## Chapter II

# Smoking and oral tobacco use 

Majid Ezzati and Alan D. Lopez

## Summary

Smoking has been causally associated with increased mortality from several diseases. This chapter provides global and regional estimates of premature mortality and disease burden in 2000 caused by tobacco use, including an analysis of uncertainty. It also describes a method for estimating the future burden of disease that could be avoided through smoking cessation or prevention.

Comparable data, especially age-specific data, on the prevalence of smoking are often unavailable or inaccurate. More importantly, current prevalence of smoking is a poor proxy for cumulative hazards of smoking, which depend on factors such as age at which smoking began, duration of smoking, the number of cigarettes smoked per day, cigarette characteristics such as tar and nicotine content or filter type, and smoking behaviour such as degree of inhalation. We used the smoking impact ratio (SIR) as a marker for accumulated smoking risk. SIR uses lung cancer mortality in excess of never-smokers as a biological marker for accumulated hazards of smoking. Lung cancer mortality data were from the Global Burden of Disease (GBD) mortality database. Neversmoker lung cancer mortality rates were estimated based on the household use of coal in unvented stoves for each subregion. ${ }^{1}$ Age-sex-specific SIR was divided into three categories: zero, medium ( $0<S I R \leq 0.5$ ), and high ( $0.5<\operatorname{SIR} \leq 1.0$ ).

Estimates of mortality and disease burden due to smoking were made for lung cancer, upper aerodigestive cancer, all other cancers, chronic obstructive pulmonary disease (COPD), other respiratory diseases, cardiovascular diseases and selected other medical causes. All diseases for which no plausible physio-biological causal mechanism is currently known were excluded from the analysis of the category "other medical causes", as were the impacts of maternal smoking during pregnancy. No estimates were made for non-medical causes (injuries). Estimates were
limited to ages 30 years and above. The American Cancer Society Cancer Prevention Study, Phase II (CPS-II), with follow-up for the years 1982-88, was the reference population and provided data on exposuredisease relationships. For China, the exposure-disease relationship was estimated from the retrospective proportional mortality analysis of Liu et al. (1998). Relative risks were corrected for confounding and extrapolation to other regions using conservative correction factors for groups of diseases. For non-fatal outcomes, we assumed that the same attributable fraction as mortality applied to all cancers and COPD (i.e. smoking changes mortality by changing incidence) and used only one half of this value for other health outcomes (i.e. assumed smoking changes mortality by changing incidence and severity/case fatality).

Estimates of reduction in risk after smoking cessation were obtained from the re-analysis of CPS-II, with follow-up for the years 1982-98, for lung cancer, COPD and cardiovascular diseases. To obtain the estimates of exposure under a "business-as-usual" scenario, we assigned male and female populations of countries to one of the ten main or transitional stages of a descriptive model of the smoking epidemic based on available prevalence data. This model was used to divide per capita tobacco consumption data into age-sex-specific estimates. Historical consumption and mortality trends were used to project lung cancer mortality and SIR under the business-as-usual scenario.

Quantitative analysis of uncertainty was conducted for five input parameters: population lung cancer mortality, never-smoker lung cancer mortality, reference population smoker and never-smoker lung cancer mortality, relative risks and relative risk correction factors. Uncertainty in population lung cancer was based on a critical review of the quality of country mortality reporting. Uncertainty in never-smoker mortality rates was based on the likely presence of other risk factors for lung cancer, and uncertainty in reference population lung cancer mortality and in relative risk estimates was estimated from the statistical uncertainty in CPS-II data and data from the Chinese retrospective proportional mortality analysis of Liu et al. (1998). Uncertainty in the correction factor was based on the potential and measured confounding of smoking hazard estimates due to other risk factors. Three other sources of uncertainty were discussed qualitatively: uncertainty associated with the use of SIR as the exposure variable, uncertainty associated with exposure to environmental tobacco smoke (ETS), and uncertainty in the estimates of non-fatal conditions.

In the year 2000, there were an estimated 4.83 ( $95 \%$ CI $3.94-5.93$ ) million deaths in the world attributable to smoking. Of these, 2.41 ( $95 \%$ CI 1.80-3.15) million deaths were in developing countries and 2.43 ( $95 \%$ CI $2.13-2.78$ ) million deaths in industrialized countries. There were 3.84 million global smoking-attributable deaths among men ( 2.02 million in developing countries and 1.81 million in industrialized countries) and 1.00 million among women ( 0.38 million in developing
countries and 0.61 million in industrialized countries). The leading causes of death due to smoking were cardiovascular diseases with 1.69 million deaths, COPD with 0.97 million deaths and lung cancer with 0.85 million deaths. In addition to those cases shared with smokers, there were an estimated 60000 deaths from oral tobacco use in SEAR-D.

Smoking and oral tobacco use accounted for $4.1 \%$ of healthy life years lost in the world in 2000. Given the demographic and epidemiological transitions and current smoking patterns in the developing world, the health loss from smoking will grow even larger unless effective interventions and policies that reduce smoking among males and prevent increases among females in developing countries are implemented.

## 1. Introduction

Tobacco is cultivated in many regions of the world and can be legally purchased in all countries. The dried leaf of the plant nicotiana tabacum is used for smoking, chewing or as snuff. Smoking has been causally associated with substantially increased risk of premature mortality from lung cancer as well as other medical causes (Doll et al. 1994; Liu et al. 1998; U.S. Department of Health and Human Services 1989; Zaridze and Peto 1986). As a result, in populations where smoking has been common for many decades, tobacco use accounts for a considerable proportion of premature mortality, as illustrated by estimates of smokingattributable deaths in industrialized countries (Peto et al. 1992).

There have been large increases in smoking in developing countries, especially among males, over the last part of the twentieth century (Corrao et al. 2000; WHO 1997). The first estimates of the health consequences of smoking in China and India have also shown substantially increased risk of mortality and disease among smokers (Dikshit and Kanhere 2000; Gupta and Mehta 2000; Liu et al. 1998; Niu et al. 1998; Gajalakshmi et al. 2003). This chapter provides estimates of premature mortality and morbidity caused by smoking in all regions of the world, with complete description of methods and data sources, including quantitative estimates of uncertainty. It also describes a method for estimating the future burden of disease due to smoking that could be avoided through cessation or prevention.

It is well-known that the accumulated hazards of smoking depend on factors such as the age at which smoking began, the number of cigarettes smoked per day, cigarette characteristics such as tar and nicotine content or filter type, and smoking behaviour such as degree of inhalation (Fletcher and Peto 1977; Liu et al. 1998; Peto 1986). Current prevalence of smoking alone is therefore an insufficient indicator of accumulated risk from smoking. Although such pattern variables have been studied in a few industrialized countries (Nicolaides-Bouman et al. 1993), few data are available elsewhere. This lack of knowledge about important parameters of smoking patterns and history, coupled with the fact that
smoking is currently increasing in many developing countries, motivates using an exposure variable that better describes accumulated risk in populations with varying smoking histories.

Peto et al. (1992) used data on absolute lung cancer mortality to obtain the proportions of mortality from lung cancer as well as various other diseases attributable to smoking. We extended this method for indirect estimation of excess mortality due to smoking to all regions of the world and also included analysis of morbidity and uncertainty. The large retrospective proportional mortality analysis in China (Liu et al. 1998) and newer studies from India provided a means for calibrating and verifying the method for developing countries using direct estimates from the world's largest countries.

### 1.1 Evidence for causality

Smoking has been one of the most extensively studied human health risks, with detailed epidemiological research dating back to the 1930s (Doll and Hill 1950; Levin et al. 1950; Mills and Porter 1950; Muller 1939; Schairer and Schoniger 1943; Schrek et al. 1950; Wassink 1948; Wynder and Graham 1950) (see Table 1 in Doll 1986 for a summary of early studies). The sample size and details of data and methods have grown in subsequent studies in a number of countries, leading to a growing list of more than 60000 publications on the hazards of smoking (Lopez 1999). The evidence for the causal relationship between smoking and all-cause and cause-specific mortality, as well as the mechanisms of disease causation have been extensively reviewed (Doll 1986, 1998b; U.S. Department of Health and Human Services 1989). Added to these are a number of recent studies, especially from developing countries such as China and India (Doll et al. 1994; Gajalakshmi et al. 2003; Gupta and Mehta 2000; Lam et al. 2001; Liu et al. 1998; Niu et al. 1998). We provide a brief summary of this evidence.

Randomized controlled trials of smoking and health, with randomization of exposure to cigarette smoking, would be impossible for ethical and logistical reasons. Therefore, research on the health impacts of smoking has been based on observational epidemiology and statistical adjustment. The first evidence for the causal relationship between smoking and mortality was from case-control studies. After the initial evidence from case-control studies, numerous prospective cohort studies were initiated to establish the relationship between smoking and mortality. These included studies in the United Kingdom of Great Britain and Northern Ireland (Male British Doctors) (Doll and Peto 1976; Doll et al. 1994), the United States of America (Males in 25 States, Males in 9 States, U.S. Veterans, California Occupations, the American Cancer Society Cancer Prevention Study Phases I and II) (Dunn et al. 1960; Garfinkel 1985; Hammond 1966; Hammond and Horn 1958; Kahn 1966; Peto et al. 1992; Thun et al. 1997a, 1997b), Japan (Hirayama 1977), Canada (Canadian Veterans) (Best et al. 1961), Sweden (Cederlof et al. 1975),
and more recently India (Gupta and Mehta 2000) and a number of other countries. Evidence for the relationship between smoking and total mortality or cause-specific mortality has been consistent among the studies. The causes of mortality from smoking include lung cancer and cancer of various other sites, cardiovascular diseases, COPD and other respiratory diseases, gastric ulcer and a number of other causes.

In addition to establishing the basic causal relationship between smoking and mortality, the results from all these studies exhibit the features and criteria that have been considered important in establishing causality:

1. consistently large risks relative to life-long non-smokers-more than a 20 -fold increase in risk for some diseases;
2. existence of a dose-response relationship that shows increasing risk with increasing number of cigarettes smoked and duration of smoking (Doll 1986; Peto 1986; Thun et al. 1997b; U.S. Department of Health and Human Services 1989);
3. consistency of mortality (in particular for lung cancer) with smoking characteristics and cigarette type (such as tar and nicotine yield) across sexes and populations (Doll 1986);
4. risk reduction with smoking cessation, and a decreasing risk gradient with increasing time since smoking cessation (Doll 1986; U.S. Department of Health and Human Services 1989); and
5. biological plausibility. Cigarette smoke contains a number of known human carcinogens and other toxics (Hecht 2003). The toxic (in particular carcinogenic) properties of cigarette smoke have also been established in studies with laboratory animals (U.S. Department of Health and Human Services 1989). More recently, the pathophysiological mechanisms for some non-cancer effects such as COPD and cardiovascular diseases have also been studied and established (see U.S. Department of Health and Human Services 1989 for a summary).

## 2. Methods and data

### 2.1 Exposure variable

## LUNG CANCER MORTALITY AS AN INDICATOR OF ACCUMULATED

 SMOKING HAZARDPeto et al. (1992) observed that the level of lung cancer mortality compared with never-smokers is an indicator of the accumulated hazard of smoking and the "maturity" of the smoking epidemic in a population. The relationship between cumulative smoking and lung cancer from various populations confirm this relationship (Peto 1986; Yamaguchi
et al. 2000). Based on this observation, the smoking impact ratio (SIR) is defined as population lung cancer mortality in excess of never-smokers, relative to excess lung cancer mortality for a known reference group of smokers. Formally, the ratio in Equation 1 measures the absolute excess lung cancer mortality due to smoking in the study population, relative to the absolute excess lung cancer mortality in life-long smokers of the reference population.

$$
\begin{equation*}
S I R=\frac{C_{L C}-N_{L C}}{S_{L C}^{*}-N_{L C}^{*}} \tag{1}
\end{equation*}
$$

$C_{L C}$ : (age-sex-specific) lung cancer mortality rate in the study population (e.g. country of analysis)
$N_{L C}$ : (age-sex-specific) lung cancer mortality rate of never-smokers in the same population
$S_{\tilde{L C}}^{*}$ and $N_{\tilde{L} C}^{*}$ : (age-sex-specific) lung cancer mortality rates for smokers and never-smokers in a reference population

Liu et al. (1998) found that in China, the relative risk of mortality from lung cancer as a result of smoking is approximately constant in different cities and villages whose non-smoker lung cancer mortality rates varied by a factor of 10 (see Figure 4 in Liu et al. 1998). A constant relative risk means that smoking results in a larger absolute excess mortality (i.e. the numerator of Equation 1) where never-smoker lung cancer mortality is higher (and smaller absolute excess mortality where neversmoker lung cancer mortality is lower). Therefore, to be converted to an indictor of the maturity of the smoking epidemic, the numerator and denominator of Equation 1 need to be normalized with the respective never-smoker lung cancer mortality rates. We defined the backgroundadjusted SIR by the following relationship:

$$
\begin{equation*}
S I R=\frac{C_{L C}-N_{L C}}{S_{L C}^{*}-N_{L C}^{*}} \times \frac{N_{L C}^{*}}{N_{L C}} \tag{2}
\end{equation*}
$$

where $C_{L C}, N_{L C}, S_{\tilde{L} C}^{*}$, and $N_{\tilde{L} C}$ are defined as above.
Following Peto et al. (1992), we used the CPS-II study population (described below) as the reference population. This is because, among the numerous studies of smoking and cause-specific mortality (U.S. Department of Health and Human Services 1989), CPS-II is one of the very few with follow-up conducted when the smoking epidemic was at its highest levels, especially for men. Therefore, the vast majority of (male) CPS-II current-smokers had been lifelong cigarette smokers. Further, the estimates of increased risk of mortality among smokers were available for both men and women and in smaller age groups than in other studies of smoking and mortality, such as the Male British Doctors cohort (Doll et al. 1994).

It is straightforward to show that SIR equals the proportion of refer-ence-population (i.e. CPS-II) smokers in a mix of smokers and neversmokers, which has the same lung cancer mortality rate as the study population (Peto et al. 1992). ${ }^{2}$ This provides a convenient interpretation of SIR: using excess lung cancer mortality over never-smokers, SIR captures the accumulated hazards of smoking by converting the smokers in the study population into equivalents of smokers in the reference population where hazards for other diseases have been measured (Peto et al. 1992).

SIR values were calculated for individual countries and then averaged (population-weighted) across the 14 reporting subregions by age group and sex. The age groups used in the analysis were $0-4,5-14,15-29$, $30-44,45-59,60-69,70-79$, and $\geq 80$, which are the reporting age groups used in the GBD study. No deaths before the age of 30 years were attributed to smoking. Peto et al. (1992) used 35 as the lowest age for considering the impacts of smoking. Because of the GBD age grouping, we also included the 30-34 age group. The number of deaths attributed to smoking among people between 30 and 34 years of age is likely to be very small.

SIR values larger than 1.0 were set to 1.0 . This occurred in the case of males in the 30-44 age group in 17 European countries and one Western Pacific island, and in the 45-59 age group in three countries in eastern Europe. Relatively low lung cancer mortality in younger ages can lead to unstable SIR values. This is particularly the case if the neversmoker rates are estimated with error, which is more likely in younger ages when lung cancer is relatively rare. Further, although a SIR larger than 1.0 may seem to imply that a population which consists of some smokers and some never-smokers had higher lung cancer mortality than CPS-II life-long smokers, factors such as the type and number of cigarettes or the age at which smoking began can result in such a pattern, especially where prevalence of smoking is high. The age of smoking initiation is particularly important for SIR values in earlier ages such as those affected in this analysis. For example, historical lung cancer mortality data show SIR larger than 1.0 among British males aged $<60$ years in some years between 1950 and 1970 and American males between 1968 and 1976. We nonetheless set the SIR for these groups to 1.0 to avoid any potential overestimation of risk.

## EXPOSURE CATEGORIES

$S I R$ is a measure of exposure in the population, vs the individual. In fact, since $S I R$ is based on the lung cancer mortality rate, it cannot be defined at the level of an individual. It is nonetheless possible to divide a population into subgroups with different SIRs subject to the constraint that the overall population SIR should remain unchanged.

Suppose that a population with a specific SIR is divided into three subgroups with $S I R_{1}, S I R_{2}$ and $S I R_{3}$. Then

$$
\begin{equation*}
S I R=a_{1} S_{1 R_{1}}+a_{2} S_{2}+a_{3} S_{2} \tag{3}
\end{equation*}
$$

and

$$
\begin{equation*}
a_{1}+a_{2}+a_{3}=1.0 \tag{4}
\end{equation*}
$$

where $a_{1}, a_{2}$, and $a_{3}$ are the fractions of the population in the three subgroups. The above system of equations is under-determined for any division of more than two subgroups. If one considers never-smokers as one of the subgroups (subgroup 1) then, by definition of the smoking impact ratio, $S I R_{1}=0$ and

$$
\begin{equation*}
S I R=a_{2} S_{2} R_{2}+a_{3} S_{3} \tag{5}
\end{equation*}
$$

If $p$ denotes the fraction of the population who have been smokers at some stage of their lives: $a_{1}=1-p$ and $a_{2}+a_{3}=p$.

After some manipulation, it can be shown that

$$
\begin{equation*}
a_{2}=\frac{S I R-p S I R_{3}}{S I R_{2}-S_{3}} \tag{6a}
\end{equation*}
$$

and

$$
\begin{equation*}
a_{3}=\frac{S I R-p S I R_{2}}{S I R_{3}-S_{2}} \tag{6b}
\end{equation*}
$$

But prevalence data ( $p$ ) are often unavailable or inaccurate, because of both differences in the definition of "ever-smoker" (someone who has smoked at least one cigarette in their life) and data collection complexity. In this work, the additional requirement for age-specific information makes the existing prevalence data-which are often defined for youth and adults only-even less useful. Therefore, in dividing the population into subgroups, the calculation of the fraction of the population in each subgroup is subject to the constraint that the overall $S I R$ remains unchanged.

The specific categories that were used correspond to $S I R_{1}=0$, $0<S I R_{1} \leq 0.5$, and $0.5<S I R_{3} \leq 1.0$. For the last two categories, the midpoints ( 0.25 and 0.75 ) were used in estimating the fraction of population in the two categories ( $a_{2}$ and $a_{3}$ ), once again subject to the constraint that the overall SIR be equal to the original population SIR. The analysis was conducted to divide each age-sex-subregion $S I R$ value into three categories.

## ThEORETICAL-MINIMUM-RISK EXPOSURE DISTRIBUTION

Because the harmful effects of smoking outweigh the potential health benefits for a small number of diseases (such as parkinsonism) by many
orders of magnitude (Doll 1986, 1998a), the dose-response relationships for smoking and overall mortality and burden of disease are monotonically increasing. Therefore, the minimum risk from smoking would occur in a population in which no one had ever smoked. Further, although such a population may not be achievable in practice, there are no physical limits to reduction of smoking. Therefore, the theoretical minimum exposure distribution was chosen as a population with a SIR of zero.

## Population and lung cancer mortality statistics

The age-sex-specific population estimates for the 191 WHO Member States were from the United Nations Population Division, and mortality statistics from WHO's GBD database. GBD mortality statistics are divided by country, sex, age (five-year age groups up to 85 and then $\geq 85$ ), and more than 150 causes of death. The sources of mortality data include vital registration and sample registration, population laboratories, and epidemiological studies. Details of mortality data and cause-of-death analysis methods are described elsewhere (Mathers et al. 2002) and are summarized below where relevant.

The reliability of the $S I R$ is determined by the reliability of lung cancer mortality estimates. In countries with good vital registration and medical certification of deaths (approximately 75 countries), lung cancer mortality is diagnosed with a high degree of accuracy. For example, microscopic confirmation of diagnosis against the cause reported on death certificates has suggested a $95 \%$ or higher confirmation rate in these settings (Percy and Muir 1989; Percy et al. 1990). In approximately another 50 countries, vital registration of mortality is incomplete and medical certification of the cause much less reliable. Standard demographic techniques (Bennett and Horiuchi 1984; Hill 1981; Preston et al. 2000) are used in the GBD project to correct all-cause death rates by age for these populations, and lung cancer rates are adjusted accordingly. Finally, for countries without vital registration, overall age-specific death rates were first determined using model life-tables (Lopez et al. 2002). Total cancer death rates are then estimated based on regional information about proportionate cancer mortality. Within this death rate, the distribution by site is based on regional incidence patterns from cancer registries reporting to the International Agency for Research on Cancer, IARC (Parkin et al. 1992, 1997). This indirect procedure is likely to entail considerable uncertainty, as we describe below.

### 2.2 RISK FACTOR-DISEASE RELATIONSHIPS

American Cancer Society Cancer Prevention Study (ACS CPS-II)

The American Cancer Society's Cancer Prevention Study, phase II (CPSII) is a prospective study of smoking and death in more than one million Americans aged $>30$ years when they completed a questionnaire in 1982,
with the latest follow-up in 1998. A complete description of the study is provided elsewhere and summarized below (Garfinkel 1985; Peto et al. 1992; Thun et al. 1995, 1997a, 1997b, 2000). In 1992, when the first six-year (1982-1988) results were obtained, mortality follow-up was virtually complete for the first two years, and about 98-99\% complete for the next four. Because some conditions that cause death in the first two years may have affected smoking habits at entry (e.g. those diagnosed with lung cancer may have stopped smoking because of their disease or related symptoms), analysis was restricted to years 3-6 inclusive (1984-1988) (Peto et al. 1992). The analysis related deaths (subdivided by cause, sex and five-year age groups at the time of death) to personyears (with accounting for incompleteness) for those who in 1982 had never smoked regularly, and for those who were then current cigarette smokers (Peto et al. 1992). Most of the CPS-II current-smokers were lifelong cigarette smokers with a mean consumption of about 20 cigarettes per day. Relative risks for cause-specific mortality among smokers in the CPS-II population are provided in Table 11.1.

## Retrospective proportional mortality study in China

In a retrospective study of one million deaths in 24 urban centres and 74 rural areas of China, Liu et al. (1998) used proportional mortality analysis to obtain relative risks for three groups of diseases (neoplastic, respiratory and cardiovascular diseases). As explained in Liu et al. (1998), proportional mortality analysis cannot estimate excess mortality for these causes of death in the reference group. Therefore, in this study (Liu et al. 1998) the attributable fraction for causes other than the above three groups was considered to be zero. At the same time, since a few of the deaths in the reference group were also due to smoking, this method would underestimate (as zero) the proportion of mortality due to the causes in the reference group. The relative risks and attributable fractions of cause-specific mortality from Liu et al. (1998) are summarized in Table 11.2.

