment for overlap

Estimates of total physical activity were obtained by combining the estimates of physical activity in each of the sub-domains (with the exception of the domestic domain). A simple summation of the estimates of activity in three domains produced country-level estimates ranging from $41 \%$ to $178 \%$ (mean 120, median 122, SD 20). High estimates of activity in more than one domain produced values well over $100 \%$. This was anticipated because it is known that at least some individuals are active in more that one domain and a simple summation would fail to take this into account. However, the magnitude of the overlap between different domains, and for men and women, across age is not well established.

In the absence of published data we explored the pattern of activity in multiple domains using data from China and the United States (Ham

2001a, 2001b, 2001c). It was observed that $6.2 \%$ of adults in the United States were active in both work and discretionary domains, $7.1 \%$ were active in discretionary and transport domains, and $0.2 \%$ were active in both work and transport domains. These relationships are shown schematically in Figure 10.18(a).

Similar analyses were repeated with data from China and are shown in Figure 10.18(b). In China, 29\% of adults were active at work and in the transport domain; $5 \%$ were active in both the discretionary and transport domains but zero per cent were active in both work and discretionary domains. Therefore the pattern of overlap is quite different compared with the United States.

Finally, data on physical activity across multiple domains were found for Finland and considered in a similar way (Luoto et al. 1998). However, without the exact data on the overlap only a hypothesized relationship between domains is shown for Finland in Figure 10.18(c). Finbalt Health Monitor data indicate that over $90 \%$ of Finnish adults are active in their discretionary time, $50 \%$ are active in transport and $13 \%$ are active at work. Accepting these values as reasonable estimates, there must be a large overlap between domains and this is shown schematically in Figure 10.18(c).

Figure 10.18 illustrates that quite different patterns of activity across different combinations of domains are possible and they are likely to vary across different countries around the world, and may vary for men and women and across age. Without additional information on these relationships it was necessary to develop a standard adjustment to our raw sum total of activity (i.e. the sum of the estimates of discretionarytime, transport-related and work-related activity), and apply this to all countries.

Figure 10.18 Schematic representation of national data for three countries showing the proportion of activity in single and multiple domains

[^39]
## Adjustment of raw domain-specific estimates

Adjustment could be made to the estimates in each of the domains ( $n=$ 3) in an attempt to reduce the absolute magnitude of the prevalence estimate of total inactivity. It was also possible to consider an additional adjustment (upward) to accommodate the missing data on activity in the domestic domain. The latter was rejected because there were insufficient data to guide such an adjustment across age, sex or country. Undertaking three separate adjustments was also rejected in favour of a single adjustment and the estimate of transport-related activity was selected as our focus. Our estimate of transport-related activity was selected for the adjustment for overlapping domains for no better reason than it was judged to be the weakest data (both in quality and quantity).

With only data on physical activity across multiple domains from China and the United States (Figure 10.18 [a and b]) we were unable to identify a clear relationship, and therefore selected to reduce the raw estimate of transport-related physical activity by $60 \%$. This gross adjustment was further refined for each country by choosing to scale the magnitude of the adjustment to a range of $50-70 \%$ based on each country's GNP. The underlying assumption was that those countries with the lowest GNP were more likely to have more active transport (cycling and walking), and therefore a smaller adjustment was appropriate (i.e. $30 \%$ reduction in absolute value of the predicted estimate). In contrast, those countries with the highest GNP were likely to have less walking and cycling so they had a larger adjustment ( $50 \%$ reduction in absolute value of the predicted estimate).

These functions are represented below:

$$
\begin{aligned}
& \text { Adjusted TRANSPORT-RELATED PHYSICAL ACTIVITY } \\
& \quad=\alpha_{\mathrm{i}}+\beta_{1}(\mathrm{CARS})+\beta_{2}(\mathrm{GNP})+\beta_{3}(\mathrm{CARS})(\mathrm{GNP}) \\
& \text { Adjusted TRANSPORT-RELATED PHYSICAL ACTIVITY } \\
& =(73-0.06 \text { CARS })(85-3.35 \mathrm{GNP} / 100)
\end{aligned}
$$

Adjusted estimates for transport-related physical activity by the indicator cars per thousand population are shown in Figure 10.19 and this can be compared to the previous unadjusted data shown in Figure 10.17.

## Step 5: Scaling and computation of final estimates of exposure

The age- and sex-specific estimates for discretionary-time activity, workrelated activity and adjusted transport-related activity were summed to create a sum total of physical activity for each age by sex cell for each of the 146 countries. Using the adjusted transport scores, the sum totals had a range of $45-135$, a mean of $95(\mathrm{SD}=20.2)$ and median of 97 . The distribution of both the adjusted and unadjusted sum totals is shown in Figure 10.20. Despite the adjustment described in Step 4, the sum total for some age by sex categories exceeded $100 \%$. Given these values are

Figure IO.19 Adjusted estimates for transport-related physical activity (cycling and walking) by the indicator cars per thousand ( $n=147$ countries)

impossible some form of recalibration of at least the upper values was necessary. Scaling offered one way to address this final problem, which in itself is deemed to be primarily a result of insufficient data on levels of exposure within and between domains.

Once again, known data were used to guide this computation. Specifically, 12 age- and sex-specific estimates of total physical activity were available for both China and the United States $(n=24)$. These data were used to investigate what value to set as the mean to enable $z$-scores to be calculated and the data to be scaled. In addition, we set the maximum value for any age by sex cell for total activity as $98 \%$. This was derived from United States data on disability that suggests approximately $2 \%$ of the whole population may not be able to achieve any physical activity in any domain. Using a maximum value of $98 \%$ and exploring various values for the mean we identified the model of best fit for the 24 agesex category data for China and the United States. Predicted estimates of total physical activity from the best fit model are shown against actual data in Figure 10.21.

The final step was to scale the scores from Step 4 to create age x sex estimates within the range of $0-100$. We calculated the $z$-scores by setting the mean at $82 \%$ and maximum at $98 \%$ and these parameters determined the SD to be 4.33 . We chose to only scale estimates above the mean using the following formula:

If TOTAL SUM SCORE $>82$ then $82+z$-score $\times$
SD of desired distribution $(=4.33)$.

Figure 10.20 Distribution of estimates of total physical activity (a) before adjustment to transport, (b) after adjustment and (c) after standardizing scores above the mean

Predicted estimates that fell below $82 \%$ were not scaled. The final distribution of estimates of total activity is shown in Figure 10.20(c).

In addition to using data from China and the United States, available prevalence estimates of total physical activity (covering at least three domains) from Egypt and the United Republic of Tanzania were used to provide a check on the face validity of our final predicted estimates

Figure I0.2I Predicted and actual age $\times$ sex estimates of total physical activity for the USA $(n=12)$

derived from the adjusted (for activity in multiple domains i.e. Step 4) and now scaled (Step 5) model.

## Step 6: Aggregation of country estimates to create REGIONAL ESTIMATES

The penultimate step was to create prevalence estimates in terms of the exposure variable physical inactivity by subtracting physical activity scores from 100. In order to create age- and sex-specific estimates for 14 subregions, each age by sex by country prevalence estimate was weighted to the age by sex population of the country. The final estimates for each subregion were obtained by calculating the mean level of activity for each age category for males and females. Actual data were substituted for predicted estimates where available.

Estimates of exposure to physical inactivity by subregion, sex and age are shown in Table 10.10 and graphically in Figure 10.22(a). Figure 10.22(b) depicts physical activity by domain and subregion.

### 2.8 Estimating prevalence of level 2 exposure (INSUFFICIENTLY ACTIVE)

Consistent with our estimates of level 1 exposure, we attempted to consider all domains in our computation of level 2 exposure. We used the results of our literature search described earlier to identify those studies with data that matched or closely corresponded to our definition of level 2 exposure, those undertaking some physical activity but not sufficient amounts to meet the Centers for Disease Control and Prevention and the American College of Sports Medicine (CDC/ACSM) public health

a As \% of total population.
recommendation of 150 minutes of moderate-intensity physical activity per week or equivalent. We found some data for the discretionary-time domain but no specific data on the level of insufficient activity in the transport- and occupation-related domains. Thus, with only a modest amount of empirical evidence we constructed a method to differentiate between those adults doing some activity but not meeting the recommended amount (i.e. level 2 exposure) and those adults meeting the current recommendations (level 3).

Figure 10.22 Prevalence of exposure by (a) subregion and (b) prevalence of physical activity by domain and subregion

$\square$ Level 1 (inactive) $\mathbb{Z}$ Level 2 (insufficiently active) $\square$ Level 3 (meet recommendations)
$\square$ Discretionary-time activity $\mathbb{Z}$ Work-related activity $■$ Transport-related activity

## Discretionary-time domain

Countries with some data on levels of insufficient activity in the discretionary-time domain were Australia, Canada, China, Estonia, Ethiopia, Finland, India, Latvia, Lithuania, the Russian Federation, the United Kingdom of Great Britain and Northern Ireland and the United States. Figure 10.23 presents the country-level estimates of \% insufficient

Figure 10.23 Prevalence of insufficiently active as a proportion of total adult population and insufficiently active as a proportion of adults who do at least some activity, in 12 countries $^{\text {a }}$

a Definitions of insufficiently active are similar but not identical in each country; comparisons should therefore be made with caution.
for these 12 countries. We emphasize that these data are not exactly comparable due to different instruments and calculations as well as slightly different definitions. With the exception of Ethiopia, these data represent levels of insufficient activity in the discretionary-time domain only.

Figure 10.23 shows that there was no clear pattern across this set of countries. For instance, Canada and Australia had similar prevalence estimates of insufficiently active, namely $23 \%$ and $25 \%$ respectively, but this represented $25 \%$ of the "active" Canadian population and $33 \%$ in Australia. In contrast, $45 \%$ of the adult population in the United States was classified as insufficient and this was $63 \%$ of the active population. Finland had a very high proportion of adults doing at least some activity ( $90 \%$ ) but of these, $63 \%$ did not meet the current recommendations. This was similar in Ethiopia. In the absence of any pattern in the proportion of adults classified as inactive with data ranging from $25-80 \%$, we assumed that $50 \%$ of adults who were doing some activity were not active enough to meet recommendations. This rule was applied to our calculations of insufficient for all countries, male and females and all ages except the lowest age category (15-29 years). Available data indicate that younger adults are more likely to meet recommended levels of activity; therefore for this age group we assumed only $40 \%$ of those active were insufficiently active.

## Transport domain

The data on physical activity in the transport domain are generally of poor quality. Some data from Europe suggest that approximately half of all walk and cycle trips are less than 3 km . Using this information, we estimated that $50 \%$ of adults classified as active in the transport domain would be classified as insufficient because at a moderate-intensity (walking pace) 3 km would take approximately 30 minutes). It is likely that trips may be longer in duration in developing countries; therefore we scaled our algorithm such that $60 \%$ of adults identified as active in countries defined as "high income" (World Bank 1999) were classified as insufficient compared with $50 \%$ and $40 \%$ of adults in "upper middle income" and the combined group of "lower middle" and "lower income", respectively. We applied no additional adjustment to account for likely age and sex differences.

## Work domain

Data on work-related physical activity are not often reported in terms of hours of different intensity activities. Our search found few data assessing this activity in this domain alone, and only data from China were reported in hours. It is suspected that there is a large degree of measurement error in self-reporting of heavy physical activity at work; therefore some proportion of those adults reporting heavy activity may be misclassified. We decided to assume that $30 \%$ of those identified as doing heavy physical activity at work in countries defined as "high income" (World Bank 1999) did not meet recommendations. In "upper middle", "lower middle" and "lower income" countries we adjusted this assumption to $15 \%$ thus allowing more work activity "to count" as recommended. We did no further adjustments based on age or sex. Moreover, we did not attempt to estimate the proportion of adults misclassified as inactive when they should have been classified as insufficient.

## Summing across domains and final adjustment of estimates

We used our age-sex-country estimates of level 1 exposure (inactive) within in each domain (discretionary, transport and work) to compute the prevalence of adults doing at least some activity for each age x sex x country category within each domain. This was simply $100-\%$ inactive. The algorithms described above were used to compute the prevalence of insufficient in each domain, which in turn were summed to derive an overall estimate for level 2 exposure.

We reviewed these data and noted the absence of any difference between males and females. In contrast, limited available data in the dis-cretionary-time domain suggest women are less likely to be undertaking the recommended level of activity (level 3, sufficient). In addition, there is evidence of a trend over age, with older adults more likely to be insuf-
ficient compared with younger adults who are more likely to be undertaking recommended levels. We therefore developed and imposed an age and sex adjustment which resulted in the best fit between our age-sexcountry estimates and available data. It was, however, not possible to get a good fit; but the results appear to reflect the regional variations even though certain individual countries may be poorly described. Computed estimates of level 2 exposure by subregion, sex and age are reported in Table 10.10.

### 2.9 Sources of uncertainty

Given the paucity of existing data in each of the domains of physical (in)activity and the complexity of the approach taken to predict estimates of exposure, there is a large degree of uncertainty around the final data. Both quantitative and qualitative approaches were taken to estimate the magnitude of this error and these steps are outlined below.

## Methods used to estimate uncertainty and compute standard error AND 95\% CONFIDENCE INTERVALS

## Level 1-Inactive

Subregions were categorized according to the level of estimate uncertainty by considering both the quantity and quality of available data within each subregion. Quantity of data was assessed using the proportion of the total subregional population represented by data. Subregions with fewer data from fewer countries were deemed to have much greater uncertainty than those subregions with more data from more countries. Quality of data was assessed by considering the source of data (national or non-national samples). The subregions were classified into four levels of uncertainty.

- AFR-D, EUR-B, SEAR-B, SEAR-D
- AFR-E, EMR-B, EMR-D
- AMR-B, AMR-D
- AMR-A, EUR-A, EUR-C, WPR-A, WPR-B

## highest uncertainty;

high uncertainty;
moderate-high uncertainty;
lowest uncertainty.

The predicted estimates within each domain (discretionary-time, work-related and transport-related), the missing data on domestic inactivity and the modelling procedures all represent sources of uncertainty. To account for these an adjustment factor was calculated for each age-sex-subregion estimate. The magnitude of the adjustment was proportional to the level of uncertainty surrounding the data and was a sliding scale inverse to the grading of data quality. The maximum adjustment was chosen to elicit a maximum coefficient of variation of approximately $30 \%$ for the least certain estimates. To achieve this the adjustment factor
was greatest for prevalence estimates in the subregions with the highest uncertainty ( $25 \%$ ) and smallest for those subregions with the lowest uncertainty $(10 \%)$. The adjustment factor for high uncertainty and mod-erate-high uncertainty were $20 \%$ and $15 \%$, respectively. The resulting uncertainty ranges for level 1 exposure are shown in Table 10.11.

The lack of data on older adults would add greater uncertainty to these estimates across all subregions. Furthermore, the omission of data (actual or predicted) on domestic-related activity may add differential levels of uncertainty to the final estimates of women compared with men and between subregions.

## Level 2-Insufficiently active

Overall there is more uncertainty around the estimates of level 2 exposure than for level 1 due to the paucity of data and the heterogeneity among the existing data. Therefore, larger rather then smaller confidence limits were used. We computed uncertainty ranges by calculating a $25 \%$ upper and lower margin of error around each age-sex-subregion predicted estimates (Table 10.11). Given a mean level of insufficient exercise of approximately $40 \%$ this produces a range of $\pm 10$ prevalence estimate points.

## 3. Estimating physical inactivity-disease RELATIONSHIPS

### 3.1 Selection of health outcomes

There is a large body of scientific evidence linking physical inactivity with a wide range of cardiovascular, musculoskeletal and mental health outcomes. All potential disease end-points were considered; however, for inclusion the following criteria had to be met:

1. the disease outcome is included in the Global Burden of Disease (GBD) disease list;
2. there was strong evidence for a causal association between physical inactivity and an increase in risk;
3. biologically plausible mechanisms exist to explain (at least partly) the association; and
4. sufficient information was available to allow quantification of hazard.

The disease end-points initially considered for inclusion were cardiovascular disease, specifically ischaemic heart disease and stroke, several site-specific cancers (colon, rectal, breast, prostate), type II diabetes, various musculoskeletal conditions (namely lower back pain, osteoarthritis, osteoporosis), falls and mental health outcomes (specifically depression). Literature pertaining to each of these was reviewed to
Table IO.II Range of uncertainty associated with estimates for level I and 2 exposure by subregion, sex and age

| Subregion | Sex | Exposure category | Age group (years) |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |

identify the level of evidence on causality. For several outcomes there is a considerable level of interest and a large number of studies, particularly in recent years, but insufficient support for the biological mechanism associated with physical inactivity. In these cases the disease outcomes were excluded but any future attempts at assessing attributable burden should update our review. Below is a brief summary of the evidence and proposed biological mechanisms associated with physical inactivity for each disease end-point considered. These are summarized in Table 10.12.

## CARDIovascular diseases

## Ischaemic heart disease

The strongest evidence for the benefits of physical activity pertains to the reduction of risk of mortality and morbidity from cardiovascular disease, particularly acute myocardial infarction and other forms of ischaemic heart disease (Berlin and Colditz 1990; Powell et al. 1987). These associations are generally strong and independent of the definition of physical activity used. Biologically plausible mechanisms for the effects of moderate and/or vigorous intensity physical activity on ischaemic heart disease have been identified through clinical and observational studies. The mechanisms or pathways include advantageous effects on athero-
sclerosis, lipid profile, ischaemia, blood pressure, thrombosis and fibrinolytic activity (Hardman and Stensel 2003).

A number of studies have shown physical activity directly and indirectly reduces the effects of excess cholesterol and other atherosclerotic agents (Durstine and Haskell 1994; Kramsch et al. 1981; Leon 1991). Participation in physical activity can improve total blood cholesterol levels (McMurray et al. 1998) and improve high density lipoprotein (HDL) subfraction profiles (Moore 1994). An increase in HDL is desirable because HDL transports cholesterol to the liver for elimination in the bile, and thus has an "anti-atherosclerotic" function. Physical activity has also been shown to increase the activity of lipoprotein lipase, which is involved in the removal of cholesterol from the blood (Stefanick and Wood 1994). There may be, however, a threshold for the relationship between physical activity and improvements in the HDL subfraction of cholesterol, with prolonged or intensive physical activity being more beneficial for HDL to cholesterol ratios (Kokkinos and Fernhall 1999).

Decreased risk of ischaemia may be due to positive adaptations in coronary circulation from structural adaptations following physical activity (Laughlin 1994; Tomanek 1994). Acute coronary events may be reduced by a reduction in thromboses by an increase in enzymatic (fibrinolytic) breakdown of blood clots and a decrease in platelet aggregation (Leon 1991).

Vigorous physical activity has been shown to decrease systolic and diastolic blood pressures (Arroll and Beaglehole 1992; Kelley and McClellan 1994; McMurray et al. 1998; Mensink et al. 1999). Moreover there is some evidence that participation in more moderateintensity activity may achieve similar or even greater effects than vigorous activity (Hagberg et al. 1989; Marceau et al. 1993; Matsusaki et al. 1992; Moreau et al. 2001). The proposed mechanisms by which blood pressure is lowered is via the immediate and temporary dilation of the peripheral blood vessels during physical activity and the ongoing effect of a reduction in sympathetic nervous system activity (Fagard and Tipton 1994).

## Stroke

A recent review of the dose-response relationship between physical activity and risk of stroke suggests current evidence remains equivocal (Kohl 2001). Only six studies from a total of 15 showed evidence of a dose-reponse relationship; eight did not and two studies suggested a "U" shaped distribution (Kohl 2001). While this presents an unclear picture, it is notable that many studies did not differentiate between the two different types of stroke: ischaemic and haemorrhagic, as we describe in detail below.

The biological mechanisms for the association between physical activity and ischaemic stroke and ischaemic heart disease are thought to be
similar, namely atherosclerosis and hypertensive disease (Kohl 2001). However, the biological pathway for haemorrhagic stroke is less clear. Given potentially different pathophysiological pathways, it follows that physical activity may be differentially related to one type (ischaemic) and not the other (haemorrhagic). In general, studies show a decrease in the risk of ischaemic stroke with increasing levels of physical activity (Ellekjaer et al. 2000; Wannamethee and Shaper 1999) but studies with separate risk by sub-type show no or smaller associations with varying levels of activity for haemorrhagic stroke (Hu et al. 2000).

Given the evidence is mixed for an association between overall stroke and physical inactivity and sufficient evidence on causality and burden exists only for ischaemic stroke, for this study, only ischaemic stroke was included.

## Type II Diabetes

A recent review (Ivy et al. 1999) showed that the benefits of physical activity in the prevention of type II diabetes are strongly supported by current research, especially among people already at risk (Kelley and Goodpaster 2001). In general, prospective observational studies show a lower incidence of type II diabetes in more active people compared with the least active in the population. Both moderate- and vigorous-intensity physical activity reduce the risk of type II diabetes in women (Hu et al. 1999), and the benefits appear to accrue also for males and in diverse populations (Folsom et al. 2000; Okada et al. 2000). Reduction in risk of type II diabetes appears to occur only from regular, sustained physical activity.