## DISEASE OUTCOMES AND HAZARD SIZE

Lung cancer mortality attributable to smoking was obtained as the difference between population lung cancer mortality and that of neversmokers (i.e. the numerator of Equation 1). For all other diseases, the relative risks from CPS-II (Table 11.1) were used. To obtain mortality from other causes, a "mixture" of CPS-II smokers and non-smokers was taken to give a SIR equal to that of the study population (as described above, the proportion of smokers in this mixture equals the SIR of the study population). This mixture was then used together with the causespecific relative risks from CPS-II (Table 11.1) to estimate population attributable fractions (PAF) in the study population for different diseases.

Table II.I Selected relative risks for cause-specific mortality for years 3-6 inclusive of ACS CPS-II prospective study of one million American adults

| Cause (ICD-9 code) | Male | Female |
| :--- | ---: | ---: |
| Lung cancer (162) | 24.22 | 12.50 |
| Upper aerodigestive cancer (mouth, oropharynx or oesophagus) <br> (I40-150 and 16I) | 7.87 | 6.95 |
| Other cancer (rest of 140-209) | 1.69 | 1.20 |
| Chronic obstructive pulmonary disease (490-492, 496) | 13.82 | 14.21 |
| Other respiratory diseases (460-466, 480-487, 38I-382) |  |  |
| $35-59$ | 3.05 | 2.69 |
| $60-64$ | 2.31 | 2.68 |
| $65-69$ | 2.09 | 2.52 |
| $70-74$ | 2.00 | 2.00 |
| $\geq 75$ | 1.54 | 1.44 |

Infectious and parasitic diseases (00I-I39, 320-323, 6|4-6|6 with the exception of those above), maternal and perinatal conditions (630-676, 760-779), neuro-psychiatric conditions (290-319, 324-359), cirrhosis of the liver (57I), congenital anomalies (740-759), and non-medical causes (injuries) (E800-999) ${ }^{\text {c }}$

| Other medical causes (rest of $000-799$ ) |  |  |
| :--- | :--- | :--- |
| $35-59$ | 3.05 | 2.69 |
| $60-64$ | 2.31 | 2.68 |
| $65-69$ | 2.09 | 2.52 |
| $70-74$ | 2.00 | 2.00 |
| $\geq 75$ | 1.54 | 1.44 |

NA Not applicable.
a For lung cancer, the population attributable fraction was obtained by direct subtraction of
population lung cancer mortality from that of non-smokers.
This category also includes tuberculosis ( $010-018,137$ ) for which there are separate estimates of
relative risk in China.

The use of relative risk models in estimating tobacco-attributable mortality has been criticized in the past (Lee 1996). While both additive and multiplicative risk models have been used in epidemiology (Moolgavkar and Venzon 1987), the use of a relative risk approach for common risk factors for common diseases is standard in epidemiological literature based on its ability to capture the "risk magnification" role of most risk factors. In the particular case of smoking, Liu et al. (1998) found that in China, the relative risks for mortality from lung cancer and other major diseases are approximately constant in different cities and

Table II.2 Selected relative risks and attributable fractions of mortality from the retrospective mortality analysis of one million deaths in China

| Cause (ICD-9 code) | Ages 35-69 years |  | Ages $\geq 70$ years |  |
| :---: | :---: | :---: | :---: | :---: |
|  | Weighted mean relative risks (SE) | \% deaths attributable to smoking | Weighted mean relative risks (SE) | \% deaths attributable to smoking |
| Male |  |  |  |  |
| Malignant neoplasm (140-208) | 1.51 (0.02) | 24.4 | 1.39 (0.03) | 18.7 |
| Lung cancer (162) | 2.72 (0.05) | 52.3 | 2.47 (0.07) | 46.6 |
| Oesophageal cancer (150) | 1.61 (0.04) | 27.9 | - | 18.2 |

villages where background (non-smoker) mortality rates for the same disease varied significantly. This finding also has been confirmed in studies which stratified on serum cholesterol for cardiovascular diseases (Jee et al. 1999).

The exception to the use of CPS-II relative risks was tobaccoattributable mortality in China, for which direct estimates of the fraction of cause-specific mortality due to smoking from 1990 were available. For China, attributable fractions for diseases other than lung cancer were obtained using relative risks from Liu et al. (1998). Since smoking has been increasing in China over the past few decades, we used SIR estimates to capture the impact of this trend. The relative risks for each smoker from Liu et al. (1998) were converted to relative risks for each unit of SIR (i.e. equivalent to life-long CPS-II smoker) by backcalculation in 1990 and used with 2000 SIR estimates. The upper aerodigestive cancer category was constructed from oesophageal cancer and cancers of five minor sites (mouth, pharynx, larynx, pancreas and bladder) by using weights based on the number of deaths in each disease category. Relative risks per unit of SIR for China (which correspond to the same level of accumulated smoking hazard as Table 11.1 for CPS-II life-long smokers), are provided in Table 11.3.

Although smokers are found to have increased mortality due to causes other than those in Table 11.1, none of the deaths from non-medical causes (injuries) and the following medical causes (for which there are no known pathways of causality) were attributed to smoking: infectious and parasitic diseases (with the exception of those in the category "other respiratory disease" for which there were estimates of hazard), maternal

${ }^{\text {a }}$ Equivalent to a CPS-II life-long smoker in Table II.I.
b Relative risks for females are likely to be unstable due to low prevalence of female smoking in China.
c Since the proportional mortality method used by Liu et al. (I998) does not allow obtaining attributable mortality for causes in the reference group, the relative risks were estimated as one. At the same time, since some deaths in this category are also due to smoking the relative risks from CPS-II were used for these causes.
and perinatal conditions (see below for discussion), neuro-psychiatric conditions, cirrhosis of the liver and congenital anomalies.

There is increasing evidence of an association between smoking and tuberculosis (Dhillon et al. 2000; Gajalakshmi et al. 2003; Lam et al. 2001; Liu et al. 1998). The role of air pollutants in increased risk of infectious pulmonary disease has also been suspected to be through weakening of lung function and defence mechanisms (Thomas and Zelikoff 1999). At the same time tuberculosis is a highly communicable disease whose transmission dynamics are affected by a number of factors. Further, progress from infection to disease and mortality is highly dependent on control and treatment mechanisms. Because of this crucial role of cofactors in tuberculosis incidence and mortality, and their concentration in specific sectors of society, we did not extrapolate relative risks for this disease from one setting to another. We considered tuberculosis as a separate cause of mortality due to smoking only in China where published direct estimates on the relationship were available. We grouped tuberculosis with the category "other respiratory diseases", which have a lower relative risk, in all other countries. Not including tuberculosis as a separate cause of death for the rest of the world is a conservative assumption. This is particularly true in the case of India where recent evidence indicates risks larger than those in China (Dhillon et al. 2000; Gajalakshmi et al. 2003).

Many deaths from burns and other injuries due to fires are also attributable to smoking. For example, pooled studies from Australia, the

United Kingdom and the United States show an attributable fraction of 0.23 for fire-related injuries due to smoking (English et al. 1995). The number of fire-related deaths and injuries are highly dependent on local circumstances including population density, housing, the availability of emergency services, etc. A relative risk approach would, therefore, be unsuitable for their analysis, which is better conducted using injury registries. Given the large burden of injuries due to fires, excluding nonmedical causes undoubtedly results in an underestimation of the health impacts of tobacco.

There has also been growing evidence of the impact of maternal smoking on maternal and child health. Specific outcomes include still births and neonatal deaths, perinatal mortality, low birth weight, primary and secondary infertility, ectopic pregnancy and spontaneous abortion and a number of other child and maternal conditions (U.S. Department of Health and Human Services 1989, 2001). Despite the evidence for the relationship, there has been little quantification of the impact of maternal exposure on child disease and mortality, especially in settings with high background levels of child and maternal mortality. Further, these estimates would require estimating what fraction of female smokers continues to smoke during pregnancy. Not including quantitative estimates of the health hazards for maternal and child health also underestimates the burden of disease due to smoking.

Before using the relative risks from CPS-II, we reduced the excess risk attributed to smoking using constant correction factors as described below. As explained by Peto et al. (1992), a constant correction factor, although arbitrary, avoids overestimating mortality due to confounding in the ACS CPS-II relative risk estimates (which were adjusted for age and sex only) as well as extrapolation of relative risk values from this population to other populations, where exposure to other risk factors that could modify the effects of smoking in a non-multiplicative way may be different. The issue of the confounding of the CPS-II risk estimates used by Peto et al. (1992) and the arbitrary nature of the correction factor were used to challenge the indirect estimates of mortality due to this risk factor (Lee 1996; Sterling et al. 1993).

In studies other than CPS-II, the overall impact of confounding due to diet on the estimates of excess risk of mortality from smoking has been found to be considerably less than half of the excess risk for cardiovascular diseases (such as those studies reviewed as a part of the metaanalysis of ETS and ischaemic heart disease [IHD] by Law et al. 1997 or in analysis of multiple cardiovascular disease risk factors in Japan Hirayama 1990). Alcohol consumption and smoking are correlated in many populations, including in the United States where the ACS CPS-II, which was used to obtain relative risks, was conducted. Alcohol may affect cardiovascular disease (in particular IHD) in both beneficial and harmful ways depending on the patterns of consumption (Britton and McKee 2000; Puddey et al. 1999; chapter 12 in this book). Alcohol
was associated with a reduction in cardiovascular disease mortality risk in CPS-II (Thun et al. 1997c). But the overall death rates were lowest among men and women reporting about one drink daily and increased with heavier drinking, particularly among adults aged $<60$ years with lower risk of cardiovascular disease (Thun et al. 1997c). It may also have been the case that CPS-II smokers had more harmful drinking patterns, which would confound the relative risk estimates for cardiovascular disease. At the same time, given that the beneficial impacts of alcohol in this cohort persisted even at higher consumption levels, any possible confounding effect on estimates of smoking hazard size is likely to be considerably less than one half of the excess risk. In the Nurses' Health Study, Kawachi et al. (1997) found that the relative risk for cardiovascular diseases as a result of smoking after adjustment for multiple covariates (3.74) was larger than the unadjusted relative risk (3.47); the change was not statistically significant. The reduction in cardiovascular disease excess risk due to adjustment for age, community, history of hypertension and diabetes, consumption of alcohol, systolic blood pressure, and frequency of walking in a study of the relationship between smoking and mortality in three United States communities was $20 \%$ for men (2.0 to 1.8). Adjustment resulted in an increase in female relative risk (from 1.7 to 1.8) (LaCroix et al. 1991); neither change was statistically significant.

Among cancers, upper aerodigestive cancers are the diseases for which confounding due to alcohol consumption may be most important. There is evidence from studies in different parts of the world on the interaction (excess over multiplicative) between alcohol and tobacco for various upper aerodigestive cancers (Flanders and Rothman 1982; Kinjo et al. 1998). As described by Flanders and Rothman (1982), this interactive effect as well as the correlation between exposure to these two risk factors, would imply larger risks from smoking than would be the case in the absence of interaction and correlation. Therefore, reduction of risk by one half is likely to not only account for potential confounding but also result in conservative estimates.

In response to the criticism about the lack of empirical evidence for confounding correction, CPS-II data were re-analysed together with adjustment for potential confounders (Malarcher et al. 2000; Thun et al. 2000). Malarcher et al. (2000) found that adjusting for multiple covariates (age, education, alcohol use, hypertension status and diabetes status) only marginally changed the fraction of mortality attributable to smoking in the United States, as shown in Table 11.4. As seen in the table, except for cerebrovascular disease (CVD) among men, adjustment for confounding had no or little effect, or even resulted in a slight increase, on the smoking-attributable mortality.

In a more detailed re-analysis of CPS-II data, Thun et al. (2000) adjusted for age, race, education, marital status, occupation ("blue collar" worker) and total weekly consumption of citrus fruits and vegetables in estimat-

ing the relative risk of mortality due to a range of neoplasms, cardiovascular diseases and respiratory diseases. In addition, the analysis for cardiovascular diseases adjusted for current aspirin use or alcohol consumption, body mass index (BMI), physical activity at work or leisure and weekly consumption of fatty foods. For lung cancer and COPD, the analysis also adjusted for occupational exposure to asbestos. Similar to the analysis of Malarcher et al. (2000), with the exception of stroke among men, whose relative risk declined from 2.9 ( $95 \%$ CI 2.3-3.7) to $2.4(95 \%$ CI 1.8-3.0) for the 35-64-year age group and from $1.8(95 \%$ CI 1.6-2.2) to 1.5 ( $95 \%$ CI 1.2-1.8) for those aged $>64$ years, excess risks increased, stayed unchanged or decreased by small amounts. As in the case of Malarcher et al. (2000), the largest decrease was in the case of stroke for males ( $17 \%$ decrease in excess risk for the 35-64-year age group and $38 \%$ for those aged $\geq 65$ years). Overall, Thun et al. (2000) concluded that adjustment for confounding reduced their estimates of mortality attributable to smoking in the United States by approximately $1 \%$.

Finally, the Chinese retrospective study provides some evidence that background disease rates do not change the proportion of mortality attributable to smoking (Figures 4 and 5 in Liu et al. 1998). In extrapolating hazard size from industrialized to developing countries, one would have to deal with availability of health services (such as medical care for cardiovascular disease patients) if extrapolation were based on absolute risk (i.e. number of deaths) because the number of fatal cases would vary based on available treatment. If extrapolation is made based on risk of mortality for smokers relative to non-smokers, however, availability of health services would not bias the estimates if smokers and non-smokers have similar access to these services.

Based on this evidence of the robustness of CPS-II relative risk estimates to adjustment for confounding and extrapolation across settings with different background mortality rates, we modified the choice of correction factor from that used by Peto et al. (1992). We used a correction factor of $30 \%$, approximately equal to the largest reduction in excess risk due to confounding seen in the re-analysis of CPS-II data, to reduce
the excess risk for all cause-specific relative risks (see also discussion of uncertainty). This choice continues to be conservative to account for any potential residual confounding or any other potential sources of overestimation arising from extrapolation across regions. For the category, "other medical causes", where the extent of confounding is still not known, we continued to attribute only one half of the excess mortality estimated by CPS-II.

The excess risk for China was reduced by $5 \%$. Confounding due to other risk factors is likely to have been negligible in China because of the more homogenous level of exposure to other risk factors (e.g. diet, alcohol, and indoor air pollution from coal) in the population compared to the CPS-II population (R. Peto, personal communication, 2001). The proportional mortality method used by Liu et al. (1998) also is not affected by confounding due to any risk factor that increases mortality in the study and reference disease categories (such as effects of alcohol on cancer and liver cirrhosis). Finally, since the relative risks are used for China only, effect modification due to other risk factors is not a concern. The $5 \%$ reduction of excess risk was used to account for the potential small level of residual confounding.

## ASSESSMENT OF MORBIDITY

Virtually all causes of mortality (diseases) that are affected by smoking are chronic diseases due to long-term exposure. Therefore, a reasonable assumption would be that smoking increases mortality by increasing disease incidence, rather than modifying case fatality among those who would already be affected by the disease. Since the non-fatal component of disability-adjusted life years (DALYs) (i.e. years lived with disability or YLD) is based on incidence, this assumption would imply that the relative risks for mortality and incidence are equal. Among the causes of mortality considered, the most obvious exception to this assumption may be asthma and respiratory infections, where smoking may affect incidence, case fatality or both. For these diseases we assumed that one half of the morbidity obtained from the above approach is due to smoking. To provide conservative estimates, we also considered that for those diseases where medical interventions may reduce case fatality (such as some cardiovascular diseases) and those for which smokers have a smaller excess risk compared to non-smokers (such as the "other medical conditions" category), the increased risk of mortality may be partially due to increased case fatality. Therefore, for these diseases also, we assumed that one half of the above attributable fraction was due to smoking. In summary, the attributable fraction of morbidity due to smoking was assumed to be the same as mortality for all cancers and COPD, and one half of the latter for all other causes.

### 2.3 Choice of never-smoker lung cancer mortality in the STUDY POPULATION

In Equation 2, $C_{L C}$ is from the GBD mortality database and $S_{\tilde{L C}}^{*}$ and $N_{\tilde{L} C}^{*}$ directly from CPS-II. The only parameter to be estimated indirectly is $N_{L C}$, since direct estimates of never-smoker lung cancer mortality are known for very few countries. Figure 11.1 shows non-smoker lung cancer mortality for the United States (from CPS-II) and China (from Liu et al. 1998). The detailed data in Liu et al. (1998) further allow dividing the Chinese rates into urban and rural areas, and the latter into coastal and inland rural.

As seen in Figure 11.1, age-specific non-smoker lung cancer mortality is considerably higher in China than in the United States for both males and females. In China itself, there are also marked differences between different parts of the country with urban areas having the highest non-smoker lung cancer mortality rates and inland rural areas the lowest (also seen in Figure 4 in Liu et al. 1998). The difference between the non-smoker lung cancer mortality rates for the United States and China, and between urban and rural regions of China is explained by the Chinese patterns of household energy use over the past few decades. Coal is a common household fuel in China, often burned in stoves and buildings without adequate ventilation (Du et al. 1996; Liu et al. 1998; Smith et al. 1993; Wang et al. 1996). Exposure to coal smoke and cooking fumes has been associated with increased lung cancer incidence in China (Du et al. 1996; He et al. 1991; Wang et al. 1996). In inland rural regions of China, where incomes are the lowest, biomass (including crop residues and wood) has been the dominant household fuel compared with coastal villages and cities where coal has been more commonly used.

The relationship between biomass fuels and lung cancer has been absent or considerably smaller than that between coal and lung cancer (Bruce et al. 2000; Ko et al. 1997; Smith and Liu 1993; Sobue 1990) as seen also in chapter 18. Although urban air pollution has been linked to increased lung cancer mortality in some studies, the size of the risk is considerably smaller than the effects of smoking or direct exposure to coal smoke (Doll 1978; Jedrychowski et al. 1990; Nyberg et al. 2000; Pope et al. 2002; Vena 1982). Further, the impact of ambient air pollution on lung cancer has been found to be smaller among non-smokers than among smokers, with one study finding increased risk of lung cancer as a result of urban air pollution among smokers only (Jedrychowski et al. 1990; Vena 1982). For example, exposure to high levels of urban air pollution, even in regions where coal was used extensively, was found to increase the risk of mortality from lung cancer by approximately $14 \%$ among non-smokers (vs $40 \%$ among smokers) (Jedrychowski et al. 1990). Coupled with the fact that only small fractions of national populations live in the most polluted urban areas,

Figure II.I Non-smoker mortality from lung cancer in different populations

Note: Chinese rates correspond to 1990. Note that the scales on the female and male charts are different to maintain the resolution for females.

Source: Ezzati and Lopez (2003).
overall population lung cancer mortality is not expected to be greatly affected by urban air pollution. For example, the lung cancer mortality rate among non-smoking American women remained constant at approximately 12 per 100000 between 1960 and 1986 despite changes in exposure to urban air pollution (U.S. Department of Health and Human Services 1989).

Based on the pattern of background lung cancer mortality rates, and the underlying risk factors for increased lung cancer mortality in China and its various regions, background (never-smoker) lung cancer rates for the different subregions were based on the estimated use of coal for domestic energy in unvented stores as provided in chapter 18. We used Chinese non-smoker rates for China, a weighted average of Chinese and CPS-II non-smoker for SEAR-D where coal is also used for household fuel (with weights for Chinese rates equal to the prevalence of coal use), and CPS-II non-smoker rates for the remaining countries of the world where domestic coal use in unvented stoves is negligible. The remaining risk factors with potential effects on lung cancer mortality (ambient air pollution, occupational hazards, indoor air pollution from radon or biomass smoke, etc.) affect all populations in varying degrees. The net impacts of these other risk factors are considered as sources of uncertainty in extrapolating never-smoker lung cancer mortality from one setting to another.

### 2.4 Risk reversibility

Estimating the burden of disease that might be avoidable as a result of exposure removal requires knowledge of risk reversibility (the decline in risk after exposure is removed) for those who are current smokers. ${ }^{3}$ For those who never begin to smoke, of course, the entire disease burden as a result of smoking is avoided. The benefits of smoking cessation for reduction of mortality risk have been reported in a number of studies (Best et al. 1961; Doll and Hill 1956; Doll and Peto 1976; Doll et al. 1994; Dunn et al. 1960; Hammond 1966; Kahn 1966; U.S. Department of Health and Human Services 1990c). Many studies have also considered the reduction in risk with time since cessation. Most of these studies have focused on the reduction in the risk of lung cancer and cardiovascular causes since cessation. Although the estimates of risk reduction time have varied among different studies, possibly due to different smoking histories and other differences (such as age at which cessation occurred) among the study populations, the benefits of cessation have been consistently demonstrated.

To capture the history and accumulated hazards of smoking, we continued to use smoking impact ratio (SIR) as the exposure variable in considering risk reversibility. We first estimated risk reversibility for lung cancer to obtain estimates of reduction in SIR values after cessation. For diseases other than lung cancer, we estimated the reduction in disease risk per unit of SIR-our exposure variable-using the studies on risk
reversibility. Together with the SIR estimates after cessation, these provided estimates of avoidable mortality for causes other than lung cancer, which also took into consideration the full history of smoking before cessation.

## LUNG CANCER

The reduction in lung cancer risk with smoking cessation has been demonstrated in a number of studies (Alderson et al. 1985; Higgins et al. 1988; Kahn 1966; Lubin et al. 1984; Pathak et al. 1986; Peto and Doll 1984; Peto et al. 2000; Sobue et al. 1991; U.S. Department of Health and Human Services 1990a). Peto et al. (2000) provided an analysis of risk reduction for those who would have been life-long smokers but stopped smoking at various ages using two case-control studies for lung cancer, and national lung cancer mortality statistics in 1950 and 1990 (see Figure 3 in Peto et al. 2000). Table 11.5 shows the reduction in risk, relative to those who continue to smoke, as a function of time since cessation. The results are presented for all ages to increase statistical stability (S. Darby, personal communication, 2001). The large difference between male and female estimates of reversibility in this study is because female estimates were based on relatively few cases of exsmokers with lung cancer (S. Darby, personal communication, 2001). Also, because the smoking epidemic for females lagged the male epidemic in the United Kingdom, as elsewhere, the comparison of 1950 and 1990 lung cancer mortality rates was likely to have included few females who had stopped smoking after the peak of the epidemic.

These estimates of decline in risk are consistent with those from a number of prospective cohort studies (summarized in Table 3 in U.S. Department of Health and Human Services 1990a) including Male British Doctors, United States Veterans, and American Cancer Society CPS-I and CPS-II. When all subjects are considered, these prospective

Table II. 5 Decline in the risk of lung cancer mortality with time since smoking cessation

| Smoking status | Male | Female |
| :--- | :---: | :---: |
| Current smoker | 1.00 | 1.00 |
| Years since cessation among former smokers |  |  |
| $0-9$ | 0.66 | 0.69 |
| $10-19$ | 0.42 | 0.21 |
| $20-29$ | 0.18 | 0.05 |
| $\geq 30$ | 0.08 | - |
| - |  |  |
| Source: Peto et al. (2000). |  |  |

studies show a consistent increase in relative risk in the first five years from the date of cessation (U.S. Department of Health and Human Services 1990a). This can be attributed to selection bias, as those who die in the first few years after cessation are likely to have stopped smoking because they had been diagnosed with a disease. This is confirmed in the separate analysis of those with and without history of chronic disease in CPS-II. In this analysis, those without a history of chronic disease have a consistent declining trend in lung cancer mortality risk compared to all respondents (Figure 11.2). To estimate lung cancer risk reversibility with cessation, we used a re-analysis of CPS-II data (1998 follow-up) excluding those subjects with a history of chronic disease (lung cancer, COPD, cardiovascular diseases) (Figure 11.2).