The biological mechanisms for this protection have not been clearly identified, but are likely to occur at systemic, tissue and cellular levels. Numerous studies and reviews have described either a short- and/or a long-term effect from participation in physical activity on glucose tolerance and carbohydrate metabolism. In general, physical activity increases sensitivity to insulin, improves glucose metabolism, reduces atherosclerosis risk, and reduces intra-abdominal fat distribution (Kelley and Goodpaster 2001). Physical inactivity appears to relate to increased risk of type II diabetes by two possible pathways, which are described in detail by Katzmarzyk et al. (1996). Briefly, one pathway involves the relationship between physical inactivity, a positive energy balance, and an increase in adiposity. The resulting insulin resistance leads to a reduction in plasma free fatty acid (FFA) clearance. Elevated blood FFA levels have detrimental effects on blood glucose, which result in increased pancreatic $\beta$ cell insulin secretion and hyperinsulinaemia in order to control blood glucose levels. The increased requirement for insulin causes $\beta$ cell impairment and reduced blood insulin levels, which increases the insulin resistant state, further reduces clearance of FFA from the blood, increases glucose levels and results in type II diabetes (Katzmarzyk et al. 1996).

A second mechanism suggests that a physically inactive lifestyle exposes a genetic predisposition in skeletal muscle, which can result in muscular insulin resistance. This results in increases in $\beta$ cell insulin secretion and hyperinsulinaemia to control blood glucose concentrations. One result of hyperinsulinaemia is a suppression of fatty acid oxidation and increases of triglyceride storage, and adipose cell hypertrophy. Adipose cells then become insulin resistant and there is a reduced ability to remove FFA from the blood. This results in an increase in glucose output from the liver and further development of muscle insulin resistance. Ultimately, the increased reliance on insulin to control blood glucose concentration results in $\beta$ cell impairment and development of type II diabetes.

The physiological adaptations that are responsible for the protective effects of physical activity subside within a short period of the cessation of physical activity, within two weeks of inactivity (Arciero et al. 1999; Dela et al. 1993; Rogers et al. 1990). Therefore physical activity must be undertaken regularly to provide benefits in terms of risk reduction.

The evidence for a causative association between physical inactivity and increased risk of type II diabetes was strong enough for inclusion.

## CANCERS

## Colon cancer

Numerous studies have shown the protective effect of physical activity on risk of colon cancer (Colditz et al. 1997; IARC 2002; Thune and Furberg 2001) and on the prevention of precancerous polyps in the large bowel (Neugut et al. 1996; Slattery et al. 1997). However, no definitive biological mechanisms have been identified to explain the relationship between physical inactivity and increased risk of colon cancer although several mechanisms have been proposed, which link physical activity and changes in physiologic measures.

One possible mechanism is the effect of prostaglandins on colon mucosal cell proliferation. Physical activity produces an increase in prostaglandin F2 alpha that increases intestinal motility, and a decrease in prostaglandin E2, which stimulates colon cell proliferation (Thor et al. 1985; Tutton and Barkla 1980). Further support for this possible mechanism comes from laboratory studies on rats and evidence in humans that aspirin and nonsteroidal anti-inflammatory drugs, also inhibitors of prostaglandin synthesis, reduce risk of colon cancer (Tomeo et al. 1999). A second mechanism relates physical inactivity and abdominal obesity and proposes that obesity may increase the risk of colon cancer via its influence on insulin-like growth factor-1 (IGF-1) and insulin-like growth factor binding proteins (IGFBP). Since insulin is a growth factor for colon mucosal cells this may promote cancerous cell production. Thus, it is possible that activity exerts its protective effect through reduced insulin levels, because physical activity has been shown
to reduce insulin levels in both obese individuals and those of healthy weight (Giovannucci et al. 1995; McKeown-Eyssen 1994; Tomeo et al. 1999). Insulin-like growth factor is associated with colon cancer risk (Giovannucci et al. 2000; Ma et al. 1999), and IGF is influenced by caloric intake and physical activity. Thus higher levels of physical activity may down-regulate IGF by increasing the production of the binding protein (IGFBP3). The nature of the evidence for an association between physical inactivity and colon cancer was sufficient to meet criteria for inclusion.

## Rectal cancer

There is less evidence for a significant causal association between physical inactivity and rectal (or colorectal) cancer. A recent review of studies in which separate risk estimates for colon and rectal cancers were provided found no association between physical activity and rectal cancer in $80 \%$ of studies included in their review (Thune and Furberg 2001). The authors suggest that the apparent protective effect of physical activity on colorectal cancer may be derived, in the main, from the association between physical activity and colon cancer (Thune and Furberg 2001). On the basis of this review rectal (or colorectal) cancer was not included in this study.

## Breast cancer

The majority of studies investigating the benefits of physical activity and breast cancer report a reduction in the risk of breast cancer among physically active women (Gammon et al. 1998; Latikka et al. 1998; Verloop et al. 2000). There is substantial evidence that discretionary-time and/or occupational physical activity is associated with approximately a $30 \%$ reduction in the risk of breast cancer in pre-, peri- and post-menopausal women (Thune and Furberg 2001). Increased number of lifetime ovulatory cycles and cyclic estrogen has been proposed as a risk factor for breast cancer (Henderson et al. 1985). The impact of regular physical activity on the secretion, metabolism, and excretion of the sex hormones estradiol and progesterone provides a biologically plausible causal mechanism for the reduction of risk for breast cancer among physically active women. However, elevated relative and absolute estrogen levels may increase the risk of breast cancer (McTiernan et al. 1996). The strength and nature of the evidence for an association between physical inactivity and risk of breast cancer meets criteria for inclusion.

## Prostate cancer

There is limited evidence showing vigorous activity may provide a protective effect against prostate cancer in men (Giovannucci et al. 1998) and other researchers have not found such a relationship (Liu et al. 2000). A recent review of 24 studies found that 14 suggested an inverse association of physical activity on prostate cancer, six showed no asso-
ciation, and an increased risk of prostate cancer was observed among the most physically active men in four other studies (Friedenreich and Thune 2001). Given these equivocal results prostate cancer was not included in this project.

## MUSCULOSKELETAL CONDITIONS

Participation in physical activity throughout the course of life can increase, maintain or reduce the decline of musculoskeletal health that generally occurs with ageing in sedentary people (Brill et al. 2000). Participation by older adults can help maintain strength and flexibility, resulting in an ability to continue to perform daily activities (Brill et al. 2000; Huang et al. 1998; Simonsick et al. 1993). Furthermore, participation can reduce the risk of falling and hip fractures in older adults. (Grisso et al. 1997; Lord 1995) Evidence for associations between physical inactivity and low back pain, osteoporosis and falls, and oesteoarthritis are examined below.

## Low back pain

Low back pain is a term applied to a group of conditions or symptoms where there is pain, muscle tension and/or stiffness in the lower back. Low back pain may or may not include sciatica and other "nerve" discomfort. Physical activity is associated with both increased and decreased risk for low back pain. Certain specific activities such as heavy physical work, lifting, twisting, pulling, pushing that generally occur in occupational or during some specific discretionary-time activities (e.g. certain sports, heavy yard work) can increase the risk of low back pain (Picavet and Schouten 2000; Vuori 2001). However, participation in certain types of exercise may also reduce risk of low back pain. Four potential mechanisms for the protective effects of specific types of physical activities were proposed by Suni (2000), namely: increased abdominal and back muscle strength; better mobility and flexibility of trunk; increased endurance of trunk muscles assisting in the maintenance of motor control and stability; and increased capacity for appropriate motor skills.

Although there is some evidence from randomized controlled trials to show that low back pain can be prevented by participation in specific exercises, the evidence on participation in general physical activity and reduction on risk of low back pain is neither consistent nor strong (Vuori 2001). The outcomes are often poorly defined in many studies and this is in part due to the problematic nature of the term "low back pain", which is used for a collection of conditions with various International Statistical Classification of Diseases and Related Health Problems, tenth revision (ICD-10) codes (M45-48). Further, the type of physical activity associated with a reduced risk of low back pain has yet to be fully elucidated. Since participation in specific types of activity can not be identified at a population level there is insufficient information on which to
quantify hazard. Low back pain therefore was not included as a health outcome in this project.

## Osteoporosis and falls

Osteoporosis is characterized by low bone mass and structural deterioration of bone tissue leading to bone fragility and increased risk of fractures. The development of osteoporosis has been shown to be associated with physical inactivity (Drinkwater 1994). The biological mechanism proposed for the benefits of physical activity is via the impact on bone density. Put simply, bone cells respond to mechanical loading by increasing bone mass through improvements between bone formation and bone resorption (Lanyon 1993) and this process is mediated by glucose-6phosphate, prostaglandins and nitric oxide (Pitsillides et al. 1995; Tang et al. 1995; Turner et al. 1995). Cross-sectional studies show that participation in weight-bearing physical activity is positively associated with bone density (Gutin and Kasper 1992). Undertaking weight-bearing activity is particularly important in the development of peak bone density for adolescents (Welten et al. 1994) and for middle-aged women (Zhang et al. 1992).

Although this mechanism is strongly supported by the American College of Sports Medicine (ACSM), their position statement on osteoporosis states the types of activity most effecting such change are still not clear (1995). A recent review came to similar conclusions (Vuori 2001).

Systematic reviews of the literature have identified the beneficial role of physical activity in reducing the risks of falls in the elderly (Gillespie and McMurdo 1998; Kujala et al. 2000). Participation in physical activity is likely to be beneficial through an increase in bone strength, muscle strength, balance and coordination (Gregg et al. 2000). Currently osteoporosis is not listed as an outcome in the GBD classification system for diseases and injuries, but rather is grouped with "other musculoskeletal conditions". Given we were unable to classify what proportion of other musculoskeletal conditions are attributable to osteoporosis, or quantify the proportion of osteoporosis attributable to physical inactivity, falls were excluded from this project. Excluding osteoporosis and falls is based upon application of the specific criteria of this report, and does not indicate that physical activity is not important in fall prevention, or that there is not evidence suggesting a causal relationship.

## Osteoarthritis

Physical activity appears to be beneficial for controlling the symptoms of osteoarthritis and maintaining the health of joints. However there is limited evidence that physical activity itself can prevent osteoarthritis.

Conversely, there is evidence that certain types of physical activity, such as sustained participation in training and competition in elite sports, can lead to injuries and may increase the risk of osteoarthritis (Kujala
et al. 1994, 1995; U.S. Department of Health and Human Services 1996). However, these studies are often based on extremely small samples and specific populations and this limits their generalization to whole populations. Moreover, participation in recreational running, as opposed to competitive athletics, over a long period was not shown to increase risk of osteoarthritis (Lane 1995). Due to a lack of evidence for a causal association, and the absence of clear biologically plausible mechanisms, osteoarthritis was excluded from this review.

## DEPRESSION

Observational studies demonstrate that participation in discretionarytime and/or occupational physical activity can reduce symptoms of depression and possibly stress and anxiety (Dunn et al. 2001; Glenister 1996; Hassmen et al. 2000; Paffenbarger et al. 1994). Physical activity may also confer other psychological and social benefits that impact on health. For example, participation by individuals can help build selfesteem (Sonstroem 1984), social skills among children (Evans and Roberts 1987), positive self-image among women (Maxwell and Tucker 1992) and improve quality of life among children and adults (Hassmen et al. 2000; Laforge et al. 1999; Morans and Mohai 1991). These benefits are probably due to a combination of participation in the activity itself and from the social and cultural aspects that can accompany physical activity.

However, interpretation of the evidence on how physical activity might improve mental health is difficult due to less than ideal methodology and inconsistencies in study designs. Often studies involve small samples and use different definitions and measures of mental health outcomes. Thus, although the literature supports a beneficial effect on relieving symptoms of depression and anxiety, and as a treatment modality, there is currently limited evidence that physical activity can reduce the risk of depression and no clear evidence for a causal association. Exclusion of depression does not indicate that physical activity is not considered important for mental health; it indicates rather that the current evidence does not provide sufficient information for compliance with the inclusion criteria for this project.

## Obesity

There is considerable interest in the role of physical activity on weight. The available literature comprises a large body of observational studies showing that habitual physical activity over a lifetime can attenuate the increase in weight normally associated with increasing age, and participation in appropriate amounts of activity can lead to weight maintenance, or even weight loss (Grundy et al. 1999). The latter is especially true if physical activity is combined with a restriction of dietary energy intake. There are several proposed biological mechanisms for the association between physical inactivity and obesity (Hill and Melanson
1999). The most simple being that obesity occurs when energy intake (dietary intake) exceeds total energy expenditure (including the contribution of physical activity).

In this book, obesity is assessed as a risk factor (see Chapter 8). Moreover, it is currently not listed as a condition in the GBD classification system, instead it is included within the group "endocrine disorders". For these reasons obesity did not meet our inclusion criteria. Like depression, osteoporosis and other excluded disease end-points, exclusion does not imply the lack of any identified association with physical activity nor any lack of importance. Indeed, for obesity there is an urgent need for research and public health interventions to control and reverse the epidemic. Many health outcomes mediated through obesity are also among those considered above.

### 3.2 Search strategies for data sources

Medline and manual searches were conducted to identify review articles, individual studies and published meta-analyses of studies on the relationship between physical activity and the selected disease outcomes. The search was limited to studies published in English from 1980 to 2001. Keywords used were physical activity or exercise, along with at least one of the relevant disease outcomes listed below.

## Coronary heart disease OR cardiovascular disease

Overall our search identified a total of seven quantitative or qualitative reviews on the relationship between physical activity and ischaemic heart disease. These were: a qualitative review by Powell et al. (1987); a quantitative replication of Powell et al. by Berlin and Colditz (1990); a qualitative review undertaken as part of the 1996 U.S. Surgeon General's report on physical activity and health (U.S. Department of Health and Human Services 1996); a quantitative meta-analysis of 12 cohort studies by Eaton in 1992; a review of the dose-response relationship by Kohl (2001); a review of physical fitness vs physical activity by Blair et al. (2001); and a recent quantitative meta-analysis of all studies included in the U.S. Surgeon General's report along with any subsequent papers by Williams (2001).

## Stroke OR cardiovascular disease

Studies included in the recent reviews by Kohl (2001), Blair et al. (2001) and the U.S. Surgeon General's report (U.S. Department of Health and Human Services 1996) were obtained. Medline and manual searches revealed only a small number of additional articles not included in these documents, and these were obtained as well.

## Colon cancer Or breast cancer

Recent reviews by Thune and Furberg (2001) and McTiernan et al. (1998) provided a comprehensive coverage of the literature. We found
and obtained only a limited number of additional articles with at least one of the exposure titles (physical activity or exercise) which had not been included in either of these reviews.

Non-Insulin-dependent diabetes Or NIDDM OR type II diabetes MELLITUS
A recent review by Kelley and Goodpaster (2001) provided a list of relevant papers. Our search revealed only one additional review and a small number of articles with at least one of the exposure titles (physical activity or exercise).

### 3.3 Criteria for study inclusion

The following criteria were established for inclusion of studies in the meta-analyses:

- timing of exposure (level of physical inactivity) preceded the health outcome;
- at least two categories of physical activity were included;
- the health outcome(s) of interest were defined separately (specifically, ischaemic heart disease could be separated from cardiovascular disease and ischaemic and heamorrhagic stroke were treated separately);
- the instrument used to measure physical activity was described;
- if the exposure variable was part of a larger intervention (e.g. effect of a combined diet and exercise programme), the physical inactivity component alone could be estimated;
- demographic information was provided on the study population;
- sample size was provided;
- loss during follow up was less than $20 \%$ (if applicable);
- relative risks were published or it was possible to calculate them; and
- confidence intervals or standard errors were published or could be computed.
In addition to the above criteria, if there were multiple publications concerning the same outcome from a single cohort or trial, only the most recent publication that satisfied the inclusion criteria was selected.

### 3.4 DESCRIPTION OF INCLUDED STUDIES, INCLUDING METHODOLOGICAL QUALITIES

## ISCHAEMIC HEART DISEASE

The search identified 43 papers on physical activity and ischaemic heart disease outcomes, representing 30 cohorts. After critically reviewing each of the papers against the inclusion criteria 20 papers were retained covering 18 separate cohorts. These studies are summarized in Table 10.13.

Six of the 23 excluded papers used fitness measures rather than a measure of physical activity (Blair et al. 1989; Ekelund et al. 1988; Hein et al. 1992; Lie et al. 1985; Mundal et al. 1987; Peters et al. 1983). Of the remainder, four presented total cardiovascular disease as the outcome (LaCroix et al. 1996; Sherman et al. 1994a, 1994b, 1999), nine were reports covering cohorts which were already included (Donahue et al. 1988; Johansson et al. 1988; Morris et al. 1980; Paffenbarger et al. 1984; Seccareccia and Menotti 1992; Shaper et al. 1991; Slattery and Jacobs 1988; Stampfer et al. 2000; Yano et al. 1984), in one case a relative risk could not be calculated (Pomrehn et al. 1982), and in three cases standard errors could not be determined (Garcia-Palmieri et al. 1982; Kannel et al. 1986; Lindsted et al. 1991).

Sample sizes were generally of the order of a several thousand people, with the median sample size around 8000 , but ranged from 636 to 99029 . Most studies adjusted for confounding factors notably age, sex and smoking. Many studies adjusted for the intermediate factors identified as being in the causal pathway, namely blood pressure and blood cholesterol.

Mortality was ascertained by linkage or review of state, municipal or national death records. Incident cases were identified through hospital discharge lists, linkage with health registers, self-report (with and without verification by hospital records), or by abstraction and examination of hospital records.

Twelve studies were conducted in western Europe and eight studies were from North America. No studies were found from Africa, Asia or the Eastern Mediterranean. Study populations were generally of middle socioeconomic status and mostly Caucasians, an exception being men of Japanese ancestry (Rodriguez et al. 1994).

Estimates of relative risk with and without an adjustment for blood pressure and cholesterol were extracted for meta-analyses where available (see Table 10.13). The total effect of physical inactivity, not the independent effect, is required to calculate the estimates of disease burden.

## ISCHAEMIC STROKE

Over 30 papers were considered for inclusion into our meta-analysis for ischaemic stroke. Only eight studies met our criteria, all of which had

Key: SE, standard error (of log relative risk); CI, confidence interval; PA, physical activity; IHD, ischaemic heart disease; AMI, acute myocardial infarction. a Name refers to the common name of the cohort study.
Adjusted for: $\mathrm{I}=$ age, $2=$ smoking, $3=\mathrm{BMI}$ or waist/hip ratio, $4=$ blood pressure, $5=$ cholesterol, $6=$ type II diabetes, $7=$ sex.
Relative risk estimate with adjustment as indicated in footnote b. Figure in brackets indicates relative risk estimate NOT adjusted for blood pressure and cholesterol and some other factors. DTPA refers to discretionary-time activity; Sports index refers to organized sporting activities; Leisure index refers to DTPA excluding organized sports; OPA refers to occupational-related activity.
Incidence includes both morbidity and mortality.

* Indicates data from study used to calculate summary relative risk for level 2 exposure (insufficiently active)
been published since 1990 (Table 10.14). The majority of studies were excluded because they did not separate the subtypes of stroke; instead they reported risk estimates for the combined outcome of ischaemic and heamorrhagic stroke. The studies included covered both males and females and the age range of $40-74$ years. Seven of the eight studies were from North America (Abbott et al. 1994; Evenson et al. 1999; Gillum et al. 1996; Hu et al. 2000; Kiely et al. 1994; Lee et al. 1999; Sacco et al. 1998) and one study was conducted in Europe (Sweden) (Harmsen et al. 1990). Median sample size was811 1473.

For stroke, cases were identified through hospital discharge lists, linkage with health registers, self-report (in some cases verified by hospital records) or by abstraction and examination of hospital records. Deaths were identified through linkage with national, state or municipal registries.

Details of each study and relative risk estimates are presented in Table 10.14.

## CANCERS

Over 100 papers published since 1980 were identified for the two sitespecific cancer types, namely, colon and breast cancer. For both types of cancer, the majority of cases were identified through hospital discharge lists, cancer registries or by direct hospital recruitment (for case-control studies). In a small number of studies, self-reported data were used, but in all but one study these data were verified by review of hospital records. Deaths were identified via linkage with national, municipal or state records.

Sample sizes varied greatly, with a median sample size of 1844 for breast cancer and 1472 for colon cancer. The studies of breast cancer included only females, a single study looking at male breast cancer was excluded. Colon cancer studies appeared to cover both sexes equally. The majority of studies controlled for various important confounding or intermediary factors including age, smoking, family history of cancer and BMI. In addition, parity, use of hormone replacement therapy, use of oral contraceptives and menopausal status were controlled for in studies on breast cancer, and alcohol consumption, caloric intake and dietary factors (such as fat and fibre intake) were considered in studies on colon cancer.

The majority of studies for both types of cancer were conducted in North America, western Europe and the Western Pacific (e.g. China and Japan) (Kato et al. 1990; Matthews et al. 2001). Details of the 43 studies on breast cancer and 30 studies on colon cancer are shown in Tables 10.15 and 10.16 .