Despite some remaining differences, the male and female reversibility estimates in Figure 11.2 are much more similar than those in Table 11.5. With better estimates of reversibility among females, we took sexspecific estimates of reversibility to be consistent with the sex-specific smoker and non-smoker lung cancer mortality rates used in the definition of SIR. For the last two cessation periods ( $30-34$ and $\geq 35$ years)

Figure II. 2 Relative risk of lung cancer among former smokers (compared with lifelong non-smokers) with time since cessation

[^40]female estimates show a slight increase in risk compared to the 25-29 year cessation period. This anomaly, which is not statistically significant, is probably due to a small number of events in these groups, itself caused by the more recent maturity of the female smoking epidemic in the United States compared to men. Too few women would have stopped smoking so long ago to have had more than 35 years of cessation and a large number of lung cancer events. For these two cessation periods, we simply assumed that the declining trend observed between the 20-24 and 25-29 year periods would continue.

Avoidable lung cancer mortality can be estimated from the difference between lung cancer risk as it would have been without cessation and the risk that results from cessation. If, as above, we denote smoker and non-smoker lung cancer mortality rates in the reference cohort as $S_{\tilde{L} C}^{*}$ and $N_{\tilde{L} \text { c }}^{*}$, and lung cancer mortality rates for those who stopped smoking $x$ years ago as $S_{\bar{L} C, x}^{*}$, then for this cohort of former smokers $S_{\bar{L} C, x}^{*}-N_{\tilde{L} C}^{*}$ is the mortality attributable to past smoking, and $S_{\tilde{L} C}-S_{\tilde{L} C, x}$ is the mortality avoidable because they stopped smoking $x$ years ago. If $R R$ and $R R_{x}$ are the relative risks for life-long smokers without and with cessation respectively, then $S_{\tilde{L} C}^{*}=R R \times N_{\tilde{L} C}^{*}$ and $S_{\tilde{L} C, x}^{*}=R R_{x} \times N_{\tilde{L} C}^{*}$. Attributable and avoidable mortality $x$ years after cessation is then $N_{\tilde{L} C}^{*} \times\left(R R_{x}-1\right)$ and $N_{\tilde{L} C}^{*} \times\left(R R-R R_{x}\right)$. Of course, for those who never begin to smoke, $S_{\overline{L C}, x}^{*}=N_{\tilde{L} C}^{*}$ and no mortality is attributed to this risk factor and $S_{\tilde{L} C, x}-N_{\tilde{L} C}^{*}$ (i.e. the whole excess mortality due to smoking) is avoidable. In Table 11.5, for example, for males who stop smoking, $34 \%, 58 \%$ and $82 \%$ of lung cancer mortality would be avoided within 10 , 20 and 30 years from cessation, respectively, compared to what would have happened had they continued to smoke. The remaining $66 \%$, $42 \%$ and $18 \%$ of mortality in these time periods is still attributable to their past smoking, despite cessation.

So far, by using CPS-II estimates of risk reversibility, we have implicitly addressed risk reversibility among those who have smoked since youth and stop smoking at a given age (because ACS smokers were lifelong smokers, including at cessation time). We argued earlier, however, that such information is rare and unreliable, and that the only measure of accumulated history of smoking is the SIR. We also showed earlier that for each population, SIR is the equivalent prevalence of life-long smokers. Therefore, to obtain estimates of avoidable burden in each cohort, a fraction of whom have smoked for some period, the estimates of attributable and avoidable mortality $x$ years after cessation are given by $\operatorname{SIR} \times\left(S_{\tilde{L} C, x}-N_{\tilde{L} C}^{*}\right)=\operatorname{SIR} \times N_{\tilde{L} C} \times\left(R R_{x}-1\right)$ and $\operatorname{SIR} \times\left(S_{\tilde{L} C}^{*}-S_{\tilde{L} C, x}\right)$ $=\operatorname{SIR} \times N_{\tilde{L} C}^{*} \times\left(R R-R R_{x}\right)$ respectively where, SIR is measured at the time of cessation (say in 2000 for estimates of avoidable burden as a result of cessation in 2000). We emphasize that this estimation, like all other uses of $S I R$, is based on the assumption that the equivalence of SIR with life-long smokers holds in estimating the benefits of cessation.

Finally, to apply this information to populations with different background (non-smoker) mortality rates, we used the results of Liu et al. (1998) who found that in China the relative risk for mortality from lung cancer was approximately constant in different cities where the nonsmoker lung cancer mortality varies by a factor of 10 . Therefore for populations whose background mortality is $N_{L C}$, the attributable burden due to past smoking $x$ years after cessation is given by $\operatorname{SIR} \times N_{L C} \times$ $\left(R R_{x}-1\right)$ and the avoidable burden as a result of cessation by $S I R \times N_{L C}$ $\times\left(R R-R R_{x}\right)$.

## SIR AFTER CESSATION

To estimate the decline in risk for other diseases, while accounting for the pre-cessation history of smoking, we needed to also estimate the value of $S I R$ after cessation. Once again noting that $S I R$ is the equivalent of life-long smokers in the population, the lung cancer mortality rate in the population as a whole, $C_{L C}$, can be re-written as:

$$
C_{L C}=S I R \times R R \times N_{L C}+(1-S I R) \times N_{L C}
$$

If the same number of life-long smokers continue to smoke, $S I R$ will remain more or less constant for the cohort and in each time period their new SIR will be given by the same relationship, with $R R$ referring to the age-specific relative risk. On the other hand, if the smokers stop smoking, after $x$ years their relative risk will decrease to $R R_{x}$ a value less than $R R$ at any time after cessation (Table 11.5). In this case, the new (postcessation) lung cancer mortality rate, $C_{L C, x}$, is given by:

$$
C_{L C, x}=S I R \times R R_{x} \times N_{L C}+(1-S I R) \times N_{L C}
$$

Replacing this value for $C_{L C, x}$ in Equation 2 to obtain the postcessation smoking impact ratio, $S I R_{x}$, gives:

$$
S I R_{x}=\frac{S I R \times R R_{x} \times N_{L C}+(1-S I R) \times N_{L C}-N_{L C}}{S_{L C}^{*}-N_{L C}^{*}} \times \frac{N_{L C}^{*}}{N_{L C}}
$$

with some algebraic simplification and noting that $S_{\tilde{L} C, x}^{*}=R R \times N_{\tilde{L} C}^{*}$,

$$
\operatorname{SIR}_{x}=\operatorname{SIR} \frac{R R_{x} \times N_{L C}-N_{L C}}{R R \times S_{L C}^{*}-N_{L C}^{*}} \times \frac{N_{L C}^{*}}{N_{L C}}
$$

or

$$
\operatorname{SIR}_{x}=S I R \times \frac{R R_{x}-1}{R R-1}
$$

In other words, smoking cessation after $x$ years results in scaling down the population $S I R$ values relative to what they would be if smoking continued, with the scaling factor equal to the ratio of excess lung cancer risk after cessation to excess lung cancer risk if cessation did not occur. ${ }^{4}$

## DISEASES OTHER THAN LUNG CANCER

The decline of relative risk for cardiovascular diseases as a function of time since cessation has been estimated in a number of studies, resulting in a range of estimates for the rate of decline (Cook et al. 1986; Dobson et al. 1991; Kawachi et al. 1997; LaCroix et al. 1991; Rogot and Murray 1980; Rosenberg et al. 1985, 1990; U.S. Department of Health and Human Services 1990c). Kawachi et al. (1997) also considered the decline in the risk of other causes of mortality, including all cancers and external causes.

To convert the estimates of relative risk reduction from the time of cessation for diseases other than lung cancer to the estimates of relative risk per unit of SIR we used the following notation: Let $R R$ and $R R^{\prime}$ be the age-specific risks of lung cancer and disease $A$ respectively for lifelong smokers in the absence of cessation; $R R_{x}$ and $R R_{x}^{\prime}$ the age-specific relative risks at some specific time, $x$, after cessation; and $R R_{S I R}^{\prime}$ and $R R_{S I R, x}^{\prime}$ the relative risks of disease $A$ per unit of SIR without and with cessation respectively. In all cases, $R R_{S I R}^{\prime}=R R^{\prime}$ since in the absence of cessation, the relative risks for life-long smokers (from CPS-II for example) would apply. It is $R R_{S I R, x}^{\prime}$ that we are interested in, which, with the decline in SIR as outlined above, is now the risk of disease $A$ "per unit of former life-long smoker". Four scenarios are possible.

1. If the rate of decline in relative risk for cause $A$ is the same as the rate of decline in relative risk for lung cancer, then the relative risk per unit of SIR would stay constant at the pre-cessation level (except for age effects). This is because, in this case, all the benefits of cessation for both disease $A$ and lung cancer (which move together) would be captured in the decline of $\operatorname{SIR}$ (to $S I R_{x}$ ). Therefore, in this case $R R_{S I R, x}^{\prime}=R R^{\prime}$.
2. If there had been no decline in lung cancer risk (i.e. $R R_{x}=R R$ and $S I R_{x}=S I R$ ) but there was a decline in the risk of disease $A$ (i.e. $R R_{x}^{\prime}<R R^{\prime}$ ), then the relative risk per unit of SIR would decline at the same rate as the decline in relative risk for disease $A$ after cessation. This is because, in this case, none of the benefits of cessation would be captured by decline in $S I R$, and therefore they need to be included in the estimates of relative risk per unit of SIR. In this case $R R_{S I R, x}^{\prime}=R R_{x}^{\prime}$.
3. If disease $A$ is an acute condition, such as an injury or death (or possibly an acute respiratory infection) due to smoking-caused fires then cessation would result in complete removal of the risk for $A$, and $R R_{S I R, x}^{\prime}=1$.
4. If cessation results in lowering of the risk for both lung cancer and disease $A$, but at different rates, then the relative risk of disease $A$ per unit of SIR after cessation, is given by the following relationship:

$$
R R_{S I R, x}^{\prime}=1+\left(R R_{x}^{\prime}-1\right) \times \frac{R R_{x}^{\prime}-1}{R R^{\prime}-1} \times \frac{R R-1}{R R_{x}-1}
$$

The product of the terms $\frac{R R_{x}^{\prime}-1}{R R^{\prime}-1}$ and $\frac{R R-1}{R R_{x}-1}$ captures the relative drop in excess risk for disease $A$ (first term) compared to lung cancer (second term). If the risk of disease $A$ declines faster than lung cancer, then the relative risk per unit of SIR will decline to capture the additional benefits of cessation for disease $A$, compared to lung cancer. On the other hand, if the risk of disease $A$ declines more slowly than lung cancer, then the relative risk per unit of SIR will rise to capture the reduced benefits of cessation for disease $A$, compared to lung cancer. ${ }^{5}$ Scenarios $1-3$ above are special cases of this general relationship.

The estimates of $R R$ and $R R_{x}$ (for lung cancer) can be obtained from Figure 11.2 for different times since cessation. To estimate $R R^{\prime}$ and $R R_{x}^{\prime}$ for COPD and cardiovascular diseases, we used CPS-II data. In the analysis of risk reversibility for cardiovascular diseases for the first six-year follow up (1988), the estimates for those who had quit for less than one year showed inconsistent patterns (Table 11.6) even though subjects with cancer, heart disease and stroke were excluded at baseline (U.S. Department of Health and Human Services 1990b). This has been attributed to both high incidence of smoking resumption and the possible inclusion of subjects who stopped smoking as a result of symptoms from undiagnosed illness (U.S. Department of Health and Human Services 1990b).

Table II. 6 Decline in the risk of cardiovascular disease mortality with time since smoking cessation

|  | $R R$ (Male) |  |  | $R R$ (Female) |  |
| :--- | :---: | :---: | :---: | :---: | :---: |
| Smoking status | $\leq 20$ cig/day | $>20 \mathrm{cig} / \mathrm{day}$ |  | $\leq 20 \mathrm{cig} / \mathrm{day}$ | $>20 \mathrm{cig} / \mathrm{day}$ |
| Current smoker | 1.93 | 2.02 |  | 1.76 | 2.27 |
| Years since cessation among former smokers |  |  |  |  |  |
| $<1$ | 1.43 | 2.56 |  | 2.13 | 1.41 |
| $1-2$ | 1.61 | 1.57 |  | 0.87 | 1.16 |
| $3-5$ | 1.49 | 1.41 |  | 1.31 | 0.96 |
| $6-10$ | 1.28 | 1.63 |  | 0.74 | 1.88 |
| $11-15$ | 0.99 | 1.16 |  | 1.2 | 1.37 |
| $\geq 16$ | 0.88 | 1.09 |  | 1.17 | 1.12 |

Source: U.S. Department of Health and Human Services (1990b).

The rate of decline in relative risk and the unstable behaviour in the early years since cessation were nonetheless consistent with other studies (see Table 2 in U.S. Department of Health and Human Services 1990b and the estimates [Kawachi et al. 1997] from the Nurses' Health Study).

Re-analysis of ACS CPS-II data (1998 follow up) with more stringent exclusion of subjects with a history of chronic disease (lung cancer, COPD, vascular diseases) shows a more consistent pattern of risk reversibility, especially if the first cessation period is considered as 2 years, which reduces the likelihood of high smoking resumption rates. Figure 11.3 shows the estimates of relative risk for COPD and cardiovascular disease with time since cessation for males and females using this re-analysis. To apply risk reversibility with cessation to the CPS-II and Chinese baseline relative risk estimates in Tables 11.1 and 11.3, we estimated the relative decline in relative risks after $x$ years of cessation (i.e. the ratio of relative risk $x$ years after cessation to current smokers in Figure 11.3) and applied this to CPS-II or Chinese relative risks (i.e. $R R^{\prime}$ ) to obtain $R R_{x}^{\prime}$.

For cardiovascular disease among men, former smokers with long cessation periods have lower risk than never-smokers (statistically not significant). This pattern, however, is implausible and is likely to be due to unobserved confounders that have affected the behaviour of former smokers (e.g. the same factor may have motivated cessation and change in diet or physical activity) and hence, lowered their risk. To account for this, we re-adjusted the values for the 25-29 and 30-34-year cessation periods based on the trends between the 20-24 and $\geq 35$ periods. For females, the estimates for cessation beyond 10 years were re-adjusted based on the male trends to asymptotically reach 1 for the longest cessation periods. The re-adjusted values are shown as dotted lines in Figure 11.3.

Given the potentially similar biological mechanisms of carcinogenesis, we assumed that all other cancers had the same rate of decline in relative risk as lung cancer. This is also seen in estimates of relative risk since smoking cessation for cancers including and excluding lung cancer analysed by Kawachi et al. (1997). Therefore, as described in scenario 1 above, the relative risk per unit of SIR remains constant for these diseases and the benefits of cessation in terms of avoidable mortality are fully captured by the decline in SIR. For all other disease categories, we used scenario 4 to estimate the risk per unit of SIR after cessation. We assumed that these diseases, for which reversibility data were not available, followed the same time pattern of decline as cardiovascular diseases, which decline more rapidly than lung cancer.

### 2.5 Analysis of uncertainty

In one taxonomy, uncertainty in quantitative risk assessment can be divided into parameter uncertainty and model uncertainty (Finkel 1990; National Research Council 1994). Parameter uncertainty includes the

Figure II. 3 Relative risk of chronic obstructive pulmonary disease (COPD) and cardiovascular diseases among former smokers

Note: Zero years represent current smokers. The estimates at 40 years represent cessation of more than 35 years in the subjects. Data are from ACS CPS-II 1998 follow up.

Source: American Cancer Society, unpublished data, 2003.
uncertainty quantifiable using random-variable methods such as that in a risk factor distribution, the magnitude of the risk factor-disease relationship, and burden of disease estimates. Model uncertainty is defined as uncertainty due to gaps in scientific theory (Finkel 1990; National Research Council 1994). In other words, model uncertainty occurs in those aspects of the analysis which are not currently quantifiable using a random-variable statistical methodology. In risk assessment, model uncertainty, broadly defined, also includes cases where exposure distributions or exposure-response relationships for populations are not known and are extrapolated from others. The uncertainty reported here is the $95 \%$ range of the combined distribution. In the following sections we describe the sources of uncertainty and the approach for quantifying parameter uncertainty.

## Parameter uncertainty

Uncertainty for each of the variables and parameters in the analysis was estimated separately. These include population lung cancer mortality and never-smoker lung cancer mortality for each subregion, lung cancer mortality for smokers and never-smokers in the reference population, and relative risks. The first four parameters are those needed for the estimation of SIR which, when combined with the relative risk of mortality, gives the fraction of cause-specific mortality due to smoking. Estimates of uncertainty for individual parameters were combined in a simulation using Latin hypercube sampling to obtain overall uncertainty for SIR and relative risk values, and eventually the fraction of mortality or morbidity due to smoking. The parameter-specific uncertainty estimates were obtained as follows:

1. Population lung cancer mortality: The GBD estimates of mortality do not currently include complete analysis of uncertainty. To obtain uncertainty estimates for population lung cancer mortality, we assigned each country into one of four uncertainty categories based on the quality of available mortality data, as we described earlier. Lung cancer mortality information for the four country categories were assigned uncertainty ranges equal to $10 \%, 20 \%, 40 \%$ and $80 \%$ of the best-estimate, with a triangular distribution. Since for countries with good vital registration, $95 \%$ or higher confirmation rates of the cause reported on death certificates have been found (Percy et al. 1990; Percy and Muir 1989), 10\% is more than double the observed uncertainty and a conservative estimate of true uncertainty. Eighty per cent uncertainty for the least certain countries, i.e. those with no established mortality reporting, implies that we have allowed nearly all of lung cancer mortality to be due to misclassification. Given that zero lung cancer mortality is implausible, higher levels of uncertainty could occur only on the upper side of these estimates, making this a conservative assumption for lung cancer mortality and SIR. Countries with less complete and/or less reliable data were

Table II. 7 Uncertainty (as \% of best-estimate) assigned to reported or estimated country level lung cancer mortality

| Uncertainty | Country $^{\text {a }}$ |
| :--- | :--- |
| I0\% | AMR-A - all; AMR-B - Chile, Costa Rica, Dominica, Uruguay; EMR-B - |
|  | Bahrain; EUR-A - all except Croatia; EUR-B - Poland, Slovakia; EUR-C - |
|  | Estonia, Hungary, Latvia, Lithuania, Russian Federation; WPR-A - all except |
|  | Brunei Darussalam |

a By subregion.
assumed to have $20 \%$ or $40 \%$ uncertainty around the best-estimate of lung cancer mortality. Table 11.7 shows the countries assigned to each uncertainty category.
2. Never-smoker lung cancer mortality: For China, estimates of the uncertainty for never-smoker lung cancer mortality rates from the proportional mortality study were used (Liu et al. 1998). For all other countries, where non-smoker lung cancer mortality rates were assumed to be those of CPS-II, we assumed an uncertainty of $15 \%$ around CPS-II estimates plus the statistical uncertainty of the CPS-II estimates themselves. Fifteen per cent is approximately equivalent to the whole (non-smoker) population being exposed to the highest levels of air pollution, such as that in the centre of the industrial city of Cracow, Poland, which resulted in a $14 \%$ increase in lung cancer mortality over the period 1980-1985 (Jedrychowski et al. 1990) or the whole (never-smoker) population being exposed to more than $10 \mu \mathrm{~g} / \mathrm{m}^{3}$ of $\mathrm{PM}_{2.5}$ (particulates below 2.5 microns in diameter) (Pope et al. 2002). Because the net difference between accumulated exposure to additional lung cancer risk factors (radon, urban air pollution, biomass smoke) in any two countries is less than the whole population, $15 \%$ is a relatively large uncertainty range for never-smoker lung cancer mortality.
3. Reference population smoker and never-smoker lung cancer mortality: We used statistical uncertainty of the CPS-II population since the reference population is constant in all regions of the world and the excess mortality of the reference population of smokers is simply a normalizing factor.
4. Relative risk: Uncertainties in relative risks were obtained directly from the CPS-II and Chinese mortality studies as well as the decline in risk due to cessation.
5. Confounding and extrapolation of relative risk and correction factor: To avoid overestimation of risk as a result of confounding in CPS-II relative risks, as well as from the extrapolation of relative risk to other regions, we have reduced the relative risk values by $30 \%$ to $50 \%$ for various diseases. To account for uncertainty in the level of the correction factor, we assumed that the $30 \%$ correction factor could vary between $10 \%$ and $50 \%$ with a triangular distribution. The lower end of this range corresponds to the typical amount of reduction in excess risk seen after adjustment for covariates in the re-analysis of CPS-II data (Thun et al. 2000) and seen in other studies such as the magnitude of confounding due to diet found by Law et al. (1997). The upper end is the conservative correction used by Peto et al. (1992) before the level of confounding was known and larger than those in the CPS-II re-analysis (Thun et al. 2000). The $50 \%$ correction factor used for the "other medical causes" group was assumed to be highly uncertain and in the range of $10 \%$ to $90 \%$ with a triangular distribution. We also assumed that the $5 \%$ correction factor for estimates of relative risk for China were in the range of $0-10 \%$ with a triangular distribution.

## Model uncertainty

Although lung cancer mortality provides a biological marker for accumulated exposure to the hazards of smoking in general, the question remains whether it equally represents the accumulated hazards for each of the diseases considered in this analysis. Two factors may reduce the accuracy of excess lung cancer and SIR as markers of accumulated hazard:

1. If the cigarette smoke characteristics that cause lung cancer are not fully correlated with those that cause the other hazard: While the carcinogens in cigarette smoke are the cause of cancer, the concentration or size distribution of respirable particles or other pollutants may be a better indicator of some of the other health effects. The validity of the SIR method compared to direct estimates in the United States was estimated by Peto et al. (1992). Comparisons with other (largely direct) methods for other countries also show consistent results (Bronnum-Hansen and Juel 2000; Valkonen and van Poppel 1997).
2. If the time-to-hazard (or hazard accumulation function as described in chapter 1) is different for lung cancer and other diseases caused by smoking: Lung cancer is caused by exposure and hazard accumulated over an extended period of time spent smoking. This property may be shared by some other outcomes of smoking, such as other cancers and COPD. Some of the other health effects of smoking, such as acute respiratory diseases, may occur after immediate exposure, and others, such as cardiovascular disease, are determined by a period of exposure that may be somewhat shorter than that of lung cancer. With these differences, when smoking is on the rise, an indicator based on excess lung cancer-which generally occurs later-would underestimate the impacts of those diseases that occur earlier. On the other hand some time after smoking begins to decline, an indicator based on excess lung cancer would overestimate the impacts of those diseases, where risk declines faster with cessation than lung cancer. ${ }^{6}$ Since smoking has been increasing in most regions of the world over the past two or three decades, the net effect of this would be an underestimation of current global mortality due to cardiovascular and some other diseases in our analysis.