## Type II DIABETES

Twenty-two recent studies (see Table 10.17) were identified addressing the relationship between physical inactivity and type II diabetes. A

Key: SE, standard error (of log relative risk); PA, physical activity.
Adjusted for: $\mathrm{I}=$ age, $2=$ smoking, $3=\mathrm{BMI}$ or waist/hip ratio, $4=$ blood pressure, $5=$ cholesterol, $6=$ family history of type II diabetes, $7=$ sex.
Relative risk estimate with adjustment as indicated in footnote a.
DTPA refers to discretionary-time activity; OPA refers to occupational-related activity.
Cohort/cross-sectional study - number of controls is total sample size.
diverse range of populations have been studied from the regions of Africa (Mauritius, South Africa and the United Republic of Tanzania), Asia (China), the Western Pacific (Japan and Fiji) as well as North America and western Europe.

For type II diabetes, cases in all case-control studies were identified using oral glucose tolerance tests (OGTT). In the majority of cohort studies, identification was by OGTT or fasting plasma glucose tests at follow-up, or by self-report, validated by physician or medical record review. In only one case was unverified self-reported data used.

Sample sizes ranged widely with a median sample size of 1113. All studies adjusted for a variety of important confounding or intermediary factors including age, BMI, blood pressure, cholesterol and family history of diabetes.

### 3.5 Methods for meta-analysis

Our general method for meta-analyses was similar to that used by Berlin and Colditz (1990) and Eaton (1992) and combined estimates of the log relative risks using an inverse-variance weighting scheme (Berlin and Colditz 1990; Eaton 1992). This method gives relatively more importance to studies with a larger number of cases and produces a wider confidence interval for the pooled relative risk estimate than would be obtained by other methods (such as the Mantel-Haenszel method). Confidence intervals for the summary risks were derived using a pooled standard error.

For ischaemic heart disease and ischaemic stroke we conducted two different meta-analyses. Firstly, we pooled risk estimates derived from analyses which had adjusted for two intermediary variables (blood pressure and cholesterol) and secondly, we pooled estimates of risk without adjustment for these intermediary variables. The former (with adjustment) removes the effect due to other factors and identifies the independent risk due to physical inactivity. Estimates of risk without adjustment for other variables in the causal pathway indicate the total effect of exposure to inactivity. The first method partials out the contribution of inactivity to various disease end-points while the second is useful in calculating the total effect of removing exposure to inactivity (Greenland 1987). We report both results to enable comparison with results from previous meta-analyses, all of which used adjusted data, and to allow computation of avoidable burden of disease (which required the unadjusted analyses). For type II diabetes and breast and colon cancer, estimates of risk were computed using only adjusted data as noted in Tables 10.15-10.17.

The problems associated with measurement of behavioural risk factors are well known and to date few satisfactory solutions are available. Given the difficulties associated with assessing a complex exposure variable like physical inactivity and the heterogeneity among the instruments used across the epidemiological studies, one approach is to intro-
duce an adjustment at the analytical stage. Adjustment for measurement error within the meta-analysis has been previously applied to other risk factors (Bashir and Duffy 1997). We employed this technique in our analyses and present the results both adjusted for measurement error and unadjusted for measurement error.

Overall three separate analytical approaches were conducted to derive summary estimates of relative risk, as summarized below.

- Adjusted for intermediary variables: This method was undertaken for all disease outcomes and used pooled relative risk estimates from studies in which the analyses had controlled for the intermediate factors (blood cholesterol and blood pressure). These results have not incorporated the adjustment for measurement error and so can be compared to other published results that have controlled for intermediaries.
- Adjusted for intermediary variables AND adjusted for measurement error: This method is the same as above with the addition of a statistical adjustment for measurement error. This method was conducted for all disease outcomes and represents an extension of the above method.
- Unadjusted for intermediary variables AND adjusted for measurement error: This method pooled relative risk estimates from studies in which the analyses had not controlled for blood pressure and cholesterol. It was conducted for only ischaemic heart disease and ischaemic stroke and, for those studies without unadjusted risk estimates, the adjusted risk estimates were included.

## MEASUREMENT ERROR

The major sources of error arise from the variability in the measurement and/or definitions of the health outcome and the exposure variable (i.e. physical inactivity). A further source of variability may be due to the timing of the exposure. These will be discussed in turn below.

## Error due to variable measures of exposure

In general, measurement error is a product of the different ways in which physical inactivity is measured and/or categorized. Using different measures and definitions can result in quite different estimates of the level of exposure to physical inactivity. We identified three main sources of potential measurement error for exposure.

Firstly, the questionnaires used in the epidemiological studies included in our meta-analyses vary in their attempt to measure physical activity undertaken in different domains. The studies included for ischaemic heart disease mostly evaluated discretionary-time physical activity (Haapanen et al. 1997; Lakka et al. 1994; Leon et al. 1987; Rosengren and Wilhelmsen 1997; Shaper et al. 1994; Slattery et al. 1989), although in
some studies this was defined as "sport" and "leisure activities" (Folsom et al. 1997) and in other studies it was extended to include other activities such as walking and stair climbing (Lee and Skerrett 2001; Lee et al. 2000; Manson et al. 1999). In the Harvard Alumni study "sports" activity plus walking and stair climbing were assessed (Sesso et al. 2000). In several studies "all" physical activity was evaluated but the exact meaning and coverage of domains required a careful inspection of the specific instruments (Morris et al. 1990; Pekkanen et al. 1987; Rodriguez et al. 1994; Salonen et al. 1988; Sobolski et al. 1987). Only one study included in our meta-analysis provided an estimate of risk based on only occupational physical activity and one other study provided separate relative risk estimates for occupational and discretionary-time activity (Menotti and Seccareccia 1985; Salonen et al. 1982). It is notable that the majority of studies published post 1980 focus more on discretionarytime activity whereas literature published between 1958-1980 is dominated by studies of work-related activity.

Pooling results from studies with measures of exposure across discretionary time, sports, walking, stair climbing and "all" activity could have a marked affect on the overall estimates of risk. One solution, previously used by Berlin and Colditz (1990), is to separately pool results from studies assessing different domains (e.g. occupation only, discretionary time only). However, in this study the pooled summary relative risk estimates were applied to prevalence estimates of exposure in which multiple domains had been considered. We therefore considered the inclusion of studies with diverse definitions of activity, possibly across more than one domain as acceptable. Nonetheless, this source of heterogeneity among the literature is noted, as is the desirability for much greater comparability of measures of exposure between studies.

A second source of measurement error could arise from the different instruments used to assess exposure in the various domains. Five of the 19 included cohort studies used the Minnesota Leisure Time Physical Activity questionnaire and three used the Harvard Alumni instrument, but the remaining 11 studies used different and sometimes unspecified survey tools. Different questionnaires have different properties and concomitant variation in the level of validity and reliability. The instruments used in the studies included in our meta-analyses assessed physical activity over differing referent time periods (e.g. the previous year, last week or usual week) and used various response formats (Folsom et al. 1997; Lakka et al. 1994; Lee and Paffenbarger 2000). To address this concern we included an adjustment for measurement error in our meta-analyses using information on the reliability of each instrument. The rationale and methodology are described below.

A third potential source of error relating to the exposure variable may result from the different ways in which physical activity data are categorized. For instance, different studies have used different methods of categorization (e.g. tertiles, quartiles, quintiles, sextiles) (Folsom et al.

1997; Lee and Paffenbarger 2000; Leon et al. 1987; Rodriguez et al. 1994; Rosengren and Wilhelmsen 1997; Sesso et al. 2000; Shaper et al. 1994), but not all studies provide a full description of the level of activity in each category to facilitate between-study comparison. In addition to the variability between studies there is also likely to be within-category variability (Blair and Jackson 2001). Indeed, Berlin and Colditz (1990) discussed this problem and concluded that this could explain why some studies failed to show a protective affect due to physical activity.

We attempted to reduce the error from pooling results from different studies using different categories by identifying from each study the categories of activity most consistent with our definitions of exposure. We selected the "sedentary" or lowest category from each study as the "most exposed" group and this was deemed most comparable to our level 1 exposure (inactive). Similarly, the categories of activity within each study were reviewed to identify the most comparable group(s) for our level 2 exposure (insufficient activity). Finally, and most importantly, we extracted from each study the estimate of relative risk pertaining to a referent group equivalent to our level 3 exposure, namely, a level of activity equal to at least 150 minutes of moderate-intensity activity per week (at least 2.5 hours of activity per week or an energy expenditure of at least $4000 \mathrm{~kJ} /$ week). Some studies did not clearly define this group and in these cases we carefully reviewed each category within the study and made a subjective assessment. In this regard, our meta-analysis differs from previous reviews which have chosen to assess the relative risk of inactivity using a referent group defined as the "most active" or "vigorous activity" or "high fitness".

## Error due to measures of disease end-points

Another possible source of measurement error arises from different definitions or classifications of the disease end-points, particularly when disease subtypes exist within a health outcome. For example, studies with ischaemic heart disease as an outcome may include mortality and/or morbidity from all types of ischaemic heart disease (including angina pectoris), only myocardial infarction or myocardial infarction and sudden death combined. However, the etiology of these conditions may differ, as may the contribution of physical inactivity.

In assessing ischaemic heart disease, Berlin and Colditz (1990) undertook separate meta-analyses for acute myocardial infarction, ischaemic heart disease incidence and for ischaemic heart disease mortality. They found no difference in the relative risk estimates from the analysis of each outcome separately, although the strength of association (defined by the range of confidence intervals) was greater for mortality than morbidity. Eaton (1992) examined the differences between pooled estimates from studies using ischaemic heart disease mortality and those using clinical ischaemic heart disease as health outcomes and also found no dif-
ference in the size or the strength of the association. Therefore, given no evidence to the contrary, we combined ischaemic heart disease mortality and morbidity in our meta-analyses.

There appears to be no association between physical activity and hemorrhagic stroke. As a result in studies assessing stroke, misclassification of subtypes may have led to null associations between physical activity level and disease outcome (Kohl 2001). Therefore, for inclusion in our meta-analyses, only studies that clearly differentiated and reported results for ischaemic stoke were included.

For type II diabetes, colon cancer and breast cancer there is a paucity of information on the level of any misclassification and the effect on relative risk estimates. However, any misclassification of colon cancer (i.e. colon, colorectal and rectal cancers) would, if random, most likely underestimate the relationship between physical activity and risk for colon cancer. The positive effect of physical activity would be diluted because of null associations included due to misclassification.

## Error due to timing and duration of exposure

Epidemiological data may also be inconsistent due to the timing of the exposure, in this case physical inactivity. However it is simpler to consider the timing of physical activity and ask when during the life course is activity required for risk reduction? For ischaemic heart disease and type II diabetes the activity is required to be regular and recent for risk reduction. However, for other conditions (e.g. breast cancer, colon cancer) activity during childhood or adolescence may be important to reduce risk.