In addition to the uncertainty in the use of SIR as exposure variable, the following other sources of uncertainty have not been quantified:
3. The impact of environmental tobacco smoke on SIR estimates: The carcinogenic effects of cancer agents are likely to apply at low levels without a threshold (Peto 1978). Therefore exposure to environmental tobacco smoke (ETS) is a likely cause of lung cancer. This relationship, as well as the impact of ETS on cardiovascular disease, has also been established in epidemiological studies (Australia National Health and Medical Research Council 1997; Environmental Protection Agency 1992; Hackshaw et al. 1997; Law et al. 1997; UK Department of Health Scientific Committee on Tobacco and Health 1998). Although we did not conduct a separate analysis of the burden of disease due to ETS, because of its relationship to lung cancer, ETS exposure affects SIR estimates.

Of the four variables in the $S I R$ relationship ( $C_{L C}, N_{L C}, S_{\tilde{L} C}^{*}$, and $N_{\tilde{L} C}^{*}$ in Equation 2), the effects of ETS are smallest on life-long smokers ( $S_{\tilde{L} C}^{*}$ ) who are almost completely affected by direct smoking. The lung cancer mortality of the population as a whole $\left(C_{L C}\right)$ is also affected more by direct smoking but nonetheless captures the effects of both direct and indirect exposure to tobacco smoke. The effects of ETS are largest on never-smokers ( $N_{L C}$ and $N_{L C C}^{*}$ ) who would otherwise not be exposed to tobacco smoke. Therefore, both $N_{L C}$ and $N_{\tilde{L} C}^{*}$ are larger in the presence of ETS than they would be in its absence. Since $C_{L C}$ is almost always smaller than $S_{\tilde{L} C}^{*}$, increasing non-smoker lung cancer rates will result in
a larger relative reduction (through subtraction) in the numerator of Equation 1 compared to the denominator, and therefore an underestimation of SIR values.
4. Estimates of non-fatal health outcomes: To obtain relative risks for non-fatal effects of these diseases, we have assumed that smoking increases mortality by increasing disease incidence (rather than modifying case fatality) for cancers and COPD. We have assumed a potential change in either the incidence or the severity/case fatality for all other causes. Given that most of the diseases affected by smoking are chronic diseases as a result of chronic exposure, this is a conservative assumption and requires further investigation using epidemiological studies on the relationship between smoking and disease incidence.
5. Future exposure and risk reversibility: Estimates of avoidable burden are possibly the most uncertain component of a risk assessment exercise because of the number of assumptions that, by definition, are needed for estimates of future burden. These include estimates of the "business-as-usual" trends of smoking and lung cancer and estimates of risk reversibility (reduction in relative risk) for those current smokers who stop smoking.

The future estimates of lung cancer mortality and SIR (see below) are based on a number of assumptions. These include the descriptive model of the tobacco epidemic and its parameters, the estimates of total tobacco consumption, and the statistical model used for estimating lung cancer based on consumption. As we discussed under risk reversibility, the estimates of decline in the relative risk for lung cancer, and more importantly for other diseases, after smoking cessation are derived from a limited number of studies and extrapolated to people of different ages, sexes and smoking histories. At the same time it may be possible that the benefits of cessation are more dependent on the specific history of smoking such as duration of smoking and age at cessation, than the current accumulated risk (which is captured by $S I R$ ) as also seen in the comparison between male and female reductions in lung cancer risk in Table 11.5. In this case, the use of $S I R$ as the indicator of pre-cessation history would create an additional source of uncertainty. At the same time, after a few decades, the potential health benefits of smoking reduction occur among those who would be prevented from smoking altogether. In this case, the longer-term estimates of avoidable burden would be less dependent on the specifics of risk reversibility and depend only on the estimates of risk among life-long smokers, which are known with much greater certainty.

### 2.6 ADdItIonal oral cancer mortality due to oral tobacco USE

Oral tobacco use, in the form of chewing of betel-quid with tobacco, is common in many parts of south Asia, and in particular in the Indian sub-continent (Bhonsle et al. 1992). Although oral tobacco use has been associated with increased risk of all-cause mortality (Gupta and Mehta 2000), we focus here on the risk of oral cancer which is the most-widely known and studied outcome of this risk behaviour (Gupta et al. 1982; International Agency for Research on Cancer (IARC) 1984; U.S. Department of Health and Human Services 1986), and a leading form of cancer mortality in the region (Parkin et al. 1997). Smoking in India is much more common among men than women whereas the prevalence of tobacco chewing is of comparable magnitude, although still higher among men (Corrao et al. 2000; Gupta 1996; WHO 1997). Given the correlation between smoking and oral tobacco use, many cases of oral cancer are likely to be affected by both habits. To report the total burden of disease due to both forms of tobacco use, we made estimates of only those cases of oral cancer that are caused by tobacco chewing in addition to smoking. The estimates were applied to SEAR-D only. Oral tobacco use is common throughout the region, whose mortality estimates are nonetheless dominated by those from India.

We obtained estimates of the fraction of total chewers who do not smoke $\left(p_{c}\right)$ and the fraction of total smokers who do not chew $\left(p_{s}\right)$ using a survey of tobacco habits in various ethnic and religious groups in India (Gupta 1996). The estimates of oral cancer for smokers who do not chew $\left(p_{s}\right)$ are included in those from the application of the SIR method. Those who both smoke and chew ( $p_{s c}$ as a fraction of total smokers), have a higher risk than smokers-only, by a factor $R R_{\text {(chewing+smoking)/smoking }}$, because of their additional chewing habit. We used $R R_{\text {(chewingtsmoking)/smoking }}$ to increase the CPS-II relative risk estimates for the upper-aerodigestive cancer category for this group, ${ }^{7}$ and applied these increased risk estimates to oral cancer mortality. The difference between these new estimates of oral cancer (using increased relative risk) and those using the CPS-II risk estimate, are the additional deaths due to oral tobacco use over and above those accounted for by smoking, among those who both chew and smoke. Finally, for those who chew only $\left(p_{c}\right)$, we used the corresponding relative risk, $R R_{\text {(chewing and not smoking) }}$, to obtain estimates of oral cancer mortality, which are independent from those obtained using the SIR method. For this group, we directly used the estimated prevalence of chewing. Although oral cancer as a result of tobacco chewing is also dependent on accumulated exposure, the relative risk estimates from recent literature are directly applicable because they were used in the same time period and region where epidemiological studies took place.

For males, we used the estimate that $20 \%$ of all smokers also chew (WHO 1997), which is close to the largest overlap of any ethnic or reli-
gious group found in a study of socio-demographic characteristics of tobacco users (Gupta 1996). Assuming a $40 \%$ prevalence of smoking and a $65 \%$ prevalence of total tobacco use, this implies that $32 \%$ of adult males smoke only, $8 \%$ of adult males both smoke and chew, and another $25 \%$ chew only, consistent with other estimates (WHO 1997). For females, we used a $33 \%$ prevalence of total tobacco use and a $3 \%$ prevalence of smoking (Corrao et al. 2000; WHO 1997). We also assumed that all female smokers also chew tobacco (Gupta 1996), hence $30 \%$ of adult females are chewers-only.

A review of studies prior to 1982 that estimated the relative risk of oral cancer due to tobacco chewing is provided by Gupta et al. (1982). We did not use these estimates since the definitions of cancer sites or control for covariates were not consistent with more recent studies. All these studies nonetheless show statistically significant increased risk of oral cancer due to tobacco chewing. A number of recent studies have estimated the relative risks for oral cancer (or one of its sub-types) based on stratification by smoking and tobacco chewing, all finding a significant increase in the risk of oral cancer among chewers regardless of their smoking habits (Balaram et al. 2002; Dikshit and Kanhere 2000; Rao et al. 1994; Sankaranarayanan et al. 1989a, 1989b, 1990). A description of recent studies and their estimates of relative risk (or odds ratio) of oral cancer due to chewing tobacco among smokers and non-smokers is provided in Table 11.8. Those studies that provided separate analysis according to the frequency of chewing also consistently show an increasing dose-response relationship. Note that in some of the studies, those who both chew and smoke tobacco had lower risk than those who used oral tobacco only. This may be because smokers chewed less tobacco than those whose only habit was tobacco chewing. We used a relative risk of 3.64 for chewing only and 1.7 for those who both chew and smoke relative to smokers. These values, which are lower than almost all other studies, are from non-drinkers in the study of Rao et al. (1994) to avoid confounding due to alcohol consumption, an important risk factor for oral cancer.

## 3. Results

### 3.1 Exposure (SIR) estimates

Figure 11.4 shows SIR estimates for females and males in developing and industrialized countries. We have also shown in the figure legend the best estimate of adult smoking prevalence for each subregion. As discussed above, prevalence estimates are uncertain and based on data from a limited number of countries. At the same time, as discussed by Jha et al. (2002), despite uncertainties in country-level and age-specific estimates, they provide a reasonable indication of current smoking status among adults in each subregion. The subregion WPR-B includes China.
Table II.8 Summary of studies on the relationship between tobacco chewing, smoking and oral cancer ${ }^{a}$

| Study location (reference) | Cancer site (ICD code) | Number of cases and control choice | Covariate adjustment | Effect size |
| :---: | :---: | :---: | :---: | :---: |
| Kerala (Sankaranarayanan et al. 1989a) | Oral tongue and the floor of the mouth (ICD 14I.I-I4I.4 and 144) | 228 cases; 453 hospital-based controls matched for age, sex and religion | Age | $\begin{aligned} & R R_{\text {chewing }}=6.13 ; R R_{\text {smoking }}=4.98 ; \\ & R R_{\text {chewing }} \text { +smoking } \\ & =7.2^{\mathrm{b}} \end{aligned}$ |
| Kerala (Sankaranarayanan et al. 1989b) | Gingiva (ICD 143.0 and I43.1) | 187 cases; 895 hospital-based controls with respiratory, intestinal, and genito-urinary infections, excluding malignancy in sites other than head and neck | Age | $\begin{aligned} & R R_{\text {chewing }}=11.76 ; R R_{\text {smokking }}=4.21 \text {; } \\ & R R_{\text {chewing+smoking }}=16.48^{\mathrm{b}} \end{aligned}$ |
| Kerala (Sankaranarayanan et al. 1990) | Buccal and labial mucosa (ICD 145.0, 145.I, and 145.6-140.3 and 140.4) | 414 cases; 895 hospital-based controls with non-malignant conditions | Age, religion | $\begin{aligned} & R R_{\text {chewing }}=14.28 ; R R_{\text {smoking }}=4.21 \text {; } \\ & R R_{\text {chewingtsmoking }}=21.46^{\text {b }} \end{aligned}$ |
| Bangalore (Nandakumar et al. 1990) | Oral cavity (140-14\| and 143-145 excluding 141.0) | 348 cases; 348 hospital-based controls with non-malignant conditions matched for age, sex and residence | Age, sex, religion and diet | $\begin{aligned} & R R_{\text {chewing }}=10.2 ; R R_{\text {smoking }}=3.5 ; \\ & R R_{\text {chewing }+ \text { smoking }}=9.2^{b} \end{aligned}$ |

Table II. 8 Summary of studies on the relationship between tobacco chewing, smoking and oral cancer ${ }^{\text {a }}$ (continued)

| Study location (reference) | Cancer site (ICD code) | Number of cases and control choice | Covariate adjustment | Effect size |
| :---: | :---: | :---: | :---: | :---: |
| Bombay (Rao et al. 1994) | Oral (excluding 141.0 and 145.3) | 713 male cases; 635 male hospital-based controls without cancer, benign tumour and infectious disease | Age and area of residence | $\begin{aligned} & \text { Non-drinkers: } R R_{\text {chewing }}=3.64 ; \\ & R R_{\text {smoking }}=1.69 ; R R_{\text {chewing+smoking }}=2.93 \\ & \text { Drinkers: } R R_{\text {chewing }}=4.32 ; R R_{\text {smoking }}=2.44 ; \\ & R R_{\text {chewingtsmoking }}=8.88 \end{aligned}$ |
| Bhopal (Dikshit and Kanhere 2000) | Oral cavity (140.0-144.9, 145.0-145.2, 145.5-145.9) | 148 male cases; 260 controls randomly selected from a survey of tobacco habits | Age | $\begin{aligned} & O R_{\text {chewing }}=10.6 ; O R_{\text {smoking }}(<10 \mathrm{cig} / \text { day })=1.0 ; \\ & O R_{\text {smoking }}(\geq 20 \text { cig } / \text { day })=4.9 ; O R_{\text {chewing }+ \text { smoking }} \\ & (<20 \text { cig } / \text { day })=8.4 ; O R_{\text {chewingtsmoking }} \\ & (\geq 20 \text { cig } / \text { day })=16.3 \end{aligned}$ |
| Southern India (Balaram et al. 2002) | Oral | 591 cases; hospital-based controls matched by medical centre, age and sex | Age, sex, medical centre, education and alcohol | $\begin{aligned} & O R_{\text {chewing }}=9.19 ; O R_{\text {smoking }} \\ & (<20 \mathrm{cig} / \text { day })=1.78 ; O R_{\text {smoking }} \\ & (\geq 20 \mathrm{cig} / \text { day })=3.69 ; O R_{\text {chewing+smoking }} \\ & (<20 \mathrm{cig} / \text { day })=8.86 ; O R_{\text {chewingtsmoking }} \\ & (\geq 20 \mathrm{cig} / \text { day })=6.69^{\mathrm{b}} \end{aligned}$ |

All studies were case-control and took place in India.
b The effect estimates are for males only since none or few of the female cases smoked.

(d) Developing countries (female) II

Figure II.4 Estimates of smoking impact ratio (SIR) by age, sex and subregion (continued)

(f) Industrialized countries (female)

[^41]Hence the aggregate estimates for this subregion are dominated by the Chinese data. This division allows the characteristics of the other countries in the subregion to also be considered, in particular given the role of higher background lung cancer mortality in China. Table 11.9 provides the SIR distribution, divided as defined earlier.

A number of important features of the global smoking epidemic can be seen in the different panels of Figure 11.4:

1. The largest accumulated risk of smoking for males aged $<70$ years in the countries of eastern Europe and the former Soviet Union (EUR-B and EUR-C). For older males (aged $\geq 70$ years), North America and western European countries have the largest accumulated risk. These two results are consistent with the very high current and recent prevalence of smoking among eastern European men which has been sustained for several decades, and the longer history of smoking among North American and western European men.

The accumulated hazards of smoking among men were lowest in AMR-D, AFR-D and AFR-E. In these subregions, the rise in smoking has been a recent phenomenon. The results for China (WPR-B) are particularly important and instructive. The background-adjusted SIR values for China were still fairly low, despite high lung cancer mortality in this country. At the time of the Liu et al. (1998) study (in 1990) the relative risk of lung cancer for a Chinese smoker was less than 3.0 because of the more recent start of the epidemic in this country. Over the next few decades, increasing accumulated exposure to smoking may well result in rising lung cancer mortality in China to levels comparable to populations with life-long smokers (such as those in North America and western Europe where the relative risks for lung cancer are approximately 20). Together with the finding of Liu et al. (1998) that smoking acts to "amplify" the high background rates of lung cancer, this increase in accumulated hazard will result in enormous lung cancer (and other) mortality in China.

Examining prevalence and SIR patterns simultaneously also emphasizes the importance of considering accumulated risks. For example, the current prevalence of smoking among adult men in AMR-A was equal to AFR-D and lower than all other subregions in the developing world. At the same time, the SIR values for AMR-A males were larger than those of most developing subregions because of the histories of smoking. In AMR-A, smoking has been declining and current prevalence would underestimate the current impacts of smoking. In developing countries, on the other hand, smoking has been rising in recent decades with current prevalence being comparable to AMR-A, but the accumulated hazards were still lower.
2. For women, AMR-A had the single highest accumulated risk from smoking. Although women in many countries in western Europe

[^42]NA Not applicable.
(EUR-A) have smoked for a long time (in particular in the United Kingdom), smoking is a more recent phenomenon in the southern parts of the continent, and therefore the overall SIR is still lower than in AMRA. SIR values for women were consistently low in developing countries except for younger and middle-aged women in AMR-B (Latin America and the Caribbean) and young adult women in EMR-B. Once again, comparing SIR values for females in AMR-A, whose current prevalence of smoking is $22 \%$ (reflecting recent declines in female smoking in North America), with those for males in many subregions of the developing world, who have higher current prevalence but lower SIR, illustrates the inadequacy of current prevalence as a marker for smoking risk. ${ }^{8}$
3. Age patterns of SIR estimates for the different subregions also provide information about the state of the smoking epidemic. For each age-sex group, SIR is excess lung cancer, relative to the same age-sex group of American smokers in the 1980s. Among men in industrialized countries, the SIR values were relatively constant across ages in AMR-A, but decline with age in other industrialized regions, with EUR-A being closest to the constant pattern. These inter-subregional and intra-subregional age patterns imply that, when compared to the same age group of American smokers in the 1980s, age patterns of smoking have been relatively constant in North America whereas smoking has been more concentrated among younger and middle-age men in Europe and the Western Pacific, especially in the former Soviet Union (EUR-C). In the developing countries of Latin America and the Caribbean, the Eastern Mediterranean, and sub-Saharan Africa, smoking also seems to have had fairly constant effects across ages, when each is compared to the same age group of American smokers in the 1980s. In Asia, on the other hand, smoking had a greater impact on younger and middle-aged male cohorts than at older ages when compared to the same age group of American smokers in the 1980s.

Overall, the age patterns of SIR were less variant among women in both developing and industrialized countries compared to men. In AMRB, EMR-B, EMR-D, and the EUR subregions there is more smoking among younger and middle-age women than at older ages, when each is compared to the same age group of female American smokers in the 1980s. In Asia, female smoking seems to peak among the middle-aged cohorts, which may reflect social factors that would prevent smoking among many young women. In North America, the distribution was more towards older age groups when compared to the same age group of female American smokers in the 1980s.

### 3.2 Mortality and disease burden due to smoking

Tables 11.10 and 11.11 provide the estimated number of smoking-attributable deaths and DALYs for males and females in developing and industrialized countries. Table 11.12 divides the estimates of global mortality
due to smoking into broad causes and age groups. Although the results were estimated for the eight age groups described in Table 11.9 (assumed to be zero for the first three age groups $<30$ years), they are reported in two age groups ( $30-69$ and $\geq 70$ years) to be comparable with previous estimates of mortality due to smoking, such as those in Peto et al. (1992). The distribution of mortality and DALYs by broad disease groups is given in Figures 11.5 and 11.6.

The 4.83 ( $95 \%$ CI $3.94-5.93$ ) million deaths due to smoking accounted for $12 \%$ of total global adult (aged $\geq 30$ years) mortality. ${ }^{9}$ The shares of adult male and female total mortality due to smoking were $18 \%$ and $5 \%$, respectively. Of these deaths, 2.69 million were among those aged 30-69 years, resulting in a larger number of life years lost to premature mortality, and 2.14 million among those aged $>69$ years. As seen in a comparison of Tables 11.10 and 11.11, although developing and industrialized countries accounted for virtually equal numbers of global mortality, the burden of disease associated with this risk factor

Note: See Table II.I for details on causes of death.
was much higher in the former. As discussed below, this is because in general smoking-caused mortality in developing countries occurs at earlier ages than in industrialized nations accounting for a larger loss of life from premature mortality. Further, a comparison of Figures 11.5 and 11.6 indicates that the relative share of cancers in terms of the total burden of disease is lower than their comparative role in mortality because of the shorter morbidity associated with cancers compared to the other categories.

Lung cancer was the disease with the highest fraction attributable to smoking. Seventy-one per cent of all lung cancers or 0.85 million deaths ( $79 \%$ or 0.69 million deaths among men and $48 \%$ or 0.16 million deaths among women) were attributable to smoking. However, cardiovascular diseases were the largest cause of death due to smoking in terms of number of deaths. One million six hundred and ninety thousand cardiovascular disease deaths ( 1.37 million among men and 0.32 million

among women) were due to smoking, accounting for $35 \%$ of all smoking-attributable deaths ( $35 \%$ among men and $37 \%$ among women). Overall, $11 \%$ of all cardiovascular deaths in the world were attributable to smoking ( $17 \%$ among men and $4 \%$ among women). Only when all cancers are considered together did they approach cardiovascular diseases as the largest cause of death due to smoking. One million four hundred and seventy thousand neoplasm deaths ( $22 \%$ of all cancer deaths; 1.24 million or $33 \%$ of all adult male cancer deaths and 0.23 million or $8 \%$ of all adult female cancer deaths) were due to smoking, accounting for $30 \%$ of all smoking-attributable deaths ( $32 \%$ among men and $23 \%$ among women).

### 3.3 Mortality in industrialized countries

Table 11.13 provides the details of mortality due to smoking in industrialized countries by age, sex and causes of death. In the year 2000,
smoking caused an estimated 2.43 ( $95 \%$ CI 2.13-2.78) million deaths in industrialized countries for people aged $>30$ years, accounting for $19 \%$ of adult mortality. One million eight hundred and ten thousand ( $95 \%$ CI 1.62-2.02) deaths were among men ( $28 \%$ of total mortality of adult males) and 0.61 ( $95 \%$ CI $0.52-0.75$ ) million among women ( $10 \%$ of total mortality of adult females). The magnitude of the years of life lost due to premature mortality becomes more obvious when we note that 1.19 million, or approximately one half, of these deaths were among those aged 30-69 years.

In industrialized countries, smoking-caused deaths accounted for $33 \%$ of total mortality among males between the ages of 30 and 69 years ( 1.00 million deaths), $24 \%$ of total mortality among males aged $>70$ years ( 0.81 million deaths), $12 \%$ of total mortality among females between the ages of 30 and 69 years ( 0.19 million deaths), and $9 \%$ of total mortality among females aged $>70$ years ( 0.42 million deaths).