Among the studies included in the meta-analyses a range of followup periods can be seen-for example, from 2 to 23 years for ischaemic heart disease, from 8 to 22 years for ischaemic stroke and from 4 to 56 years for breast cancer. Measurement error associated with assessing long-term physical activity patterns by a questionnaire administered only at baseline is likely to be important. It was, however, not possible to account for this in our meta-analyses but it is highly recommended that this issue be explored in future research.

## Adjustment for measurement error

We considered the issue of measurement error associated with self reported recall of physical (in)activity and concluded that such error could lead to an underestimate of the association between physical activity and disease end-points. Thus, an adjustment for measurement error was made to each estimate of relative risk extracted from the individual studies based on the reliability of the instrument used to measure exposure. Specifically, the adjustment involved multiplying the beta coefficients (log relative risks) by the inverse of the study-specific test-retest correlation coefficient as previously used with other risk factors (Bashir
and Duffy 1997), although we found no prior evidence of its use with physical inactivity.

The test-retest coefficient for each instrument was obtained in the first instance from the article as cited by the authors of the epidemiological study. When this was not available we searched the published literature including a compendium of instruments which contained an excellent summary of test-retest reliability data for many instruments (Pereira et al. 1997). If no information was found for a specific instrument but a sufficiently detailed description was available, we assigned a test-retest coefficient based on the correspondence between characteristics of the instrument as described by the authors and other known instruments. In those cases where little or no information on the instrument was provided the average score of known instruments was applied. This process was undertaken for all studies included for each of the disease outcomes. Table 10.18 reports the test-retest coefficient for the instruments used in studies addressing ischaemic heart disease.

## Heterogeneity

Although the fixed-effects model gives relatively more importance to bigger studies than smaller studies in the summary relative risk estimate, the effect of any heterogeneity not accounted for by study size remains. Despite our study inclusion criteria heterogeneity among the studies was significant for all conditions, except for ischaemic heart disease, as we describe below. No attempt to identify the sources of heterogeneity was undertaken. However, it is probable that differences in study design such as combining studies with different types of physical activity, different measurement instruments, different follow-up time, and differences in disease outcomes contributed to the heterogeneity (Berlin and Colditz 1990). Tests of heterogeneity and bias were conducted to assess the quality of the data as well as to reveal any evidence of heterogeneity and/or publication bias. The extent of bias was assessed by regressing the standard errors to the relative risk estimates and testing whether the regression coefficient was equal to zero (Sterne and Egger 2001).

Heterogeneity was assessed using funnel plots by drawing $95 \%$ confidence limits around the summary risk estimate for various values of the standard error. In the absence of heterogeneity, $95 \%$ of the point estimates should lie within these limits.

### 3.6 Attenuation for age

The relative risk associated with physical activity and some disease endpoints has been shown to be lower for older age groups compared with younger age groups (Sesso et al. 2000). This is consistent with an age attenuation seen in other intermediate risk factors such as systolic blood pressure and cholesterol (MacMahon et al. 1990). It is desirable for any calculation of attributable burden to include an attempt to better represent the differential risk across age. However, overall there were too few

Table IO.I8 Test-re-test reliability for instruments used in studies on ischaemic heart disease

data on physical inactivity by age to compute age-specific estimates of relative risks.

In lieu of this, the summary relative risk estimates from our metaanalyses were applied to the age categories 30-44 years, 45-59 years and 60-69 years on the basis that this age range was well represented by the studies included in our analyses. In addition, the summary estimate was applied to the 15-29-year age group for all disease end-points except breast cancer. In this case there was sufficient evidence to support differential relative risk estimates for pre-/peri- and postmenopausal women and we classified these groups as $15-44$ years, and $\geq 45$ years, respectively.

Reviewing data from two studies on ischaemic heart disease in which older age cohorts were examined (Bijnen et al. 1998; Sesso et al. 2000)
we found older adults had around half the excess of the average risk estimate from all other studies combined. This formed the basis of age attenuation estimates. Specifically, $25 \%$ of the excess risk was used to estimate risk for the $70-79$-year age group and $50 \%$ of the excess risk was used for the age group $\geq 80$ years. These algorithms were used to compute age attenuated estimates for all other disease end-points. It is possible that there is no attenuation across age for increased risk of cancer, employing the age attenuation described may have added to the likely underestimation of burden.

### 3.7 Extrapolation of hazard estimates

In general, there was a paucity of data on the effects of physical activity and reduction in risk of disease among populations not of European decent. For ischaemic heart disease and ischaemic stroke, the majority of studies were conducted with men of primarily European descent. For colon and breast cancer the population base was broader but still mostly of North American and European origin. Studies on type II diabetes included data from a much wider range of regions and the reduction in risk was in the same direction across different population groups. Like previous reviews (Powell and Blair 1994), we found no established reasons to suggest that the association between physical inactivity and chronic diseases would differ across diverse populations. Thus, in the absence of evidence to the contrary, we assume that the relative risk estimates for all conditions can be applied across all populations.

### 3.8 Estimated hazards

Where possible, separate relative risks for males and females were used to derive the summary estimates. If studies provided specific risk estimates for various age groups and/or for different domains of activity in addition to an overall summary risk, the estimate across all age groups and/or across all domains was extracted for our analyses (e.g. Morris et al. 1990). If no summary score was presented, the age/domain specific estimates were included as one study in the meta-analysis (e.g. Gillum et al. 1996).

## IsCHAEMIC HEART DISEASE

Table 10.19 reports the summary risk estimates from meta-analyses undertaken with and without an adjustment for measurement error. Funnel plots showed little evidence of bias but some heterogeneity in these meta-analyses (Figure 10.24). The regression test showed no evidence of bias ( $P=0.34$ ).

## IsCHAEMIC STROKE

The analyses described above for ischaemic heart disease were repeated for ischaemic stroke and the results are reported in Table 10.20. Funnel plots (Figure 10.25) showed some evidence of heterogeneity and large

bias in these analyses (regression $P<0.001$ ). We were unable to account for this bias, however publication bias (i.e. preferential publication and increased citation of studies with significant results) and the restriction to studies published in English may have contributed.

## BREAST CANCER

Summary risk estimates were computed for pre- and peri-menopausal women combined and for post-menopausal women. These estimates

were applied to the 15-29- and 30-44-year age groups and those groups of women aged $\geq 45$ years, respectively. The results shown in Table 10.21 indicate a somewhat stronger association between level 1 exposure and breast cancer for post-menopausal women (1.34) compared to pre- and peri-menopausal women (1.25). This relationship is also evident for level 2 exposure. Funnel plot (Figure 10.26) revealed some evidence of bias and heterogeneity. The regression test showed significant bias among studies of post-menopausal women $(P=0.002)$ but not among pre- and peri-menopausal women ( $P=0.23$ ).

## COLON CANCER

Table 10.22 reports the results of risk associated with colon cancer for men and women. Separate analyses by sex were conducted but showed a non-significant difference, thus pooled estimates are provided (data not shown). Funnel plots showed some evidence of bias but little heterogeneity (see Figure 10.27), however the regression test revealed a significant bias $(P<0.001)$. This bias would appear to be attributable to the inclusion of three studies which each had relatively large estimates of risk and small standard errors (Gerhardsson et al. 1988; Longnecker et al. 1995; Tang et al. 1999). Excluding these studies resulted in a regression test p-value of 0.30 and had no effect on the summary risk estimates.

measurement adjustment). Age attenuation was applied to the age groups of $70-79$ years and $\geq 80$ years.

The funnel plot showed no evidence of heterogeneity (Figure 10.28) but strong evidence of bias for these analyses (regression test $P<0.001$ ). We were unable to account for this bias, however it is possible that publication bias may have contributed.

## Discussion of relative risk estimates

Overall the results from our set of meta-analyses are similar to previous reports. For instance, the summary estimate of the independent effect of inactivity (1.38) is similar to previous findings of Eaton (1992) and the

Table 10.23 Summary relative risk estimates for type II diabetes for level I (inactive) and level 2 (insufficiently active) exposure, by age and sex

recent findings reported by Williams (2001). Eaton (1992) found an association between physical inactivity and ischaemic heart disease of 1.37 (1.27-1.48) from a set of 14 studies that assessed discretionary time and/or well-defined occupational physical activity, with ischaemic heart disease mortality or morbidity as disease end-points. More recently, Williams (2001) pooled results from 16 cohorts with measures of dis-cretionary-time physical activity or "all physical activity" and ischaemic heart disease end-points. The author reported pooled relative risk estimates against percentiles of activity and showed relative risks of between $0.65-0.75$ for the 70th percentile and above of activity compared with the referent group of zero activity. Inverting his result to allow comparison with this study produced a relative risk of about 1.4.

Figure 10.28 Funnel plot of studies used in type II diabetes meta-analysis for ischaemic heart disease, level I exposure (inactive)

Our results are also consistent with earlier reviews undertaken by Powell et al. (1987) and Berlin and Colditz (1990) when the differences in protocols are reviewed. Powell et al. (1987) pooled 47 studies with diverse methodological properties and included studies with exposure of either fitness or physical activity. Their qualitative summary estimate of relative risk was 1.9 but the authors noted the magnitude of this association ranged from 1.5-2.4. Berlin and Colditz (1990) replicated the work of Powell et al. with the addition of any subsequent published work, and reported several estimates of relative risk specific to occupational physical activity and non-occupational activity, and for separate cardiovascular disease outcomes. Also, they undertook separate analyses for studies with two and with three levels of exposure. Using only those studies included by Powell et al., they computed a summary estimate of risk for discretionary-time inactivity and ischaemic heart disease (morbidity) of 1.6 with a confidence interval of 1.3-1.8 (see published paper Table 4, analysis B) (Berlin and Colditz 1990). This did not change substantially when additional studies were added ( $\mathrm{RR}=1.5,95 \% \mathrm{CI}$ 1.4-1.7, see published paper Table 5, analysis B).

Berlin and Colditz refined their analyses by separating studies based on epidemiological criteria and classified studies as "satisfactory" and "unsatisfactory". Including only the former studies, relative risk estimates ranged from $1.3(0.7-2.6)$ to $1.9(1.0-3.6)$ for ischaemic heart disease mortality (see published paper Table 6). Thus, comparing our
results with the intricate set of analyses of Berlin and Colditz and other previous work of Powell et al. (1987), and Eaton (1992) revealed our results are similar and well within the range of published confidence limits.

We found a weaker relationship for the effect of physical activity on ischaemic stroke than on ischaemic heart disease, the relative risk estimate for the inactive group being 1.53. The existence of a dose-response relationship between physical activity and stroke is not yet established (Kohl 2001) and there is no evidence of a dose-response effect seen in this study, with the relative risk of the insufficiently active group being no different from 1 .