The fraction of smoking-attributable mortality among men was highest in the EUR-C and AMR-A subregions, causing 0.55 million and 0.35 million smoking-attributable male deaths, respectively. These were $32 \%$ and $28 \%$ of all adult male deaths ( $36 \%$ and $24 \%$ of all deaths for $30-69$ and $\geq 70$ age groups in EUR-C; $31 \%$ and $26 \%$ of all deaths for $30-69$ and $\geq 70$ age groups in AMR-A reflecting the fact that the two subregions are at different stages of the tobacco epidemic). Among women the highest fraction of smoking-attributable mortality was in AMR-A where 0.29 million deaths ( $22 \%$ of all mortality) $(27 \%$ and $20 \%$ of all deaths for the $30-69$ - and $\geq 70$-year age groups, respectively), were caused by smoking. The lowest fraction of smoking-attributable mortality among men in the industrialized world was in WPR-A ( $22 \%$ of all deaths; $18 \%$ and $24 \%$ of all deaths for $30-69-$ and $\geq 70$ year age groups, respectively) and among women in EUR-C (4\% of all deaths; $6 \%$ and $4 \%$ of all deaths for $30-69$ - and $\geq 70$-year age groups, respectively) and EUR-B ( $6 \%$ of all deaths; $10 \%$ and $5 \%$ of all deaths for the 30-69- and $\geq 70$-age groups, respectively).

For both males and females in all subregions and age groups, lung cancer was the cause of death with the largest fraction attributable to smoking, ranging from a low of $45 \%$ among females aged $\geq 30$ years in EUR-C to a high of $91-94 \%$ among males aged $\geq 30$ years in AMR-A, EUR-A, EUR-B and EUR-C. Overall $92 \%$ of all lung cancer deaths among adult ( $\geq 30$ years) males ( 0.40 million lung cancer deaths) and $71 \%$ of all lung cancer deaths among adult ( $\geq 30$ years) females ( 0.12 million lung cancer deaths) in industrialized countries were caused by smoking.

Despite the predominance of smoking as a cause, lung cancer accounted for only $22 \%$ ( 0.40 million) of smoking-attributable deaths among men and $19 \%$ ( 0.12 million) among women in industrialized countries. In fact, in terms of the fraction of all causes of death due

to smoking, cardiovascular diseases led the grouping used in Table 11.1 and accounted for $42 \%$ and $44 \%$ of deaths caused by smoking among men and women, respectively ( 0.75 million male deaths and 0.27 million female deaths from cardiovascular diseases due to smoking). When all cancers are considered together, however, the numbers approached cardiovascular diseases for men. Neoplasm deaths accounted for $37 \%$ and $26 \%$ of all smoking caused deaths among men and women, respectively, in industrialized countries ( 0.66 million male deaths and 0.16 million female deaths from all cancers due to smoking accounting for $43 \%$ and $13 \%$ of all cancers among men and women, respectively).

### 3.4 Mortality in developing countries

Table 11.14 provides the details of mortality due to smoking in developing countries by age, sex and cause of death in 2000. The number of deaths attributable to smoking among people aged $>29$ years in developing countries in 2000 was 2.41 ( $95 \%$ CI 1.80-3.15) million accounting for $9 \%$ of total adult mortality in these countries. Of the smoking-attributable deaths, 2.02 ( $95 \%$ CI 1.56-2.50) million were among men ( $14 \%$ of total adult male mortality) and 0.38 ( $95 \%$ CI $0.25-0.65$ ) million among women ( $3 \%$ of total adult female mortality). About twice as many- 1.5 million deaths-deaths were among those between 30 and 69 years compared with 0.91 million among those aged $>69$ years.

In developing countries also, lung cancer was the disease with the highest fraction due to smoking. Fifty-five per cent of all lung cancers or 0.33 million deaths $(67 \%$ or 0.29 million deaths among men and $25 \%$ or 39000 deaths among women) were attributable to smoking. But lung cancer accounted for only $14 \%$ of all smoking-attributable mortality ( $14 \%$ among men and $10 \%$ among women) vs $21 \%$ in industrialized countries. As in the industrialized countries, cardiovascular diseases were the largest cause of death due to smoking, followed very closely by COPD. Six hundred and seventy thousand cardiovascular deaths (0.57 million among men and 97000 among women) were due to smoking, accounting for $28 \%$ of all smoking-attributable deaths ( $28 \%$ among men and $25 \%$ among women). Six hundred and fifty thousand COPD deaths ( 0.50 million among men and 0.16 million among women) were due to smoking accounting for $27 \%$ of all smoking-attributable deaths $(25 \%$ among men and $41 \%$ among women). This high contribution from COPD is consistent with direct observations of Liu et al. (1998) in China, where the high background (non-smoker) rates of COPD mortality due to other risk factors result in an even larger mortality due to smoking from this cause. Further, the lower contribution of cardiovascular diseases to smoking-caused mortality compared to the $42 \%$ in industrialized countries is likely to be due to lower overall cardiovascular disease mortality in these populations. Future changes in dietary risk factors and

increased exposure to other cardiovascular disease risks in developing countries, even with similar attributable fractions, would result in a rise in tobacco-caused mortality in these subregions. As for the global total and in industrialized countries, when all cancers are considered together, they approach cardiovascular diseases and COPD as the largest cause of death due to smoking. Six hundred and fifty thousand neoplasm deaths ( $16 \%$ of all cancer deaths; 0.58 million or $26 \%$ of all adult male cancer deaths and 69000 or $4 \%$ of all adult female cancer deaths) were due to smoking, accounting for $27 \%$ of all smoking-attributable deaths $(29 \%$ among men and $18 \%$ among women).

In general, there was larger variation in mortality due to smoking among different subregions of developing countries than industrialized countries, because of the variability in the stages of the smoking epidemic. In the sections below, we discuss the estimates for different areas of developing countries, including comparisons with direct estimates where available.

## China

Liu et al. (1998) estimated that smoking caused 0.6 million deaths in China in 1990 and expected this number to rise to 0.8 million in 2000 if the fraction of mortality due to smoking remained unchanged. Since smoking had been rising rapidly in China since the 1970s, the fraction of deaths due to smoking was expected to rise, resulting in more deaths than the 0.8 million estimate. The 2000 estimates were based on a projected total adult ( $\geq 35$ years) mortality of 9 million in China in 2000. ${ }^{10}$

In fact, total adult mortality in China in 2000 from the GBD mortality database was 7.5 million deaths, reflecting recent health gains in China. Applying the 1990 cause-specific mortality and total mortality attributable fractions from Liu et al. (1998) to the 2000 mortality estimates in China would result in approximately 0.6 million smokingattributable deaths, with 0.51 million male deaths and 0.09 million female deaths. Actual mortality is expected to be higher, in particular among men, because of the rising trend of smoking (Corrao et al. 2000; WHO 1997). Further, since the proportional mortality analysis of Liu et al. (1998) cannot estimate mortality from those causes in the reference group, smoking-attributable mortality is underestimated (to zero) for these causes, to the extent that smoking caused some deaths from these diseases.

As described above in the section on methods, in estimating smoking-attributable mortality in China, we converted the 1990 relative risks for smoking estimated in Liu et al. (1998) to relative risks per unit of SIR. We then estimated the SIR for in China in 2000 to capture the impacts of the more recent increase in smoking. Mortality was then estimated by applying the relative risk estimates from 1990 (with some correction for potential confounding) to 2000 SIR estimates. The
exception is for diseases in the category "other medical causes" in Table 11.1, for which proportional mortality analysis does not estimate relative risks. For these causes, we used the relative risks of CPS-II from Table 11.1.

Using this method for China we estimated that smoking caused 0.59 million deaths, 0.49 million of which are among men ( $13 \%$ of total adult male mortality) and the remaining 0.10 million among women ( $3 \%$ of total adult female mortality). In China, deaths caused by smoking accounted for $11 \%$ of total mortality among males between the ages of 30 and 69 years ( 0.22 million deaths), $15 \%$ of total mortality among males aged $>69$ years ( 0.27 million deaths), $2 \%$ of total mortality among females between the ages of 35 and 69 years ( 32000 deaths), and 3\% of total mortality among females aged $>69$ years ( 66000 deaths).

The relatively small fraction of mortality among women due to smoking remained constant between 1990 and 2000, reflecting the stable, low prevalence of smoking among Chinese women. The fraction of mortality among men dropped for the 35-69-year age group from $13 \%$ to $11 \%$, and increased from $12 \%$ to $15 \%$ for the $\geq 70$-year age group. The increase among the older men is due to demographic shifts in smoking patterns. Tobacco consumption in China increased between 1970 and 1990 and then stabilized (Corrao et al. 2000; WHO 1997). Therefore, while many of the younger smokers in 1990 and in 2000 had started smoking around the same age, those in older age groups in 2000 are likely to have smoked for a longer time than those of similar age in 1990. This slight increase in the fraction of mortality attributable to smoking among the older age cohorts with the maturity of the smoking epidemic is consistent with historical trends in age-specific attributable fractions in Canada, the United Kingdom and the United States. The decline among the younger age groups was partially due to the $5 \%$ correction factor applied to the hazards for this country.

Lung cancer accounted for $20 \%$ and $18 \%$ of smoking-attributable mortality among men and women, respectively, in China, resulting in 98000 male deaths and 17000 female deaths. The fractions of smokingattributable mortality from all cancers were $44 \%$ ( 215000 deaths) for males and $29 \%$ (28000 deaths) for females. This suggests that the contribution of smoking to mortality from cancers other than lung cancer is larger in China than in industrialized countries (Lopez 1998). In China, COPD also accounted for a large fraction of smoking-attributable mortality with $33 \%$ ( 163000 deaths) and $61 \%$ ( 60000 deaths) of smokingcaused mortality among men and women respectively.

INDIA AND SEAR-D ${ }^{11}$
Seven hundred and fifty thousand deaths among adult men and 110000 among adult women were attributable to smoking in SEAR-D accounting for $18 \%$ and $3 \%$ of total mortality, respectively. Six hundred and thirty thousand of these deaths occured before the age of $70(13 \%$
of total mortality) and the remaining 230000 among those aged $\geq 70$ years ( $8 \%$ of total mortality).

Adult male lung cancer mortality, $82 \%$ of which ( 84000 deaths) in this subregion is caused by smoking, accounted for $11 \%$ of smokingattributable male mortality, the lowest fraction among males in any subregion. The 6000 lung cancer deaths among females attributed to smoking ( $26 \%$ of all female lung cancer deaths) was likewise the smallest fraction ( $6 \%$ ) of smoking-attributable deaths compared with other subregions. When all cancers are considered together, smoking caused 0.18 million neoplasm deaths in SEAR-D in 2000 ( 160000 among men and 14000 among women). Cardiovascular diseases, with 0.28 million deaths ( 240000 or $16 \%$ of all cardiovascular deaths among men and 34000 or $2 \%$ of all cardiovascular deaths among women), were the cause of death with the highest number due to smoking and accounted for $33 \%$ of all smoking-attributable deaths ( $33 \%$ among men and $31 \%$ among women), reflecting the large contribution of this cause to adult male mortality in this subregion.

No direct nationally representative study of mortality due to smoking was available from India or other countries in SEAR-D at the time of writing. Estimates from specific regions within India as well as indirect national estimates, however, are available and can be used for comparison with our results. Gupta and Mehta (2000) estimated that the relative risk for mortality from all causes in a mixed cohort of male smokers and non-smokers aged >34 years in India relative to non-users of tobacco is approximately 1.63. Assuming, as in the case of CPS-II relative risks, that $30 \%$ of the excess risk is due to confounding (because of covariates such as chewing tobacco, diet, etc.) this relative risk and a smoking prevalence of $40-50 \%$ imply that $15-18 \%$ of all male mortality is due to smoking, a result consistent with our estimate of $18 \%$ of male mortality attributable to tobacco. Applying the relative risk of 2.1 obtained by Gajalakshmi et al. (2003) with the same correction factor will result in an even higher attributable fraction (23-28\%) than ours. The estimates of total mortality in this chapter are lower than those by Gupta (1989) who attributes at least $19 \%$ of adult male mortality and $4 \%$ of adult female mortality to tobacco use, as well as those in a recent case-control study that finds an unadjusted attributable fraction of approximately $20 \%$ for all adult deaths among Indian men (Gajalakshmi et al. 2003).

## Additional oral cancer mortality due to oral tobacco use

Using the methods described above, we estimated that there were 60000 additional cases of oral cancer due to oral tobacco use (tobacco chewing) in SEAR-D, accounting for an additional $50 \%$ of oral cancers in the subregion. Of these, 39000 were among men ( $48 \%$ of male oral cancer deaths) and 22000 among women ( $54 \%$ of female oral cancer
deaths). We emphasize that these estimates are those cases of oral cancer that are caused by tobacco chewing in addition to smoking. Since many cases of oral cancer are likely to be affected by both habits, the overall effects of tobacco chewing are larger. Important sources of uncertainty in the estimates are the prevalence of oral tobacco use and relative risk estimates as well as the extent of overlap between tobacco smoking and chewing, especially for men.

## Other developing countries

The fraction of total adult mortality due to smoking ranged from a low of $2-4 \%$ in AFR-D, AMR-D and AFR-E to a high of $11 \%$ in SEAR-B and $18 \%$ in WPR-B (excluding China). For males the lowest fraction of total mortality due to smoking was in AMR-D (3\%), AFR-D (5\%) and AFR-E ( $6 \%$ ), reflecting the more recent smoking epidemic in these subregions. Given that the current prevalence of smoking among adult men is approximately $25-30 \%$ in AFR-D and $35-45 \%$ in AFR-E, this finding emphasizes the fact that current prevalence is a poor marker of accumulated smoking risks (see also Figure 11.4).

The highest fractions of adult male mortality due to smoking were in WPR-B (excluding china) ( $26 \%$ ), SEAR-B ( $19 \%$ ), EMR-B ( $15 \%$ ) and AMR-B $(15 \%)$. For females, the fraction of total mortality due to smoking in 2000 was equal to or below $2 \%$ in AFR-D, AFR-E, AMRD, EMR-D and SEAR-B. The highest fractions of female mortality were in AMR-B ( $6 \%$ ) and WPR-B (excluding China) ( $8 \%$ ), reflecting more recent increases in female smoking in these subregions, especially with increasing urbanization and economic development.

## 4. Discussion

We applied the indirect method of Peto et al. (1992), which uses absolute lung cancer mortality in a population as a marker for accumulated hazards of smoking, to estimate the mortality and disease burden due to smoking in different subregions of the world. We chose the parameters of the model, such as relative risks and non-smoker lung cancer mortality, based on direct estimates or by extrapolation from other subregions based on best available evidence, explicitly stating the assumptions and reasons for each choice.

Using this method, we estimated that in 2000, approximately 4.83 ( $95 \%$ CI $3.94-5.93$ ) million deaths worldwide were due to smoking, accounting for $12 \%$ of global adult mortality. Of these deaths, 2.41 ( $95 \%$ CI $1.80-3.15$ ) million were in developing countries, marking a transition to an era in which smoking killed as many people in developing countries as in industrialized nations. In fact, even in the earlier stages of the tobacco epidemic, more men died from smoking in developing countries than in the industrialized nations ( 2.02 million vs 1.81
million). In addition to those cases shared with smokers, there were an estimated 60000 deaths from oral tobacco use in SEAR-D. Premature mortality and morbidity caused by smoking accounted for an estimated $4.1 \%$ of the global burden of disease.

As we discussed under sources of uncertainty, using lung cancerwhich has a longer lag than cardiovascular diseases-as the marker for accumulated smoking hazard, would result in an overestimation of hazard where there has been sharp drops in smoking and underestimation of hazard where there has been large increases in smoking. The former is most likely to apply to North America and among males in some countries in western Europe where smoking has declined (partially or fully offset by a continued choice of conservative relative risk estimates). On the other hand, the underestimation scenario would be applicable to most developing countries where smoking has been on the rise in the past few decades.

Total male mortality in terms of numbers of deaths was considerably higher than female mortality- 3.0 fold in industrialized nations and 5.3 fold in developing countries. The decline of the male-to-female mortality ratio from 3.6 to 3.0 in industrialized countries between 1990 and 2000, however, reflects the recent relative increases in female smoking in these countries. 2.69 million deaths, more than one-half of the all global deaths due to smoking, were in the 30-69-year age group.

Due to differences in methodology and presentation, the estimates reported here are not fully comparable with those for previous years. The existing estimates of consumption, prevalence and mortality, however, generally indicate that mortality due to smoking (in terms of the fraction of cause-specific or all-cause mortality) has been relatively stable in industrialized countries over the past ten years. Some countries in the established market economies category have seen a small decline in male mortality while in most of these countries female mortality has increased, reflecting differential time trends in male and female smoking. Industrialized countries also have seen a small decline in the fraction of mortality in the $30-69$-year age group and an increase in the $\geq 70$-year group, confirming that in these countries as a whole, the smoking epidemic may be shifting with the effects increasingly being felt among the older age groups. There were, nonetheless, subregional differences, and the share of mortality at ages 30-69-years is in fact rising among females in some subregions including AMR-A and EUR-A.

Mortality and disease burden attributable to smoking, including its share of total mortality and sex or age patterns, varied importantly among different geographical regions of developing countries. This interregional variation, which is larger than that observed in industrialized countries, occurs because the nature and maturity of the smoking epidemic is highly affected by the varying economic and cultural determinants of smoking in these populations. A few general statements can nonetheless be made about the health effects of smoking in developing
countries. First, current hazards of smoking in these populations are highly concentrated among men. Given that the prevalence of smoking among women is still low in developing countries (with the exception of Latin America and the Caribbean and some countries in Asia), the current level of male mortality should provide an indicator of the large health losses that may well occur if female smoking increases over the next few decades. Second, relative to industrialized countries, developing countries have a higher proportion of smoking-attributable mortality in the $30-69$ age group than in the $\geq 70$ group ( $62 \%$ in developing countries vs $49 \%$ in industrialized countries). Coupled with the 1990-2000 trends in mortality for the two age groups in China, this suggests that as people (mostly men) who began smoking over the past three decades in developing countries become older, mortality due to smoking will continue to rise as a share of cause-specific mortality; and almost inevitably as a share of total mortality.

Smoking prevalence in some developing countries appears to have stabilized, albeit at very high levels. In others, it is still rising. Given the gradually shifting disease patterns and because most of the growth in global population is expected to take place in the developing world, the health effects of smoking, already one of the most important global health hazards, will continue to rise unless effective interventions and policies that curb and reduce smoking among males and prevent increases among females in these countries are implemented.

## 5. Projected future exposure

Many diseases caused by smoking, in particular various malignant neoplasms and COPD, occur after long delays. This motivated using SIR as the exposure variable for estimating the accumulated hazards of smoking. Disease burden due to smoking in the next few decades will depend on both past and future smoking patterns. There is therefore a need to link estimates of accumulated current exposure, which are in the form of SIR estimates, with future exposure, which is often in the form of projections of prevalence of smoking or tobacco consumption (whether under the business-as-usual scenario or some counterfactual). Further, the combination of past and projected future exposure must be presented in the form of a single exposure variable which accounts for hazard accumulation. We used the following steps to estimate future smoking prevalence and tobacco consumption and convert these to estimates of lung cancer mortality and SIR.

1. We estimated past and current age-sex-specific smoking prevalence under the business-as-usual scenario based on a descriptive model of the smoking epidemic (Lopez et al. 1994), calibrated to regional characteristics of the epidemic for different subregions. The tobacco epidemic was divided into five stages (early, rising, peak or maturity, declining and late)
as well as five transitional stages as seen in Figure 11.7. Historical evidence from multiple industrialized countries consistently shows that the youngest and oldest age groups at any stage of the epidemic have lower smoking prevalence (Gajalakshmi et al. 2000; Nicolaides-Bouman et al. 1993), the former probably because of economic and social constraints and the latter because of a higher mortality rate among smokers. The prevalence distribution is also based on the observation that in the rising stages of the epidemic, younger adults begin to smoke more than the older adults but as the epidemic matures the age-pattern becomes more stable (Gajalakshmi et al. 2000). Finally, as observed in historical data we assumed that the prevalence of female smoking is lower than that of males at every stage of the epidemic.

In calibrating the level of the prevalence curves for different regions, we used the available comparative data on current and historical smoking prevalence (Corrao et al. 2000; Gajalakshmi et al. 2000; WHO 1997). Recent data on smoking prevalence show that the male epidemic has peaked at lower levels in Latin America and the Caribbean as well as in sub-Saharan Africa compared to North America, Europe and Asia, possibly because of the economic crises in these regions in the last two decades of the 20th century. Although for most regions female smoking is still in the early stages of the epidemic, we assumed that the peak of the epidemic would be lower in developing countries than what was observed in industrialized countries in the past. This assumption was because in those developing countries where female smoking has been on the rise, prevalence is lower than levels previously observed at similar stages in industrialized countries.

In each country, males and females were assigned to one stage of the epidemic in 2000 (Table 11.15) based on the best available data on smoking patterns in recent years (Corrao et al. 2000; WHO 1997).
2. We divided country-level per capita consumption data into age-sexspecific per capita consumption of smoking based on the above estimates of prevalence. The Tobacco Free Initiative (TFI) of WHO provides timeseries estimates of tobacco consumption based on production, export, and import data from the Food and Agriculture Organization of the United Nations (FAO). The consumption numbers are reported as equivalent cigarettes per adult (aged $\geq 15$ years) for each country. We used the above estimates of prevalence to divide the past and current countrylevel per capita consumption numbers (corrected for smuggling and other sources of error whenever possible) into age-sex-specific per capita consumption.

In addition to differences in prevalence, male smokers smoke more cigarettes per day than female smokers (Gajalakshmi et al. 2000; Nicolaides-Bouman et al. 1993). Differences between age groups also exist (Gajalakshmi et al. 2000; Nicolaides-Bouman et al. 1993). The

Figure II. 7 Descriptive model for the main stages of the tobacco epidemic based on the parameter values in industrialized countries

Female

Note: For some developing regions, lower peak values were chosen based on observed prevalence data. The vertical axis scales are different for males and females to increase resolution. The number next to each curve indicates the epidemic stage. An additional transitional stage is also assumed between each pair. With appropriate policies, one can assume declining prevalence even beyond stage 5 . We assumed that the business-as-usual scenario would not include this achievement, which is considered as a part of our counterfactuals.

Table II.I5 Status of the tobacco epidemic in 2000 among (a) males and (b) females
(a)

| Epidemic stage ${ }^{\text {a }}$ | Country ${ }^{\text {b }}$ |

a The stages of the epidemic refer to those in Figure II.7.
b By subregion.

Table II.I6 Ratios of number of cigarettes smoked per day for various demographic groups from historical data in industrialized countries

|  | Ratios of number of cigarettes smoked |  |
| :--- | :--- | ---: |
| Age group (years) | Male | Female |
| $15-19$ | 1.00 | 1.00 |
| $20-29$ | 1.22 | 1.15 |
| $30-39$ | 1.42 | 1.24 |
| $40-49$ | 1.37 | 1.34 |
| $50-59$ | 1.26 | 1.21 |
| $60-69$ | 1.15 | 1.04 |
| $70-79$ | 1.15 | 1.04 |
| $\geq 80$ | 1.15 | 1.04 |
| Male | 1.0 |  |
| Female | $1 / 1.25$ (stages 4 and 5); ${ }^{\text {a }} \mathrm{I}$ I/I.5 (stage 3); |  |

a The stages of the epidemic refer to those in Figure II.7.
ratios for the number of cigarettes smoked per day between different age groups and men and women have been estimated for industrialized countries (Gajalakshmi et al. 2000) and are presented in Table 11.16. We assumed a lower female-to-male ratio in the earlier stages of the female epidemic.

We emphasize that because the prevalence estimates from the descriptive model are used to divide existing total per capita consumption into age-sex-specific estimates, it is only the various male-female and age ratios that affect the estimates, rather than the absolute values. Therefore, the age-sex-specific consumption estimates are not sensitive to the level of the prevalence curve or assumptions about the stage of the epidemic, provided that male-to-female and age ratios are close to actual values (i.e. under- or over-estimating male and female prevalence by the same factor would not affect the consumption estimates).
3. We projected age-sex-specific lung cancer mortality based on consumption projections and a statistical model of the relationship between lung cancer mortality and lagged consumption (Girosi and King 2002). Finally, the projections of lung cancer mortality were converted to the projections of SIR using the definition of SIR above.

## Acknowledgements

We thank R. Peto and J. Boreham for discussions on methodology and for providing data from the Chinese retrospective proportional mortal-
ity study; M. Thun and J. Henley for discussions on methodology and for additional re-analysis of data from the American Cancer Society CPSII cohort; S. Darby for data on lung cancer risk reversibility in the United Kingdom; E. Guindon and P. Jha for data on the prevalence of smoking and tobacco consumption; and P. Gupta for discussions on methods and data for oral tobacco use risk. The generous assistance of these individuals and their organizations greatly improved the data sources used in this chapter. The participants in the comparative risk assessment (CRA) project review meetings and anonymous reviewers provided valuable comments on methods and assumptions.

## Notes

1 See preface for an explanation of this term.
2 If the fraction of smokers in the mixture is $x$, then the lung cancer mortality for the mixture is $x S_{\dot{L} C}^{*}+(1-x) N_{\tilde{L} C}^{*}$. Since the SIR of the mixture has to equal that of the population, excess lung cancer mortality in the mixture has to be equal to that of the study population. Therefore $x S_{\tilde{L C}}^{*}+(1-x) N_{\tilde{L} C}^{*}-$ $N_{\tilde{L} C}^{*}=C_{L C}-N_{L C}$. Solving this equation gives $x=\frac{C_{L C}-N_{L C}}{S_{L C}^{*}-N_{L C}^{*}}$ which is equal to SIR when the study and reference populations have the same non-smoker lung cancer rates. When non-smoker lung cancer rates are not the same in the study and reference populations, the same result can be obtained with algebraic manipulation of Equation 2, accounting for differences in neversmoker rates.

3 The discussion in this section is based on age-specific risk estimates. In other words, a decline in risk as a result of cessation does not necessarily imply that risk stops rising in absolute terms. Rather, it implies that at all ages after cessation, relative risk is less than it would be if smoking continued.
4 These estimates also assume no new smokers in the cohort.
5 No disease with this latter characteristic is known.
6 Note that this applies only to current exposure and not to future exposure (avoidable risk) since the difference in decline time is accounted for in estimating risk reversibility, as described earlier.
7 Note that the estimates of oral cancer for smokers are based on SIR as the exposure variable to capture the accumulated hazards of smoking and not on prevalence. Therefore the fraction of smokers who also chew ( $p_{s c}=1-p_{s}$ ) was applied to SIR estimates rather than direct prevalence. Estimating chewing-caused oral cancer by increasing the relative risk for this condition in the SIR framework implicitly assumes that the accumulated hazards of the two habits are similar. If oral tobacco use has a longer history in the region, this would result in an underestimation of accumulated hazards.
8 Given that SIR values are estimated relative to reference populations of the same sex and age, female and male estimates are not directly comparable. At the same time, the large differences are illustrative of the relative magnitudes.

9 All fractions are based on mortality in the respective age groups $30-69, \geq 70$, and $\geq 30$ years.
10 Mortality estimates for China were combined with the remaining countries in WPR-B to obtain subregional estimates.

11 Eighty-three per cent of the population of SEAR-D lives in India. Therefore the estimates for the subregion are dominated by, and comparable in terms of fractions with, those from India.

## Chapter I 2

Alcohol use<br>Jürgen Rehm, Robin Room, Maristela Monteiro, Gerhard Gmel, Kathryn Graham, Nina Rehn, Christopher T. Sempos, Ulrich Frick and<br>David Jernigan

## Summary

Alcohol has long been known as a risk factor for disease. The 1990 Global Burden of Disease (GBD) study (Murray and Lopez 1996a, 1996b) identified alcohol as one of the major global risk factors, accounting for $1.5 \%$ of global deaths, $2.1 \%$ of years of healthy life lost owing to premature mortality, $6.0 \%$ of years of life lost owing to disability and $3.5 \%$ of disability-adjusted life years (DALYs).

Based on the epidemiological literature, and modelling the relationship between alcohol exposure and disease, two dimensions of alcohol consumption were defined as exposure variables:

- average volume of alcohol consumption; and
- pattern of drinking.

Average volume of consumption was estimated using both existing estimates of country-specific adult per capita consumption (based on production and sales data) and self-reported alcohol consumption from general population surveys. Country-specific patterns of drinking were defined using indicators of high-volume drinking occasions and types of drinking situation (e.g. drinking with meals). These indicators were drawn from key informant surveys and general population surveys, where available. Optimal scaling procedures were used to determine whether drinking patterns formed a single dimension and the relative impact of the underlying indicators on the pattern value.

The relationship between exposure and various disease categories was estimated by the following methods. Estimates of the relationship between categories of average volume of alcohol consumed and chronic disease were based on disease-specific meta-analyses. Estimates of the relationship between average volume of alcohol consumption and acute disease were based on alcohol-attributable fractions (AAFs) published in the literature. To estimate the impact of patterns of drinking on the risk
of ischaemic heart disease (IHD) and injuries, multilevel modelling with random intercept and random slope was used.

Effects of alcohol on someone other than the drinker were either included in the AAFs of the literature (e.g. alcohol-related injury) or were modelled indirectly (e.g. in the case of the effect of alcohol on the newborn).

Both average volume of alcohol consumption and patterns of drinking varied markedly across subregions. ${ }^{1}$ Average volume of drinking was highest in EUR-A, EUR-C and AMR-A, and lowest in EMR-B, EMR-D and SEAR-D. Patterns were most detrimental in EUR-C, EUR-B, AMRD and AFR-E. Patterns were least detrimental in EUR-A and WPR-A.

Existing research indicates causal relationships between average volume of consumption and more than 60 International Statistical Classification of Diseases and Related Health Problems (ICD) codes, including both chronic diseases (malignant neoplasms, neuro-psychiatric conditions, cardiovascular diseases, gastrointestinal conditions) and injuries (intentional and unintentional). Although most of these relationships involve a detrimental impact of alcohol, there are beneficial relationships between alcohol and IHD, cerebrovascular disease and type II diabetes for certain combinations of average volume of consumption and patterns of drinking. Patterns of drinking were also associated with the level of injury burden from alcohol, although no pattern of drinking had beneficial effects on injury.

The present analysis found that alcohol-related burden of disease is considerable: $3.2 \%$ of global mortality and $4.0 \%$ of the global burden of disease measured in DALYs. In terms of alcohol-related mortality, almost half of the global burden is related to acute causes, i.e. unintentional and intentional injuries, particularly unintentional injuries. The next most important category comprises malignant neoplasms with $20 \%$ of the overall alcohol-related mortality burden, followed by cardiovascular diseases ( $15 \%$ of all alcohol-attributable deaths) and other noncommunicable diseases, primarily liver cirrhosis (13\%). However, although the overall proportion of cardiovascular deaths attributable to alcohol reflects a net result of $15 \%$, this figure does not give a clear picture of the underlying structure of the relationship between alcohol consumption and cardiovascular disease. In particular, although alcohol was estimated to cause a total of almost 600000 cardiovascular deaths in the year 2000, exceeding even the alcohol-related deaths of unintentional injuries, this figure was partly "offset" by the beneficial effects of alcohol on IHD and stroke. Across all diseases, more males than females die from the effects of alcohol, with a ratio of about $10: 1$.

In terms of DALYs, $4.0 \%$ of the overall global disease burden was attributable to alcohol. The biggest differential effect of alcohol on mortality vs morbidity was for neuro-psychiatric diseases. Neuropsychiatric diseases are often disabling, but not fatal, and this is reflected in the markedly higher proportion of overall disease burden caused by
this category compared to alcohol-attributable mortality $(38 \%$ of alcohol-attributable DALYs vs $6 \%$ of alcohol-attributable deaths). As with alcohol-related mortality, males have more than five times the alcohol-related disease burden in terms of DALYs than females.

Alcohol-attributable disease burden is expected to further increase in the future. This is due partly to increases in consumption in developing and emerging economies in south-east Asia and partly to shifting patterns of morbidity and mortality, in particular the increased significance of chronic diseases and injuries related to alcohol. This trend, however, could be reversed quickly, as much of the disease burden of alcohol is almost immediately preventable ( $40 \%$ of the overall alcohol-attributable burden is from acute conditions). While a total ban on alcohol is not realistic, there are other alcohol policy measures that could be implemented to reduce the resulting disease burden.

## 1. Introduction

### 1.1 Definition of alcohol as a risk factor

The relationship between alcohol consumption and health and social outcomes $^{2}$ is complex and multidimensional. Figure 12.1 gives an overview.

Alcohol consumption is linked to long-term biological and social consequences through three intermediate outcomes: intoxication,

Figure I2.I Model of alcohol consumption, intermediate outcomes and long-term consequences

[^44]dependence and direct biochemical effects. Examples of such biochemical effects are the promotion of blood clot dissolution and direct toxic effects on acinar cells triggering pancreatic damage. ${ }^{3}$ Figure 12.1 shows only the main causal pathways. Intoxication may, for example, lead to chronic social consequences (e.g. when a drunken driver kills somebody and thereafter loses his or her job and social standing). Most of the consequences of intoxication are nonetheless covered by acute health and social consequences.

- Direct biochemical effects of alcohol consumption may influence chronic disease, either beneficially or in a harmful way. Beneficial effects include the influence of moderate drinking on IHD by reducing plaque deposits in arteries, protecting against blood clot formation and promoting blood clot dissolution (Zakhari 1997). Examples of harmful effects include increasing the risk of high blood pressure, direct toxic effects on acinar cells triggering pancreatic damage (Apte et al. 1997) and hormonal disturbances (Emanuele and Emanuele 1997). The term "direct toxic and beneficial effects" is used to summarize all the biochemical effects of alcohol on body functions other than intoxication and dependence.
- Intoxication is a powerful mediator, mainly for acute outcomes such as accidents, intentional injuries or deaths, domestic conflict and violence, although episodes of intoxication can also be implicated in chronic health and social problems. The effects of alcohol on the central nervous system mainly determine the subjective feeling of intoxication. These effects are felt and can be measured even at consumption levels that are light to moderate (Eckardt et al. 1998).
- Alcohol dependence is a disorder in itself, but is also a powerful mechanism sustaining alcohol consumption and mediating its impact on both chronic and acute physiological and social consequences (Drummond 1990).

Biological mechanisms have historically been the most important criteria in establishing the causal link between alcohol consumption and health outcomes (English et al. 1995; Hill 1965; Rothman and Greenland 1998a).

Total consumption or average volume of consumption has been the usual measure of exposure linking alcohol to disease (Bruun et al. 1975). Average volume was linked to more than 60 disease conditions in a series of recent meta-analyses (English et al. 1995; Gutjahr et al. 2001; Ridolfo and Stevenson 2001; Single et al. 1999a).

As shown in Figure 12.1, average volume of consumption as a risk factor works mainly through biochemical effects or through dependence to produce long-term consequences. Although average volume is somewhat correlated with intoxication, this correlation is not of sufficient strength to adequately predict acute effects of alcohol related to injury
and death. Such effects are much better predicted by patterns of drinking (Rehm et al. 1996). For example, the same overall average volume of alcohol can be consumed in small quantities regularly with meals (e.g. two drinks a day with meals) or in large quantities on few occasions (e.g. two bottles of wine on a single occasion every Friday). Data on the influence of patterns of drinking are less available than data on overall consumption, but evidence is accumulating that patterns of drinking affect the link between alcohol and disease (Bondy 1996; Puddey et al. 1999; Rehm et al. 1996, 2003) and between alcohol and mortality (Rehm et al. 2001d). In other words, the impact of an average volume of consumption on mortality or morbidity is partly moderated by the way alcohol is consumed by the individual, which in turn is influenced by the social context (Room and Mäkelä 2000). It should be noted that patterns of drinking have been linked not only to acute health outcomes such as injuries (Greenfield 2001; Rossow et al. 2001) but also to chronic diseases such as IHD and especially sudden cardiac death (Britton and McKee 2000; Chadwick and Goode 1998; Puddey et al. 1999; Trevisan et al. 2001a, 2001b).

### 1.2 Choice of exposure variable

To determine the impact of alcohol on burden of disease, both average volume of consumption and pattern of drinking have to be considered and included in the analysis. Unfortunately, average volume of consumption and pattern of drinking are not independent at the level of the individual drinker, because average volume is often determined by heavy drinking occasions (Rehm and Gmel 2000a). Consider someone who drinks eight drinks per day. This person has by definition both a high average volume of consumption and many heavy drinking occasions. On the aggregate level, however, the two dimensions can be statistically independent, as described below in section 2.3.

Average volume of drinking is a relatively simple concept, at least on a theoretical level. It is more difficult to conceptualize patterns of drinking on a worldwide scale. For the comparative risk assessment (CRA) project (see also WHO 2002), aspects of drinking patterns likely to contribute to consequences were identified as a first step in this process (see also Rehm et al. 2001a, 2001b). Table 12.1 provides an overview of the results of this exercise.

### 1.3 Choice of theoretical minimum

Because the relationship between alcohol and disease or injury stems from two potentially interrelated dimensions-average volume of alcohol consumption and drinking pattern-the theoretical minimum or other counterfactual scenarios that provide a reference for hypothetical risk reduction should take both dimensions into account. One obvious and important counterfactual would be total abstinence from alcohol. If all effects of alcohol on health were negative, this would obviously be

Table I2.I Patterns of drinking relevant to CRA

| Pattern indicators | Link to disease |
| :---: | :---: |
| Proportion of the adult population who abstain from alcohol | The same adult consumption per capita will have more detrimental effects in countries where drinking is concentrated among fewer people. This variable was later dropped from the pattern analyses, as it has been incorporated into the average drinking categories |
| Heavy drinking occasions ${ }^{\text {a }}$ <br> High usual quantity of alcohol <br> per occasion <br> Proportion of drinkers who drink <br> daily or nearly daily <br> Proportion of drinking occasions <br> when drinkers get drunk <br> Festive drinking common-at <br> fiestas or community celebrations | The fewer occasions on which a given amount of alcohol is consumed, the more detrimental the consequences (Puddey et al. 1999; Room et al. 2002; Walsh and Rehm 1996). Heavy drinking occasions lead to an increase in injuries. Also, heavy drinking occasions have been shown to lead to detrimental cardiovascular outcomes |
| Drinking with meals-how common to drink with meals | Drinking with meals has been shown in epidemiological and biological research to be less detrimental than drinking at other times (Gentry 2000; Ramchandani et al. 2001; Trevisan et al. 2001a) |
| Drinking in public places-how common to drink in public places | Drinking in public often requires transportation, and thus has been linked to traffic accidents and injuries (Fahrenkrug and Rehm 1994) |
| Drinking linked to violence | Alcohol-related violence is an important cause of injuries. This variable confounds exposure and a potential consequence and was thus dropped in subsequent analyses |

a This is often termed "binge drinking". However, the definition of binge drinking varies widely (e.g. from heavy festive drinking with intoxication lasting more than one day to having five or more drinks on one occasion). It was therefore decided not to use the term in this work.
the ideal theoretical minimum. However, it has been shown that alcohol, if consumed in a regular pattern of light to moderate doses, has protective effects against IHD and potentially other ischaemic diseases (Ashley et al. 2000; Puddey et al. 1999).

The cardioprotective effect has the most relevance to countries with established market economies, which tend to have the longest life expectancy and the highest proportion of deaths from ischaemic disease (Murray and Lopez 1996a). In addition, the pattern of light regular drinking associated with this protective effect, when it occurs, is found mainly in these countries. Drinking to intoxication, heavy drinking occasions and other more detrimental drinking patterns, on the other hand, are often the prevalent drinking style outside established market economies ${ }^{4}$ (see Table 12.3 for an overview of country-by-country drinking patterns). Economic development and patterns of drinking are correlated to a higher degree than volume of alcohol consumption and economic development (Pearson correlation of 0.6 between patterns and per capita gross national product [GNP] on the 2001 data set of the CRA
with 89 countries, where the correlation between average volume of consumption and GNP is 0.2 ; see Rehm et al. 2001a, 2001b). Unfortunately, insufficient research has been carried out to identify the causal determinants of this relationship.

It is proposed to establish the following counterfactual scenarios for measuring the effects of alcohol consumption:

- total abstinence, which would mean an increase in the disease burden of some cardiovascular categories for established market economies and countries with a general pattern of light to moderate drinking;
- as a sensitivity analysis, the current status in patterns of drinking with different scenarios for volume of drinking;
- as a sensitivity analysis, the current status in average consumption with different values for patterns of drinking; and
- changing both average volume of consumption and drinking patterns towards light, regular drinking.

The overall attributable burden of disease should be calculated using abstainers as the comparison group, as this provides the global theoretical minimum. Owing to the large contribution of neuropsychological disease and injuries, neither of which benefits from alcohol consumption, it is also likely that at the population level in every subregion except AMR-A, EUR-A and WPR-A abstinence results in the lowest population risk. The cardioprotective effect will be included in established market economies with light to moderate drinking patterns by using relative risks smaller than 1, thus subtracting "prevented burden" from the burden of disease for these countries.

## 2. Estimating Risk Factor levels

### 2.1 Measuring average volume of alcohol consumption and patterns of drinking

To quantify the effects of alcohol on population health, it is necessary to measure the two key exposure variables, average volume of alcohol consumption and patterns of drinking, at the population level around the world.

## Average volume of alcohol consumption

There have been a number of attempts to gather country-level data on average volume of alcohol consumption, most recently by the World Health Organization (WHO) in the Global status report on alcohol (1999). Most attempts have tried to arrive at an aggregate figure per country, i.e. per capita consumption or adult per capita consumption (i.e. per capita consumption for all inhabitants aged $>15$ years). For several reasons, however, this aggregate figure is insufficient for health impact
assessment. First, as a global figure, this approach does not allow disaggregation into different groups (e.g. as defined by sex and age), which is needed for valid estimates of burden of disease. Second, per capita consumption estimates are usually based on production figures or sales data, and thus do not include consumption of home-made or illegally imported alcohol (see discussion of unrecorded consumption in Giesbrecht et al. 2000; Leifman 2001; Summer 2000).

On the positive side, the production and trade or sales data required to calculate per capita consumption have traditionally been collected by various sources (including the alcoholic beverage industry and international agencies such as the Food and Agriculture Organization of the United Nations [FAO]) and are available for most countries of the world. FAO collects production and trade data for different alcoholic beverages, mainly from ministries of agriculture and customs departments. For some countries, estimates include data on alcoholic beverages outside the usual beer, wine and spirits categories (e.g. palm wine and sorghum beer) but they do not systematically include home production or illicit production.

To use per capita consumption data for detailed risk analysis, we combined this source with survey data from various countries. Survey data are especially important in determining the proportion of abstainers in a country, as well as in dividing the overall volume into drinking categories by sex and age groups. In addition, some surveys can be used to estimate unrecorded consumption (e.g. Kühlhorn et al. 1999; and the current WHO-supported efforts in Brazil, China, India and Nigeria). ${ }^{5}$

Although survey data are essential for refining per capita estimates, they also have problems that preclude them from being used as the single source of data. In particular, survey data from many established market economies considerably underestimate total volume (Midanik 1988; Midanik and Harford 1994; Rehm 1998a; de Vries et al. 1999). ${ }^{6}$ In addition, survey data are less available than per capita consumption data on an international level (Rehm and Gmel 2000b; WHO 1999). Nevertheless, by combining both kinds of information one may arrive at disaggregated estimates. In this combination, the per capita estimates based on production and sales (combined with data on unrecorded consumption where available) are taken as the overall value. Surveys are then used to estimate the distribution of this overall volume among various groups, as defined by abstinence and different levels of drinking, and by sex and age.

## Patterns of drinking

Existing general population surveys cover some of the patterns of drinking listed in Table 12.1, but rarely would one find all features in one representative survey in a particular country. Moreover, not all surveys on drinking patterns are recent. Therefore, to develop drinking pattern estimates for the 14 subregions used in the CRA, key informant question-

Table I2.2 Countries with returned key informant questionnaires

| Subregion | Countries that returned questionnaires in at least one phase | Total no. of countries in subregion |
| :---: | :---: | :---: |
| AFR-D | Burkina Faso, Nigeria, Seychelles | 26 |
| AFR-E | Congo, Namibia, South Africa, Zambia | 20 |
| AMR-A | Canada, USA | 3 |
| AMR-B | Argentina, Brazil, Costa Rica, Mexico, Trinidad and Tobago | 26 |
| AMR-D | Peru | 6 |
| EMR-B | None | 13 |
| EMR-D | None | 9 |
| EUR-A | Austria, Belgium, Czech Republic, Denmark, Finland, France, Germany, Greece, Iceland, Ireland, Israel, Italy, Malta, Netherlands, Norway, Portugal, Slovenia, Spain, Sweden, Switzerland, United Kingdom | 26 |

| WPR-B | China, Fiji, Malaysia, Micronesia, Palau, Papua New Guinea, Philippines, Republic of Korea, Solomon Islands | 22 |
| Total |  | 191 |

naire studies were undertaken in early 2000 (Rehm et al. 2001b; for the key informant questionnaire see Appendix 1 in European Addiction Research 2001) and repeated in 2001, using a slightly modified questionnaire. ${ }^{7}$ In 2000, 61 questionnaires were sent out, 52 of which were returned, and in 2001 another 155 were sent out, 40 of which were returned. Table 12.2 lists, by subregion, the countries for which key informant surveys were received. Together with survey data, the responses from the survey on patterns provided sufficient data for a first estimate of patterns of drinking for all subregions.

## Summary of data sources used

The following country level measures of alcohol consumption were used in the analysis:

- adult per capita consumption based on sales data or production and trade data;
- unrecorded consumption based on various estimates;
- survey data on abstinence, average volume consumed in different sex and age groups, and patterns of drinking; and
- key informant information on various aspects of patterns of drinking.

Data for all years after 1998 were considered. Data were checked for consistency across time and for internal consistency (e.g. survey vs per capita estimates of average volume of consumption).