The relative risk of physical inactivity associated with developing type II diabetes was 1.45 (1.37-1.54) and this was applied to men and women. Previous studies have reported a differential protective effect across sex, however we found only modest evidence for level 1 exposure and no evidence for level 2 exposure. Any apparent difference may have been due to the large degree of heterogeneity among studies. A dose-response relationship across levels of exposure was observed and this is consistent with a recent review of the benefits of physical activity in preventing or delaying the development of diabetes (Kelley and Goodpaster 2001).

The relative risk associated with colon cancer was 1.68 (1.55-1.82) for inactive adults compared with those who are reaching recommended levels of activity. The insufficiently active group had a lower relative risk of 1.18 (1.05-1.33) compared to the referent group. These results indicate a dose-response relationship across exposure and this is consistent with previous research (Thune and Furberg 2001). No previous quantitative meta-analyses have been undertaken on physical inactivity and colon cancer, although the recent review by Thune and Furberg (2001) concluded that the majority of studies showed an independent protective effect ranging in magnitude of between $10 \%$ and $70 \%$ (2001).

We found the relative risks associated with breast cancer were 1.25 (1.20-1.30) for women aged 15-44 years and 1.34 (1.29-1.39) for women aged 45-69 years. These results are consistent with a previously published qualitative review that showed a $30 \%$ reduction in risk of breast cancer among pre-, peri- and post-menopausal women, with a graded dose- response seen in around half of the studies reviewed (Thune and Furberg 2001). Evidence of a dose-response effect was observed with the relative risk of 1.13 (1.04-1.22) associated with the insufficiently active group.

In summary, our estimates of risk of ischaemic heart disease are consistent with previous research, given a careful inspection of the study inclusion criteria and treatment of the data. There are less data by which to compare our results on ischaemic stroke and no previous quantitative reviews addressing type II diabetes and breast and colon cancers. Across
all health outcomes, except ischaemic stroke, a dose-response relationship was observed, with the most inactive (level 1 exposure) associated with having the greatest risk. There is considerable heterogeneity across studies aimed at answering apparently similar questions. This is a notable limitation to conducting meta-analyses. This field of research would benefit from improved measures of exposure; and greater consistency in the reporting of results between studies would advance this field.

### 3.9 RISK REVERSIBILITY AND TEMPORAL ASPECTS OF THE RISK FACTOR-DISEASE RELATIONSHIP

There is little direct evidence on risk reversibility associated with increases in levels of physical activity. This is primarily due to the lack of randomized controlled trials and the fact that a long period between exposure to physical inactivity and disease outcomes is required for assessment. Further, the few data that are available mostly relate to risk reduction in all-cause mortality and ischaemic heart disease and predominantly among white men from middle to upper socioeconomic groups. Despite these limitations, we reviewed the available literature and attempted to estimate the magnitude and time lag associated with change in level of activity and change in risk. Our conclusions for each health outcome are summarized below.

## Ischaemic heart disease and ischaemic stroke

Increase in levels of physical activity can reduce the risk of ischaemic heart disease (Paffenbarger et al. 1994). Among Harvard alumni, physically inactive men who started a moderate-vigorous physical activity routine reduced risk of ischaemic heart disease mortality by $41 \%$ compared with men who remained inactive (Paffenbarger et al. 1993). This is consistent with findings on the benefits of changes in cardiorespiratory fitness, which although not included in this review may help inform the potential nature of risk reversibility due to physical inactivity (Blair et al. 1995). Blair et al. (1995) reported a reduction in risk of ischaemic heart disease due to improvements in cardiorespiratory fitness. They found that men classified as unfit at their initial examination and fit at their subsequent examination had a $44 \%$ reduction in risk of ischaemic heart disease mortality than did men who were unfit at both examinations (Blair et al. 1995). Furthermore, these associations were independent of other potentially confounding factors (e.g. smoking, BMI, systolic blood pressure, cholesterol) (Blair et al. 1995, 1996). Moreover, there is evidence to suggest that recent participation in physical activity, rather than activity performed in the past, is required for reduction in risk of ischaemic heart disease (Paffenbarger et al. 1978).

Although there is limited empirical support, there are indications that reversibility for ischaemic heart disease could be complete, and could occur within a relatively short period of time following reversal of exposure, perhaps as short as several months or up to two years. This assump-
tion is based on the available evidence pertaining to changes in physical inactivity, indirect evidence from studies using fitness parameters, and known acute effects of physical activity on elements of the physiological pathways which reduce cardiovascular risk.

There is little evidence to guide the estimates of risk reversibility for ischaemic stroke following changes in exposure to physical inactivity. As the biological pathways are considered to be the same as those for ischaemic heart disease, it is possible that there may be a similar relationship for a reduction in risk.

## BREAST CANCER AND COLON CANCER

There are no data to help quantify what degree of risk reduction may occur over what time frame for breast cancer. The paucity of data on physical activity and risk reduction required us to use indicative information on which to base such estimates. Studies on the cessation of postmenopausal hormone replacement therapy and breast cancer rates provide indirect estimates, as the biological pathways (i.e. through hormone levels, as described in section 1) are considered to be similar to that assumed for physical activity's impact on breast cancer.

Major reviews of the epidemiological evidence suggest complete reversibility. That is, women who stop postmenopausal hormone replacement therapy generally revert to the same breast cancer rates as women who had never had hormone replacement therapy, over a period of two to five years (Collaborative Group on Hormonal Factors in Breast Cancer 1997; La Vecchia et al. 2001). There is, however, debate on the biological plausibility and mechanisms of this observed reduction in risk (Bieber and Barnes 2001).

Again there are few data to indicate what the magnitude of risk reduction may be over time for colon cancer. Lee et al. (1991) suggested that although a lifetime or at least consistent participation during adulthood in physical activity is required for greatest protection from risk of colon cancer, some reduction ( $13 \%$ over $11-15$ years) is seen in men who become active after being inactive.

## Type II Diabetes

There are two sources of information to help with risk reversibility for type II diabetes. Data from the Nurses' Health Study show that women who increased their physical activity levels over six years experienced $29 \%$ lower rates of type II diabetes than those who remained inactive over the same period $(R R=0.71)$ (Hu et al. 1999). However, women who were active at the beginning and remained active over the six years still had lower rates of type II diabetes than those who became active ( $\mathrm{RR}=0.59$ ). Recently, the Diabetes Prevention Program Research Group (2002) showed that, among people who had impaired glucose tolerance, a lifestyle intervention combining moderate amounts of physical activity
with a controlled diet resulted in a $58 \%$ reduction in the incidence of type II diabetes over 2 to 5 years. Since this risk reduction resulted from a combined lifestyle intervention with a population already at increased risk, the effect of only changes in physical activity in the general population is assumed to be less. These estimates suggest a risk reversibility of $25 \%$ over five years for sedentary adults becoming sufficiently active and $35 \%$ over four years for insufficiently active adults becoming sufficiently active.

## 4. Burden of disease attributable to PHYSICAL INACTIVITY

The fraction of burden (mortality and morbidity combined) attributable to physical inactivity for each disease end-point is shown in Figure 10.29. Globally physical inactivity contributed to an estimated $22 \%$ of ischaemic heart disease, $11 \%$ of ischaemic stroke, $14 \%$ of type II diabetes, $16 \%$ of colon cancer and $10 \%$ of breast cancer. The results show small differences between males and females, due in part to differences in the level of exposure and to the different distribution of events between the sexes. There were small, non-significant differences in the attributable fractions across subregions (data not shown). For ischaemic heart disease the subregional differences ranged from $21 \%$ (SEAR-D, EMR-D and WPR-B) to $23 \%$ (AMR-B, EUR-C and WPR-A). A slightly wider range was seen for ischaemic stroke $9 \%$ (AFR-D) to $14 \%$ (EUR-C).

The number of deaths and number of DALYs were computed for each disease outcome (Figures 10.30 and 10.31, respectively). Over one

Figure 10.29 Attributable burden of disease due to physical inactivity for ischaemic heart disease, ischaemic stroke, type II diabetes, colon cancer and breast cancer

Figure I 0.30 Attributable mortality due to physical inactivity for ischaemic heart disease, ischaemic stroke, type II diabetes, colon cancer and breast cancer

Figure I 0.31 Attributable DALYs due to physical inactivity for ischaemic heart disease, ischaemic stroke, type II diabetes, colon cancer and breast cancer

million deaths due to ischaemic heart disease were attributable to physical inactivity ( 730000 males and 634000 females). Another 308000 deaths from ischaemic stroke were also attributable to inactive and insufficiently active lifestyles. Combined with deaths from type II diabetes (116000), colon cancer (90000) and breast cancer (45000) a total of 1.92 million deaths could be prevented from increasing levels of physical activity (Figure 10.30). Similarly inactive lifestyles contributed to a loss of 19 million DALYs worldwide.

## 5. Discussion

The attributable fraction for ischaemic heart disease morbidity and mortality ( $22 \%$ ) is slightly lower than previous estimates that range from $23 \%$ (Hahn et al. 1990) to $35 \%$ (Powell and Blair 1994). This variation is explained by differences in the estimates used for prevalence and relative risk. Previous attempts have used rounded estimates of risk (1.9) (Powell and Blair 1994). We estimated relative risks that are consistent but marginally lower than previous reports because we only accepted data from studies reporting an exposure of physical activity not physical fitness; risk of exposure was computed relative to the current public health recommendations not a referent group of "high level of activity" or "vigorously active"; an adjustment for attenuation of risk over age was included; and, perhaps most importantly, we used a trichotomous not continuous measure of exposure. We acknowledge that no attempt was made to account for the additional benefit associated with being highly active and/or engaging in activities of vigorous intensity.

Furthermore, past estimates of exposure have been based on only one domain, namely discretionary time. Single domain estimates will overestimate exposure by not including activity undertaken in other domains. Another important difference with previous estimates is in the number of categorical levels used in the analyses. We created a trichotomous measure; in contrast previous work had used four levels of exposure (Powell and Blair 1994). Estimates of level 2 exposure should be interpreted with great caution. Available data were the most difficult to compare and we acknowledge our assumptions will inevitably include some misclassification. Our global estimate of insufficiently active was $41 \%$, although data show that in different countries it can range from $20 \%$ to $70 \%$. For both level 1 and level 2 there is greatest uncertainty around prevalence estimates for Africa, Asia and the Eastern Mediterranean and across all subregions for adults aged $>60$ years. There is a corresponding high level of uncertainty around the estimates of disease burden for these subregions and age groups. A difference of $\pm 10 \%$ in prevalence estimates would make a considerable difference in the estimated magnitude of the disease burden.