### 2.2 DATA SOURCES FOR AVERAGE VOLUME OF ALCOHOL CONSUMPTION

Data on adult per capita and unrecorded consumption were taken from the Global status report on alcohol (WHO 1999) and from the WHO Global Alcohol Database, created by the Marin Institute for the Prevention of Alcohol and Other Drug Problems and currently maintained by the Swiss Institute for the Prevention of Alcohol Problems. Surveys were also collected from this database, but additional surveys were accessed based on individual contacts (including several experts from each subregion) and by announcing this project on a specific WHO listserve and at the Annual Alcohol Epidemiology Symposia of the Kettil Bruun Society for Social and Epidemiological Research on Alcohol. Data on drinking patterns were collected from researchers and health officials known to WHO who had the knowledge to serve as key informants for their countries or regions. Key informant information was collected by surveys in early 2000 and in mid 2001.

Categorical levels for average volume of alcohol per day in relating consumption to chronic disease were selected to be consistent with previous meta-analyses (English et al. 1995; Gutjahr et al. 2001; Ridolfo and Stevenson 2001; Single et al. 1999a; for a discussion of the background to these categories see English et al. 1995; Holman et al. 1996) and were defined as follows:

- abstainer: a person not having had a drink containing alcohol within the last year;
- average volume drinking category I: for females $0-19.99 \mathrm{~g}$ pure alcohol daily; for males $0-39.99 \mathrm{~g}$ pure alcohol daily;
- average volume drinking category II: for females 20-39.99g pure alcohol daily; for males $40-59.99 \mathrm{~g}$ pure alcohol daily; and
- average volume drinking category III: for females 40 g or more pure alcohol daily; for males 60 g or more pure alcohol daily. ${ }^{8}$

This categorization of average drinking, rather than using a continuous measure of consumption, makes it possible to derive different shapes of risk curve (linear, J-shape, threshold, etc.) while, at the same time, allowing inclusion of data from studies in which only categorical information on levels of alcohol consumption were collected. Using per capita consumption data derived from production and trade or sales data plus unrecorded consumption as the first estimate of overall alcohol con-
sumption, the following strategy was adopted to generate age- and sexspecific prevalence rates.

- For each subregion, the average adult per capita consumption, including unrecorded consumption for the population aged $\geq 15$ years, was estimated as a population-weighted average of country-specific per capita consumption data. All entries per country after 1998 were taken and averaged to obtain a stable estimate for 2000 . The weights were derived from the average population aged $\geq 15$ years in each country for the years after 1998, on the basis of United Nations population data. Country-specific adult per capita data were estimated for 132 countries (see Table 12.3). Per capita consumption was known and adult per capita consumption could be calculated for more than $90 \%$ of the world's population. Survey information on abstinence was available for 69 countries, in particular from almost all countries with population larger than 100 million resulting in more than $80 \%$ of the world population with available survey data. This means that more than $50 \%$ of the countries for which data were available on per capita consumption also had survey data available.
- Country-specific survey data of the ratio of male to female consumption were used to allocate proportionally the overall adult per capita consumption to adult male and adult female per capita consumption.
- Based on surveys, the age-specific prevalence of drinking was calculated on the assumption that the average per capita consumption and the proportions of male and female abstainers were correct.

### 2.3 DATA SOURCES FOR PATTERNS OF DRINKING

Initial estimates of drinking patterns across a range of countries were based on two surveys of key informants selected by WHO staff, conducted in early 2000 and mid 2001. The surveys covered relevant drinking characteristics within different countries or regions. In most cases, respondents had access to national or regional survey data, although these data had not always been published in the international literature. In addition, the informants provided a confidence rating for their responses (i.e. whether based on surveys or just best guesses). This information was used for decisions about inclusion of data when conflicting information existed. As listed in Table 12.1, the survey considered five main areas of drinking patterns that might be expected to affect the impact of volume of drinking: proportion of abstainers, heavy drinking occasions, drinking with meals, drinking in public places and drinking linked to violence (later dropped from analyses because of its interference with outcome measures).

The key informant ratings were analysed using optimal scaling analysis (Bijleveld et al. 1998, chapter 2). This analysis is similar to factor analysis, but permits the simultaneous inclusion of ordinal and categor-
ical data. As with factor analysis, this statistical technique allows the analyst to determine the number of underlying dimensions and the relation of items to each dimension. In the analysis of patterns of drinking, one global dimension was identified and labelled as detrimental impact (for details see Rehm et al. 2001b).

The results of the optimal scaling analysis were very similar to a score derived simply by summing the ratings of the key informant survey (Pearson correlation: 0.93). To further simplify the pattern values into robust general categories based on these scale values, the countries were placed in four categories and assigned values from 1 to 4 . By the time the final pattern values were constructed, additional survey data were available as well as the second wave of key informant data, allowing refinement and corrections of estimates. Also, the proportion of abstainers was no longer included as one of the parameters of pattern weights, because rates of abstinence were taken into account separately as one of the average volume of consumption categories. The underlying variables and the scoring pattern can be found in Appendix A.

To apply pattern values to estimate the burden of disease attributable to alcohol, countries with missing data on drinking pattern values were assigned the same category as that of neighbouring countries, taking into consideration geographical and cultural proximity. The pattern values for more than 130 countries worldwide can be seen in Table 12.3. ${ }^{9}$

Patterns of drinking thus defined were found to be unrelated to volume: the overall Pearson correlation between pattern values and per capita consumption for the countries included is -0.126 and the more appropriate Spearman correlation is -0.072 . Both correlations do not achieve statistical significance; that is, they are not significantly different from zero (both correlations based on 132 countries with data on both variables). This suggests that drinking pattern may provide important unique information about the risks of drinking alcohol beyond that captured by per capita consumption.

Although this procedure allowed us to derive drinking pattern values from a combination of empirical data and expert judgement, these patterns still needed to be validated empirically to demonstrate that they were, in fact, related to outcomes. In other words, pattern values serve as a description of one aspect of exposure that is theoretically postulated to be related to harm, but such a relation still has to be empirically established. In addition, the degree of influence of patterns on harm (i.e. how much weight to assign to drinking pattern in calculating the burden of disease attributable to alcohol) had to be estimated. Moreover, the weight to be assigned to drinking pattern may vary by type of outcome, sex and age. A later section of this chapter describes how these weights were developed.

### 2.4 Methods for obtaining estimates where more than one data source exists

For estimating overall consumption, clear hierarchies were used for integrating per capita data into the WHO Global Alcohol Database and subsequently into this work.

- Scientifically derived and well documented local estimates (e.g. from the National Drug Research Institute in Australia, see Catalano et al. 2001) were given first priority.
- Production/sales data were used, such as the annual data on per capita consumption published by the alcohol industry (e.g. Productschap voor Gedistilleerde Dranken 1999, 2000).
- FAO production and trade data were used where other data were not available.

If more than one data point existed for the time after 1998 (e.g. per capita estimates for 1998 and 1999), data points were averaged. With respect to survey data, if more than one representative survey with more than 2000 persons existed, the most recent survey estimates were used. Survey data were always given priority over key informant estimates in estimating pattern values.

### 2.5 Methods for obtaining estimates where no data SOURCE EXISTS

Most regions had sufficient data for estimating prevalence of average volume of drinking, based on per capita consumption (including unrecorded consumption) plus the sex-specific ratio of abstinence derived from surveys. Survey data on abstinence were available for 69 countries ( $52.3 \%$ of all 132 countries included), and were additionally estimated for 39 countries ( $29.5 \%$ of all the countries). Estimation was based on abstinence rates in adjoining countries. Survey data on abstinence were available for many of the countries with large populations: Brazil, China, India, Mexico, Nigeria, the Russian Federation, South Africa, the United States of America and the major (western) European countries. These surveys were taken as indicators for the respective subregions. Regional numbers are to a large degree influenced by a limited number of highly populated countries. Thus, it is important to get the numbers for these countries correct by investing limited resources in estimating alcohol consumption for these countries, rather than attempting to improve the data for all countries in the world. ${ }^{10}$

Data were scarcer with respect to patterns of drinking. Only 44 countries ( $33.3 \%$ of 132 countries) had sufficient information on patterns to compute a pattern score. For another 88 countries ( $66.6 \%$ ), data on patterns had to be estimated. Clearly, it is a priority for future estimates that more data on drinking patterns be collected for use in these analyses (see
also Rehm and Gmel 2000b). As with per capita consumption, ratings on drinking patterns for countries for which no data were available were based on social and cultural factors (Muslim vs non-Muslim country, type of drinking culture, etc.) and on drinking patterns in surrounding countries.

### 2.6 DESCRIPTION OF DATABASES, INCLUDING METHODOLOGICAL QUALITIES

A description of the WHO Global Alcohol Database can be found in the Global status report on alcohol (WHO 1999). The Swiss Institute for the Prevention of Alcohol Problems constantly updates and expands the Database, which includes both adult per capita and survey data. In addition, many surveys were directly sent to the first author of this work, especially from countries that also supplied key informant information. Additional surveys from developing countries can be found in a WHO collection (WHO 2001). The data in the WHO Database are selected and scrutinized according to set criteria. The data from established market economies are usually based on more reliable sales data and better-quality surveys than those from developing countries.

### 2.7 Characteristics of excluded studies/Databases

Studies were excluded only if better survey information was available for the same country. Better survey information was defined in terms of how recently the survey had been conducted, the availability of a probability sample of at least 2000 respondents, or other quality criteria (e.g. a representative survey based on probabilistic sampling of the whole country vs a non-representative survey or regional survey; better alcohol measures, such as quantity-frequency measure vs frequency-only measure; or larger survey at the same time).

### 2.8 Estimates of COUNTRY DATA AND EXPOSURE DIMENSIONS BY subregion, age and sex

Table 12.3 provides country-specific information on alcohol consumption, drinking patterns, percentage abstainers and validity ratings for estimates. Also shown are the relevant subregion and the population aged $\geq 15$ years in 2000 .

Table 12.4 gives estimates of the proportion of population in each of the four categories of average alcohol consumption described above by subregion, sex and age. The CRA required two age groups for people aged $>70$ years: $70-79$ years and $\geq 80$ years. With a lack of evidence to differentiate between these two age categories, both were assumed to have the same prevalence and risk relations.

These figures assume no alcohol consumption leading to harm for young people under the age of 15 years. This is certainly not true for young people in established market economies, where drinking starts early and where alcohol-related harm can be found (though not with a

high prevalence) before the age of 15 years (Hibell et al. 2000). However, as data for this age group are scarce and as the prevalence rates for drinking and harm are low, the conservative approach of estimating no alcohol-related harm for this age group was adopted. The decision to model alcohol-related harm at zero for people's own drinking does not mean that there will be no alcohol-related harm estimated in this age group altogether. Rather, owing to the nature of effects, we must deviate from the standard epidemiological model and include effects of drinking on other externalities. To give just one example of this type of harm, a drunken driver may kill innocent bystanders or passengers driving in his car who are younger than 15 years, and this would be a fatality caused by alcohol.

The following distribution data were based on survey-based information on abstainers for 69 countries. For distributional information on drinkers, the following sources were considered:

- AFR-D, Nigeria (Mustonen et al. 2001 and newer survey data reported in the key informant questionnaire from I. Obot/O. Gureje);
- AFR-E, South Africa (Department of Health 1998, South African Demographic and Health Survey);
- AMR-A, Canada and the United States (surveys provided by E. Adlaf for Canada and T. Greenfield for the United States);
- AMR-B, Brazil (São Paulo) (Galduróz et al. 2000) and Mexico (surveys provided by the Mexican Institute of Psychiatry); see also WHO (2001) for country reports on Costa Rica and Mexico, and Jutkowitz and Hongsook (1994);
- AMR-D (survey data for Peru and Jutkowitz and Hongsook 1994);
- EMR-B and EMR-D (only per capita information and general distribution information as approximately log-normal ${ }^{11}$ with some data on abstinence);
- EUR-A (based on the average of many country surveys);
- EUR-B, Poland (based on survey information provided by key informants);
- EUR-C, the Russian Federation (published national and regional survey data from Bobak et al. 1999; Malyutina et al. 2001);
- SEAR-B, Sri Lanka and Thailand (survey estimates provided by key informants);
- SEAR-D, India (regional survey data provided by key informants);
- WPR-A, Australia and New Zealand (survey data, see English et al. 1995; Ridolfo and Stevenson for Australia and http://www. aphru.ac.nz/projects/Larger for New Zealand); and
- WPR-B, China (Wei et al. 1999 and additional information by the first author).

The numbers in Table 12.4 are given as a proportion of the age-sexspecific population. Thus, for females aged 15-29 years in WPR-B, $67.4 \%$ are estimated to abstain, $32.6 \%$ are estimated to drink the equivalent of between 0 g and 20 g pure alcohol per day, $0.1 \%$ are estimated to drink between 20 g and 40 g , and less than $0.05 \%$ are estimated to drink more than 40 g . In the oldest age group, $89.8 \%$ of females are estimated to abstain, $10.2 \%$ to drink the equivalent of up to 20 g pure alcohol per day, and less than $0.05 \%$ to drink more.

Currently, pattern values assigned to each country and then computed as a population-weighted average for each subregion are not specific by sex and age (see Table 12.5). This may change in the future when survey data on patterns become more available.

### 2.9 QUANTITATIVE AND QUALITATIVE SOURCES OF UNCERTAINTY

## UNCERTAINTY ANALYSIS

As described, alcohol consumption as a risk factor has two dimensions: average volume and patterns. It is thus proposed to base the uncertainty analysis on the weighted average of the available information for both dimensions for each subregion. Uncertainty analysis is undertaken to give an indication on uncertainty, based on different characteristics such as the source or variability of the estimated data. It will also be used to calculate the confidence intervals (CIs) of the alcohol-related burden. Classically, CIs for prevalence are determined by sample size, assuming that the underlying individual data are representative of the subregion. For some subregions, however, we do not have probabilistic samples. As alcohol consumption is a social activity and can vary markedly from one country to another within a region, one cannot automatically assume that the countries without surveys would have the same alcohol distribution as the countries with surveys. Thus, the procedure based on sample size cannot be used here. Moreover, prevalence was derived from both aggregate- (per capita consumption) and individual-level data in a triangulation of information, for which there is no statistical theory for readily deriving CIs.

The algorithms specified below were developed after extensive discussions with experts in the field. They are intended to reflect the quantity and quality of the underlying data sources. Aggregate-level data exist for all countries. To estimate average volume of alcohol consumption, we propose to base uncertainty analysis on the amount of survey information available in a subregion. The procedure allowed the estimation of lower or upper limits, even if no survey information existed. In Pakistan, for example, per capita alcohol consumption set clear upper boundaries for the highest drinking categories, since some values would

[^45]Risk factor: alcohol-first dimension: average volume of consumption.
Units: grams of pure alcohol per day.
Definitions of categories of risk factor levels

| Level I: | Abstinence | abstainer |
| :--- | :--- | :--- |
| Level 2: | D I | drinking category I: women $>0-<20 \mathrm{~g} ;$ men $>0-<40 \mathrm{~g}$ |
| Level 3: | D II | drinking category II: women $20-<40 \mathrm{~g} ;$ men $40-<60 \mathrm{~g}$ |
| Level 4: | D III | drinking category III: women $>40 \mathrm{~g}$; men $>60 \mathrm{~g}$ |

not be physically possible within the overall volume consumed in this country.

In operationalizing these principles, the validity of the abstainer category was selected (for values in individual countries see Table 12.3). This variable was aggregated using the population aged $\geq 15$ years as a

Table 12.5 Patterns of drinking by subregion

| Subregion | Pattern value ${ }^{\mathrm{a}}$ | Validity of pattern value |
| :--- | :---: | :---: |
| AFR-D | 2.48 | 0.52 |
| AFR-E | 3.09 | 0.24 |
| AMR-A | 2.00 | 0.97 |
| AMR-B | 3.14 | 0.77 |
| AMR-D | 3.10 | 0.38 |
| EMR-B | 2.01 | 0.00 |
| EMR-D | 2.35 | 0.00 |
| EUR-A | 1.34 | 0.92 |
| EUR-B | 2.93 | 0.31 |
| EUR-C | 3.62 | 0.75 |
| SEAR-B | 2.50 | 0.22 |
| SEAR-D | 2.95 | 0.93 |
| WPR-A | 1.16 | 0.98 |
| WPR-B | 2.15 | 0.93 |

[^46]weight. The resulting values were treated in the uncertainty analysis as follows:

For aggregated validity values of 0 Base prevalence estimate on full range from 0 to twice the point estimate (i.e. point estimate plus $100 \%$ of the point estimate).

For aggregated validity values $>0$ and $<0.5$

For aggregated validity values $\geq 0.5$ and $<0.75$

Point estimate $\pm 50 \%$ of point estimate of prevalence.

Point estimate $\pm 25 \%$ of point estimate of prevalence.

For aggregated validity values $\geq 0.75$ Point estimate $\pm 10 \%$ of point estimate of prevalence.

This applies to both sexes, as most surveys include both males and females. Further corrections were made based on per capita consumption for subregions where certain distributions were not plausible because the known per capita consumption could not be derived with less than a certain proportion of abstainers (for EMR-B: maximum CI for abstainers $\pm 15 \%$, minimum: $\pm 1 \%$; for EMR-D: maximum $\pm 10 \%$, minimum: $\pm 1 \%$; for SEAR-B: maximum $\pm 10 \%$, minimum: $\pm 1 \%$; for SEAR-D and WPR-B: minimum: $\pm 0.2 \%)$. The results can be seen in Table 12.6.

Similarly, for constructing CIs around patterns of drinking (see Table 12.7), the validity of the underlying pattern values was used. Again, using the weighted average on the validity ratings of the pattern value (see Table 12.3 for the underlying country data), the following uncertainty ranges were proposed:

For validity of pattern value of 0 Uncertainty analysis on full range of pattern values (i.e. using pattern values 1 and 4 as bounds).

For validity of pattern value ranging from $>0$ and $<0.5$

For validity of pattern value ranging from $\geq 0.5$ and $<0.75$

For validity of pattern value ranging from $\geq 0.75$

Point estimate $\pm 0.5$.

Point estimate $\pm 0.25$.

The validity of pattern value ranged from 0 (e.g. only expert judgements for pattern in EMR-B and EMR-D with no underlying data) to values above 0.95 for several subregions (theoretically 1 if all the pattern values of constituent countries were derived from survey estimates).

The suggested procedure clearly reflects our range of knowledge. For example, we have no knowledge about patterns in EMR-B and EMR-D, where the uncertainty estimates consequently varied between 1 (best possible pattern) and 4 (most detrimental pattern), whereas we have good data for many other subregions (e.g. all the A mortality strata subregions), where the uncertainty estimates vary by only $\pm 0.25$ (e.g. EURA, between 1.09 and 1.59 ).

## Overall evaluation of quality for Exposure data

Data on production and trade or sales required for estimating adult per capita consumption have been collected systematically for decades in most countries. In this sense, alcohol as a risk factor for global health is privileged compared to some other risk factors, where exposure data are

Table I2.6 Estimated uncertainty range ( $\pm \%$ ) around point estimate for prevalence of average volume of consumption categories

| Subregion | Sex | Average volume of consumption category | Age group (years) |  |  |  |  |  |

available only in established market economies, if at all. Unfortunately, adult per capita consumption figures per se, as described above, cannot be used as exposure data for global burden of disease because these figures do not give any specification about who consumed alcohol, when and in what quantities. This can only be specified by using representative surveys of the general population. Thus, for the current exercise, adult per capita figures had to be supplemented by survey data and, where such data were not available, by expert judgements. This procedure may have introduced errors at different points.

- Errors in adult per capita consumption estimates. Because per capita estimates are derived mainly from production and trade or sale, other sources (home brewing, cross-border smuggling, illegal production, etc.) are often ignored. There is a long tradition of trying to estimate this unrecorded consumption, but mainly in established market economies where the proportion of unrecorded to recorded is low relative to other parts of the world. For example, see the recent European Comparative Alcohol Study (ECAS) estimates for Europe (http://www.fhi.se/pdf/ECAS_2.pdf; Leifman 2001) compared to the estimates of unrecorded consumption for sub-Saharan Africa given below. In addition, estimation of unrecorded consumption is particularly difficult in regions where alcohol is prohibited for religious reasons. In summary, although these sources of error exist, the global aggregate estimates on adult per capita consumption are among the best and most reliable sources for global risk factors.

Adult per capita consumption figures then were used to derive prevalence rates for specific drinking categories for different age-sex groups. This derivation was based on survey data with the following potential sources of error.

- Survey measurement error. Alcohol surveys are subject to measurement errors that apply generally to surveys (for an overview see Groves 1989). However, the most important sources of error relating to estimating alcohol consumption include non-probabilistic sampling, sampling schemes that exclude groups with a high alcohol consumption, and measurement bias. The major problem with survey estimates of alcohol consumption is that surveys generally account for $66 \%$ or less of alcohol produced or sold (Midanik 1988; Midanik and Harford 1994; Rehm 1998a; de Vries et al. 1999). However, combining survey and aggregate (i.e. per capita) estimates may ameliorate the problem of underreporting that is characteristic of survey estimates.
- Errors in combining adult per capita and survey data. Although combining survey and aggregate data can rectify the underreporting of survey data, other sources of error may be created by this procedure. This is especially true if the difference in overall adult consumption between aggregate and survey estimates is large. There are theoreti-
cally several ways in which the survey estimates could be used to arrive at the per capita figures. For example, the prevalence of all drinking categories could be proportionally increased to cover the difference between survey and per capita estimates. This is not possible, however, as the rate of abstainers would automatically change as well. Thus, a procedure must be selected to keep the proportion of abstainers from the survey fixed and proportionally increase the higher consumption categories at the expense of the middle category. Even if this procedure is plausible it may introduce error, such as when survey underreporting differs for different age-sex groups. Nevertheless, the overall benefits of combining surveys and adult per capita data seem to outweigh this disadvantage.

There are other potential sources of error in the exposure estimates.

- Errors in estimating missing survey data. Survey data are available for only some countries, so that regional figures had to be estimated from selected countries where surveys were available. This introduces error, and overall the lack of data for some countries is probably the most important source of error for exposure estimates. The more survey data are lacking, the more severe is this problem. Thus it is least severe for those who abstain from alcohol, because even when survey data on the amount of alcohol consumed were not available, many countries had survey data in which respondents were asked whether or not they consumed alcohol. The problem of error in estimating missing survey data was most severe for estimates of drinking patterns, where expert judgements had to be used to supplement survey results, and where no production and trade or sale estimates were available for triangulation.

Overall, this listing of sources for potential errors and biases clearly indicates that the results of CRA, while based on the best available sources, are accompanied by large uncertainties, only some of which could be quantified.