Given the noted differences between our input variables and those used in previous reports, our global estimates of attributable fraction appear consistent, but we suggest that they too are likely to underestimate the true burden due to inactive lifestyles. Moreover, a number of the limitations combine to make it more difficult to compare with other continuously measured risk factors such as blood pressure and cholesterol.

In summary, the multiple model of exposure provided a useful platform for these analyses of attributable burden but recent, comparable country-level data on inactivity would be far more preferable. This would require, however, having more countries systematically collect
data on the distribution of physical inactivity. Well developed, culturally appropriate measurement instruments should be used to collect comparable data. While there are examples of progress in this area (Craig et al. 2003), with few exceptions, instruments to assess exposure across the diverse cultures of Africa, Asia and the Eastern Mediterranean have yet to be well tested or widely used.

Emerging evidence is pointing towards the important role of physical activity in avoiding outcomes (e.g. falls, poor mental health) as well as other disease end-points (e.g. osteoarthritis and osteoporosis) that did not meet our inclusion criteria. Future replications of this work should review the evidence to ensure a complete a picture as possible is obtained on the burden attributable to inactivity. Across these outcomes as well as those included, the exact nature of the dose-response relationship across all disease end-points is not well defined. Moreover, the heterogeneity across studies is notable and represents a limitation to conducting meta-analyses in this field. Researchers are encouraged to pursue this research agenda systematically to maximize the expedient pooling of data and furthering of our knowledge.

Physically inactive lifestyles account for $3.3 \%$ of deaths and morbidity worldwide. Successful promotion of more active lifestyles would prevent at least 2 million premature deaths and almost 20 million DALYs worldwide. Success in prevention requires greater commitment through policy development and resource allocation at the national and local level. Diverse challenges face developed and developing countries as they consider the current and future rapid changes in patterns of activity by domain.

## 6. Projected estimates of future exposure

Calculation of the avoidable burden of disease requires predicated estimates of exposure in the future. Estimates are usually based on trends and patterns seen over past years adjusted based on assumptions and models of factors likely to influence exposure in the future. We looked for data on patterns of activity over time for predicting level 1 and level 2 exposure in 2010, 2020 and 2030. Our search found few trend data and those available were mostly from developed countries and had similar limitations regarding their comparability as previously discussed.

### 6.1 Methods

In the absence of data on trends to guide our calculations of future exposure we considered the factors that might influence inactivity in the next 30 years. Considering each domain separately and in combination, we proposed that economic development was a central factor to changes in the level of physical activity undertaken in the work place, at home, through transportation and in leisure time. As economies develop, new mechanical, computer and biological technologies will reduce the

Figure 10.32 Predicted ${ }^{\text {a }}$ estimates of physical activity for 145 countries in 2000, by domain and GNP per capita

a Actual physical activity estimates for countries were used when available.
demand for physical tasks in the work place as well as drive the shift in employment from agriculture to manufacturing and service industries. Both factors will result in lower levels of physical activity in the occupational domain. Furthermore, as economies develop and individuals have higher incomes, there will be a shift in travel behaviour, specifically walking and cycling will decrease in favour of modes of personal transportation (motor vehicle) and to a lesser extent public transit. Discretionary time is likely to increase as economies develop and there is a higher level of wealth. While there is more time for discretionary physical activity there also will be more alternative options, many of which will require low levels of physical activity, for example, computer-based entertainment and television. Figure 10.32 shows our predicted estimates for physical activity in 2000 by domain and GNP.

We also considered whether the changes in physical activity within each domain over time could have a lag effect, such that increases in available leisure time would result some time after the shifts in the work place and changes in transportation. However, we had insufficient data to model future change in each domain separately or to explore our hypothetical time lag. Instead we used the net effect or the summary estimate of physical inactivity and GNP (shown in Figure 10.33) to model the association based on current (year 2000) levels. We then used dif-

Figure I0.33 Per cent physically inactive (level I exposure) for 145 countries by GNP per capita

ferentiation to compute the change in inactivity associated with a change in GNP over time and predicted estimates of GNP to solve the equation and compute estimates for physical inactivity in 2010, 2020 and 2030. This method is described in detail below.

## METHODS FOR THE PROJECTION OF FUTURE ESTIMATES OF LEVEL 1 EXPOSURE

Prevalence of inactivity was related to GNP per capita for each country and prevalence of malnutrition (at the regional level rather than country level) as below. Malnutrition (as measured by childhood underweight) was included in the model along with GNP because preliminary regression analyses using per cent childhood mortality improved the model fit substantially for developing countries. However, future predictions for child mortality were not available therefore malnutrition was used as a proxy measure. Because country level estimates of malnutrition also did not exist, predicted estimates at the regional level were used (see chapter $2)$.

$$
\begin{aligned}
& \log \left(\% \text { Inactivity }_{2000}\right) \\
& \quad=\mathrm{B}_{1}(\mathrm{GNP} \text { per capita } 2000)+\mathrm{B}_{2}(\% \text { malnutrition } 2000)
\end{aligned}
$$

Linear regression was used to estimate $B_{1}$ and $B_{2}$. The relationship between GNP per capita in 2000 and the prevalence of inactivity for

Table 10.24 Mean (range) GNP per capita and \% malnourished for years 2000 and 2030

| World Bank income <br> classification | GNP per capita (US\$ IO00) |  |  | \% children malnourished |  |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: |
|  | 2000 | 2030 |  | 2000 | 2030 |
|  | $3.6(0.5-14.9)$ | $8.2(0.9-53.8)$ |  | $18.8(2.3-45.9)$ | $18.4(0.0-50.7)$ |
| High income | $22.7(12.3-33.6)$ | $59.6(31.9-105.9)$ |  | $3.1(2.3-8.1)$ | $0.0(0.0-0.5)$ |

2000 showed that inactivity increased with GNP per capita when GNP was less than US\$ 5000 and decreased when GNP was greater than US\$ 5000 (Figure 10.33). Therefore, we divided countries into two groups using World Bank income classification: a low/middle-income group, and high-income group (including Organisation for Economic Co-operation and Development [OECD] and non-OECD countries). The two groups were modelled separately to give two sets of parameter estimates for $B_{1}$ and $\mathrm{B}_{2}$. Inactivity ( $\%$ ) was log-transformed and all variables were centred to reduce collinearity and to set the regression intercepts to zero by using mean \% inactivity equal to zero. Change in physical inactivity over time was computed using predicted changes in GNP per capita (from World Bank estimates) and predicted change in malnutrition (World Bank 1999; chapter 2).

The assumption that the relationship seen in year 2000 would continue to characterize countries in year 2030 is examined in Table 10.24. Mean GNP increases in both groups between year 2000 and 2030 with a considerable increase in the ranges with only a small overlap between groups. Malnutrition, predicted at the regional level and aggregated to create a group estimate showed only a very small decrease over time in the low/middle-income group reflecting the worsening conditions predicted for some regions (e.g. Africa). For high-income countries malnutrition is predicted to approach zero by 2030 (chapter 2).

## Methods for the projection of future estimates of level 2 exposure

Age by sex estimates of level 2 exposure (insufficiently active) were computed by holding constant our predicted values for year 2000 and applying these uniformly for 2010, 2020 and 2030. We chose this simple approach based on evidence that changes in the population distribution of physical (in)activity occur between levels of both inactive and insufficiently active, as well as between insufficiently active and sufficient (level 3 unexposed). We had no data on which to estimate the magnitude of the shift between level 2 and level 3. Thus, our predicted values of level 2 exposure are based on the assumption that the changes calculated for level 1 (predicted based on changes in economic development as described above) are equal to the change from level 2 to level 3 -the net result of which is that level 2 estimates remain unchanged over time.

This approach is clearly limited but without more data from different populations on both current trends and patterns over time it was the only feasible approach.

### 6.2 Results

The parameter estimates for the model used to estimate future level 1 exposure show the different relationship between physical inactivity estimates in 2000 and GNP per capita and \% malnutrition for each group (see Figure 10.33). Final age by sex estimates for 14 subregions for 2010, 2020 and 2030 are shown in Tables $10.25,10.26$ and 10.27 , respectively. These data indicate an increasing physical inactivity in all subregions, for males and females and across all age groups. The magnitude of increase in level 1 exposure was of the order of $3-4 \%$. We did not model any change in level 2 exposure. Recent evidence suggests these data are likely to grossly underestimate change in exposure. Between 1999 and 2002, Western Australia experienced a $4 \%$ decline in the proportion of the population meeting recommended levels of physical activity (McCormack et al. 2003). These data may be more indicative of the possible magnitude of negative change to expect in developed market economies in coming years if no action is undertaken. Taken in combination with the changing patterns of lifestyle people will experience in developing economies, the future burden of disease attributable to inactivity may be considerable.

## Acknowledgements

The authors wish to extend their sincere thanks to all the colleagues and researchers worldwide who assisted in either providing existing data, re-analysing data and/or providing contacts. The generous contributions of the following people helped us complete this project: Erinaldo Adrande, Ahmed al-Hashemi, Hazzaa al-Hazzaa, Jawad al-Lawati, Wahid al-Kharus, Terry Aspray, Adrian Bauman, Angèle Beaulieu, Pascal Bovet, Steve Blair, Clareann Bunker, Nick Cavill, L. Cavalli-Sforza, Beatriz Champagne-Marcet, Dr Chandran, Constanza Cilley, William Cockerham, Cora Craig, Catherine Cross, Constanza Cilley, Maximilian de Courten, Kathy Douglas, Michael Engelgau, Ted Forbes, Gauden Galea, Bill Haskill, Louise Hayes, Francisco Holway, Frank Hu, Toni Hunt, Enrique Jacoby, Konrad Jamrozik, Andrea Kriska, Darwin Labarthe, Vicky Lambert, I-Min Lee, N Mallick, Beatriz Champagne Marcet, Miguel Martinez-Gonzalez, Sandra Matsudo, Victor Matsudo, Willem Van Mechelen, Abdulrahman Musaiger, Norio Murase, Anoop Misra, Pekka Oja, Andrzej Pajak, Rimma Potemkina, Joceline Pomerleau, Barry Popkin, Antonio Prista, Jasem Ramadan, Srinath Reddy, Vikram Singh, Christine Snead, Eugene Sobngwi, Soeharsono Soemantri, Michael Sjöström, Elena Subirats, Roger Vaughan, Guijing Wang, Dr Yang, C. Yajnik, Helena Zabina.

In addition, the authors wish to extend particular thanks to Barbara Ainsworth, David Buchner and Carl Caspersen for their internal review and to the anonymous external reviewers who provided valuable comments on the methods and assumptions. Finally, the authors thank colleagues leading the CRA project Majid Ezzati, Alan Lopez, Anthony Rodgers and Steve Vander Hoorn for their support and technical assistance.

## Note

1 See preface for an explanation of this term.