## 3. ESTIMATING RISK FACTOR-DISEASE RELATIONSHIPS

### 3.1 OUTCOMES TO BE ASSESSED, EVIDENCE OF CAUSALITY and ExClusions

Average volume of alcohol consumption has been related to more than 60 categories of the ninth revision of the ICD (ICD-9). This review restricts itself to categories that have already been identified in systematic meta-analyses, together with depression, which we describe in more detail below. Specifically, the following meta-analytical reviews were used: Gutjahr et al. 2001; English et al. 1995; Ridolfo and Stevenson 2001; Single et al. 1996, 1999a.

The categories that have been selected in modelling the impact of patterns of drinking are based on our own literature reviews. The analyses involving drinking patterns include the two main ICD categories for which sufficient evidence of a causal link to drinking patterns has been established: IHD and injuries. In addition, we restricted modelling of the protective effects of moderate regular drinking on type II diabetes and stroke to established market economies with the best drinking patterns (AMR-A, EUR-A and WPR-A), as there is evidence that patterns influence these diseases as well (for detailed reasoning, see below).

## ASSESSMENT OF CAUSALITY

Following the procedure described by English et al. (1995), the evidence of causality between alcohol consumption and disease outcomes (including both harmful and protective effects for particular diseases) is assessed in accordance with the Australian National Health and Medical Research Council's (NHMRC) Guidelines for the development, implementation and evaluation of clinical practice guidelines, which are the most used in the alcohol field and close to the criteria of Hill (1965). Sufficient evidence of causality includes outcomes for which the evidence indicates that an association (positive or negative) exists between alcohol consumption and the disease or injury and that chance, confounding variables and other bias can with reasonable confidence be ruled out as factors in this association. This judgement was made using the usual criteria for establishing causality in epidemiology (Hill 1965; Rothman and Greenland 1998a), with the most weight placed on the following four criteria:

- consistency across several studies;
- established experimental biochemical evidence of mediating processes, or at least physiological plausibility;
- strength of the association (effect size); and
- temporality (i.e. cause before effect).

Two examples of judgements regarding somewhat controversial outcomes may illustrate this process. For lung cancer, meta-analysis showed a consistent effect with a relatively large effect size (English et al. 1995; but see the meta-analysis of Bagnardi et al. 2001, which came to a different conclusion), after adjusting for smoking in at least some studies. However, evidence for the possible biological mechanisms is not conclusive at present (Bandera et al. 2001) and residual confounding from smoking cannot be excluded as an alternative explanation. Thus, consistent with a recent review of the epidemiological evidence, the evidence for alcohol causing lung cancer was not judged sufficient to establish causality according to the criteria listed above (Bandera et al. 2001), and thus lung cancer was excluded as an alcohol-related disease outcome in this work.

On the other hand, although English et al. (1995) concluded that there was not sufficient evidence linking alcohol consumption and breast cancer, recent advances both in biological and epidemiological research have changed this evaluation (especially Smith-Warner et al. 1998; Singletary and Gapstur 2001; see below for detailed reasoning), so that breast cancer now is included in the list of alcohol-related outcomes.

It was concluded that there was limited evidence of causality when an association (positive or negative) was observed between alcohol consumption and the disease or injury for which a causal interpretation was considered to be credible, although chance, confounding variables or other bias cannot be ruled out with reasonable confidence. These diseases were not included in determining either alcohol-related mortality or burden of disease.

It was concluded that there was inadequate evidence of causality when the available studies were of insufficient quantity, consistency or statistical power to permit a conclusion regarding the presence or absence of a causal connection.

It was concluded that there was evidence suggesting lack of causality when several adequate studies, covering the full range of levels of alcohol consumption in the population, indicated a lack of a relationship (positive or negative) between alcohol consumption and the disease or injury. This conclusion is inevitably limited to diseases and injuries, levels of consumption and lengths of observations covered by the available studies, and the possibility of very small risks at the levels of exposure studied can never be excluded.

## EXCLUDED OUTCOMES AND REASONS FOR EXCLUSION

A list of outcomes considered and excluded can be found in English et al. (1995). Some of these outcomes had been reconsidered in subsequent reviews (Gutjahr et al. 2001; Ridolfo and Stevenson 2001; Single et al. 1999a) and we followed Gutjahr et al. (2001) for the final selection of outcomes. Otherwise, the only restriction was one of age. Outcomes for people under 15 years of age who had been drinking themselves and subsequent alcohol-related consequences were excluded for two reasons:

- there are not enough global data on drinking in these age groups; and
- the epidemiological basis linking drinking to health outcomes is scarce.

Based on these considerations, the conservative choice was made not to include these outcomes.

As stated above, this does not mean that no alcohol-related outcomes are calculated for the age group under 15 years. On the contrary, socalled second-hand effects of alcohol (somebody else's drinking causing alcohol-related harm to a person) are included in the estimation.

### 3.2 Overview of methods

Meta-analyses on average volume of Drinking and disease
Meta-analyses were the bases for estimating the risk relationships between average volume of alcohol consumption and chronic disease. In alcohol epidemiology, there is a tradition of conducting such metaanalyses as part of social cost studies (English et al. 1995; Gutjahr et al. 2001; Ridolfo and Stevenson 2001; Single et al. 1999a). We used the results of the most recent existing meta-analyses (Gutjahr et al. 2001) for most outcomes, and Ridolfo and Stevenson (2001) for breast cancer and the subtypes of stroke. Details such as inclusion and exclusion of studies are described below.

## Multilevel modelling to determine pattern weights

For estimating the contribution of patterns of drinking applied to IHD and injuries, a new methodology had to be developed. Details of this method are described and discussed in Rehm and Gmel (2000b) and Gmel et al. (2001). It consists of combining multilevel ${ }^{12}$ models with pooled cross-sectional time series models, and aims at maximizing methodological rigour and practical feasibility for the data available to undertake such an analysis. The principal variables for the present study are time series of adult per capita alcohol consumption and mortality for different countries, and one value measuring drinking patterns in a country. One could imagine conducting time series analyses separately for each country and then relating the patterns measured with the different estimates obtained for the relationship between alcohol consumption and mortality. However, time series data on both mortality and alcohol consumption for any single country are commonly too short (Rehm and Gmel 2001a) to perform reliable estimation and hypothesis testing, and there are no time-specific data on patterns of drinking within a country to determine pattern weights in this manner. Even for established market economies, there are at most 40 consecutive years of data from the same source (see e.g. Table 12.12 for the length of time series on IHD mortality and adult per capita consumption). In many developing and emerging economies, however, if data are available at all, they cover less than 10 consecutive years. Similarly, for many countries, owing to social and political changes (e.g. the countries of the former Soviet Union), longer time series inherently do not exist.

A common strategy to overcome such data shortcomings for parameter estimation is pooling of data across countries ${ }^{13}$ to increase overall sample size, and to set constraints for several parameters (Greene 2000). Examples of such constraints could be to assume similar (i.e. differences statistically not significant) error variances (homoscedasticity) across countries, or to estimate the same regression parameters across all countries, or to assume a distribution for varying parameters (e.g. fixed vs random).

The approach adopted for the present study consists of pooling time series of differing lengths across countries and conducting multilevel analysis. For this approach, statistical problems arise from three major sources.

1. Pooling of data may violate the independence assumption in regression analysis. This concerns at least two aspects. First, the variability of measurements made in different countries is usually much greater than the variability of measurements within one country. Thus, data points are not independent of each other. In addition, within-country variability itself may differ among countries (heteroscedastic variances). Second, as countries provide different numbers of disease and consumption data points, countries with more data points (mainly established market economies) would have a higher impact on an overall estimate of the association between alcohol consumption and mortality than countries for which fewer data points exist (mainly developing and emerging economies). Such a disproportionate contribution to an overall regression estimate would be aggravated by the fact that the population sizes of countries would be often inversely related to the number of data points contributed to the regression analysis by such countries. For IHD mortality, for example, Switzerland ( 31 data points) and Norway ( 33 data points) would far outweigh the more populous South Africa (3 data points) and the Russian Federation ( 8 data points), even though they do not contribute substantially to the global burden of disease.
2. The estimation of time series needs further attention as regards to stationarity (stochastic or deterministic trends in the data) and the correlation of residuals within a country over time (autocorrelation).
3. The use of pooled cross-sectional time series analysis complicates estimation compared to a single time series alone, as errors (or residuals, both are used synonymously in this chapter) may co-vary across sections, and the degree of stationarity or autocorrelation may vary across sections (see below).

It should be noted that it was not possible to estimate all potential effects simultaneously. Either estimation of parameters failed to converge (potential explanations will be discussed below), the available standard software did not include the estimation of more complex models, or estimation of models was not applicable in the present context. To give an example of the latter, the estimation of cross-sectional correlation of errors would need time series that are equal in length (so-called balanced panels), at least with the available software used for estimation (Shazam: Whistler et al. 2001; STATA: StataCorp 1999; HLM: Bryk et al. 1996; MLWin: Yang et al. 1999). It was not possible to test models that include
cross-sectional autocorrelation in the present context, since balanced panel data are not available.

As not all potential shortcomings and drawbacks of multilevel and pooled cross-sectional time series models could be considered in one single model, sensitivity analysis was performed in two phases.

In phase 1, to determine pattern weights, multilevel analyses were conducted using a pilot sample of 29 European countries ${ }^{14}$ for which data were available for at least three consecutive years in the 1990s on each of the following variables: adult per capita alcohol consumption, standardized mortality and per capita GNP (level-1 variables) and an estimate of patterns of drinking (level-2 variable assumed to be timeinvariant). Calendar year was used to control for omitted variable bias and the time structure (Gmel et al. 2001); ${ }^{15}$ per capita GNP was included to control for economic strength as a potential confounder. The analyses to elucidate pattern weights for IHD and injuries have, for the present work, used the same methodology (for details see Gmel et al. 2001). For the sensitivity analysis and for the final pattern weights to calculate burden of disease in this chapter, data were taken from the following sources.

- Mortality data (either all-cause mortality in the sensitivity analysis or IHD/injury) were obtained from the WHO Mortality Database and age-standardized using United Nations population estimates. Direct standardization of mortality rates was performed using the latest WHO world standard population (Ahmad et al. 2000). The reference population is quite "young" with regard to the age distributions of populations in established market economies, but better reflects developing and emerging economies. On the other hand, the new WHO standard takes into account the reduced mortality rates in the older age groups nowadays, which have made the distribution a little "older" than the formerly widely used SEGI standard (Segi 1960).
- Adult per capita alcohol consumption data were again taken from WHO Global Alcohol Database described above.
- Per capita GNP data were taken from World Bank statistics, which used the Atlas method to arrive at standardized, de-inflated values in US dollars for the year 2000.

For all countries in this phase, time series data were collected from 1962 onwards on the four level- 1 variables-standardized mortality (either all-cause mortality in the sensitivity analyses or IHD and injury in the final estimates), calendar year, adult per capita alcohol consumption and per capita GNP.

In phase 2 , different models were run to especially take into account the cross-sectional time series structure, i.e. to assess the impact of eventually violating statistical assumption in hierarchical multilevel models.

For this exercise, data on countries where a long time series exists were used to try to estimate effects such as heteroscedasticity and error structure (autocorrelation) with some precision. Per capita consumption and data on all-cause mortality for 15 countries were obtained from ECAS, and are extensively described in the February 2001 supplement to Addiction (e.g. Norström 2001). Briefly, per capita alcohol consumption, measured in litres of pure alcohol per inhabitant aged $\geq 15$ years, was obtained from the Brewers Association of Canada (1997). Age-specific data on all-cause mortality were obtained from the WHO Mortality Database and standardized to the WHO 1998 standard population (Ahmad et al. 2000). For all countries, time series were available for a time span of at least 40 years. Worldwide, few if any countries exist that would be able to provide longer time series (say 60 or more years) of annual data.

## Sensitivity analysis, phase 1: multilevel models

The main difference between multilevel models and simple regression models is that the association between the outcome (mortality) and the independent variables (adult per capita consumption; calendar year as a control variable) is not fixed but varies across cross-sections (i.e. countries). Therefore, multilevel modelling analytically takes into account the lack of independence stemming from a potentially lower variability of data within a country compared to the variability between countries.

Essentially, this problem is the same as in cluster sampling, where variation between clusters is usually also higher than variation within clusters. Two approaches to account for cluster sampling have been suggested (see Lehtonen and Pahkinen 1994). One, the design-based approach, treats cluster sampling and the effect of it on parameter estimates as a nuisance. The information on variation across different clusters and variation within clusters is not included in the model. The estimation of CIs for relevant parameters (e.g. slopes and intercepts in regression analysis) without considering cluster sampling, however, is usually biased. Commonly, standard errors of parameters are underestimated, i.e. CIs are estimated to be narrower than they really are. The design-based approach accounts for these effects by adjusting the standard errors for the impact of the design, e.g. the cluster sampling, but does not model the effects explicitly. The other approach, the modelbased approach, treats the different variability across clusters as one parameter of interest in the study and explicitly models this variability. For this approach, multilevel (random coefficient) models are used. Comparison of the two approaches has shown that they yield similar results, but that the model-based (random coefficient) approach yields additional information as it is partly able to model the variability of estimates, and therefore to explain it (Skinner et al. 1989).

Our modelling is one variant of the model-based random coefficient approach. The rationale of multilevel models in the present context is described in detail by Rehm and Gmel (2000b); see also Bryk and Raudenbush (1992); Hox (1995); Kreft and de Leeuw (1998). Briefly, intercept and slopes are assumed to vary randomly ${ }^{16}$ across sections. In a two-level analysis this variation can be predicted by variables at the level of the cross-sections (e.g. per subregion). In the present study the variation in the slopes of adult per capita consumption to predict mortality will be explained by drinking patterns per country. Thus, it is assumed that drinking patterns moderate the association between adult per capita consumption and mortality. The corresponding model (without control variables) can be described as follows:

$$
\begin{equation*}
\text { mortality_rate }_{\mathrm{tc}}=\beta_{0 \mathrm{c}}+\beta_{1 \mathrm{c}} \times \text { alcohol }_{\mathrm{tc}}+\varepsilon_{\mathrm{tc}} \tag{1}
\end{equation*}
$$

where $t=$ index of time
$c=$ index of countries
The coefficients $\beta_{0 c}$ and $\beta_{1 c}$ symbolize random variables, which vary across countries. Therefore, the simplest way to model this random variation is given by the following equation:

$$
\begin{equation*}
\beta_{00}=\gamma_{0 c}+\mu_{0 c} \tag{2}
\end{equation*}
$$

where $\quad \gamma_{00}=$ global intercept of mortality rate
$\mu_{0 c}=$ country-specific variation of intercepts of mortality rates
similarly $\beta_{1 \mathrm{c}}=\gamma_{10}+\mu_{1 c}$
where $\quad \gamma_{10}=$ global slope of impact of alcohol (level-2 intercept of alcohol)
$\mu_{1 \mathrm{c}}=$ country specific variation of alcohol impact
Influences of country-specific drinking patterns on the slopes of per capita consumption can then be modelled as:

$$
\begin{equation*}
\text { pattern_weight }=\beta_{1 \mathrm{c}}=\gamma_{10}+\gamma_{11} \times \text { pattern_value }{ }_{c}+\mu_{1 \mathrm{c}} \tag{3}
\end{equation*}
$$

The impact of one unit of per capita consumption on mortality is thus assumed constant in time but specific for each country, and is denoted by $\beta_{1 c}$. This impact itself (throughout this chapter called "pattern weight") is regarded both as a dependent variable and as a predictor variable, for which the value not only varies across countries but also systematically depends on drinking pattern (i.e. pattern value) observed in the respective country.

The coefficient $\gamma_{10}$ can be regarded as a baseline measure for the impact of per capita consumption on mortality. ${ }^{17}$ The country-specific deviations
are introduced by the patterns of drinking in the country and a country specific error term $\mu_{1 c}$.

Note that if we estimated, in a simple one-level analysis, a global coefficient $\beta_{1}$ (not varying across countries), this measure would not necessarily be the same as $\gamma_{10}$ in a random coefficients model including level-2 variables. The coefficient $\gamma_{11}$ can be regarded as the contribution of drinking patterns to modifying the detrimental effects of per capita consumption on mortality. This modifying effect per unit of drinking patterns is treated as being the same for all countries. But clearly drinking patterns vary between countries, and therefore the impact on mortality $\beta_{1 \mathrm{c}}$ is specific to each country. There may remain unexplained variation in these country-specific impact coefficients. This is expressed by the level- 2 error term $\mu_{1 \mathrm{c}}$.

Figure 12.2 shows the modifications in residuals for different models. Figure 12.2(a) reflects a simple regression model in which all countries were simply pooled into one data set and analysis was performed without any multilevel modelling (i.e. standard multiple regression; in terms of multilevel modelling this would be a model with constant intercepts and constant slopes). Vertical lines in Figure 12.2 separate residuals within a country from those in other countries. It can be seen that residuals $\left(\varepsilon_{\mathrm{c}}\right)$ are clearly not independent, as for some countries all residuals were greater than zero whereas for other countries all residuals were below zero. In addition, residuals within a country clearly exhibit trends over time, which also violates the independence assumption. In Figure 12.2(b), a random intercept model was used. This means that for each country a separate intercept was estimated but the association between alcohol consumption and mortality was constant (i.e. it was estimated that the global level of mortality differed across countries, but the association between alcohol consumption and mortality was assumed to be the same across all countries). In this model residuals were more clustered around zero (owing to the random intercept), although there were still trends in the residuals. In the final model also, slopes were allowed to vary across countries (i.e. the association between alcohol consumption and mortality could vary across countries). In addition, control for confounding (GNP as constant slope term) and for omitted variable bias and potential deterministic trend stationarity (calendar year as a random slope term) was included in the multilevel model. The residuals of such a model (Figure 12.2 [c]) look very much as they should, as they exhibit neither visible trends nor autocorrelation. Thus, such a model not only turned out to be feasible but it also seemed to account for most of the undesirable aspects of residuals in time series analysis, such as nonstationarity and autocorrelated residuals. Nevertheless, the variability of errors still seems to be different across countries (heteroscedasticity).

Figure I2.2 Level-I residuals of multilevel models: a) constant intercept and constant alcohol slope; b) random intercept and constant alcohol slope; c) random intercept and random slope (including control for confounding, i.e. constant slope for GNP and random slope for calendar year)

## Sensitivity analysis, phase 2: pooled cross-sectional time series models

The models discussed above could also be seen as pooled cross-sectional time series models in so far as data used consisted of time series. The models discussed here, however, include special features to deal with the structure of residuals, namely correlations in time. For the models discussed above, the order of data points in time within a country is not taken into account and could be randomly rearranged within each country. In time series analysis, however, it is often assumed that (within each country) values that are closer in time may be more correlated than values that are more separated in time. Thus, the time span between two values must be taken into account. This could not be done by the multilevel modelling, only indirectly by including calendar year into the models.

The sensitivity analyses of different pooled cross-sectional time series models used data on 15 countries from the ECAS project. As a starting point we analysed the data with multilevel models as outlined for Figure 12.2(c), using three different estimation techniques with three different statistical software packages ( 2 -stage OLS with STATA; iterative GLS with MLWin; restricted ML with HLM). Parameter estimates across the three models were comparable and differed less than those from models discussed below (for details of findings see Gmel et al. 2001; for details of differences in estimators see Kreft and de Leeuw 1998).

The simplest model of a pooled time series design, called the "constant coefficient model" (Sayrs 1989) or "population-averaged model with independent errors" (StataCorp 1999), would stack all observations across time points and cross-sections into one data file and analyse the combined data by standard regression techniques (e.g. OLS regression for an interval-scaled dependent variable). Such a model would assume that observations across time and cross-sections are completely independent of each other. This model equals a "multilevel" model with a single fixed intercept and a single fixed slope. This means that neither the ordering in time nor the grouping within cross-sections (countries) must be obeyed and, hence, that there is no association between the time points within a cross-section or between time points over cross-sections, and that there is no relationship between the cross-sections within a time point or between time points. The constant coefficient model often serves as a reference model only. It could be written as follows.

1. Zero expectation of errors for all cross-sections:

$$
\mathrm{E}\left(\varepsilon_{\mathrm{ct}}\right)=0 \quad \text { for all } \mathrm{c}, \mathrm{t}
$$

2. Constant error variance for all cross-sections:

$$
\mathrm{V}\left(\varepsilon_{\mathrm{ct}}\right)=\sigma^{2} \quad \text { for all } \mathrm{c}, \mathrm{t}
$$

3. Uncorrelatedness of errors within and across cross-sections:

$$
\operatorname{COV}\left(\varepsilon_{i t}, \varepsilon_{\mathrm{it}}\right)=0 \quad \text { for any } \mathrm{i}, \mathrm{j}, \mathrm{t}
$$

where $t=$ index of time
$c, i, j=$ index of countries, where it $\neq j t$
Assumptions 1 and 2 would be violated when, for example, mortality in a country is always higher than the overall prediction across all countries and all time points. For such a country all errors would be positive. Similarly, the error variances may vary across countries (heteroscedasticity) owing to the fact that, for example, mortality is measured with different reliability in different countries. Typical for time series data, errors may be correlated within a country (autocorrelation within cross-section) but also at the same time point across countries, which would violate assumption 3. An example of such a pattern may be seen in the Nordic countries, where there are similar alcohol policies.

Related to the corresponding procedures in STATA (StataCorp 1999) two sets of models were run. The first set uses GEE estimation (Liang and Zeger 1986) and allows different descriptions of the correlation matrix within cross-sections, subject to the constraint that the same correlation matrix applies to all cross-sections. The following models were used, with $R_{t, s}$ being the $t, s$ element of the correlation matrix, where $t$ and $s$ describe time points (here, years).

1. The independence structure (i.e. $\mathrm{R}_{\mathrm{t}, \mathrm{s}}=1$ for $\mathrm{t}=\mathrm{s}$ and 0 otherwise) is equivalent to a model for which all observations are pooled into one file and analysed as if all data come from the same underlying population.
2. The autoregressive (AR) structure (i.e. for an autoregressive structure of order $1, R_{t, s}=1$ for $t=s$ and $\rho^{|t-s|}$ otherwise) models an exponentially decaying correlation in time within a cross-section, hence assuming that the less observations are correlated the more they are separated in time.
3. The stationary structure (i.e. for stationarity of order $1, R_{t, s}=1$ for $\mathrm{t}=\mathrm{s}, \rho$ for $|\mathrm{t}-\mathrm{s}|=1$, and 0 otherwise) permits a correlation only between two consecutive time points.
4. The nonstationary structure (i.e. for nonstationarity of order $\mathrm{g}, \mathrm{R}_{\mathrm{t}, \mathrm{s}}=1$ for $t=s, \rho_{t s}$ for $\left.g \geq|t-s|>0\right)$ permits correlations for all observations separated by up to $g$ time points. The correlation may differ with the number of time points between two observations, and with the location in time (i.e. a different correlation between 1950 and 1951 and between 1974 and 1975). A completely unconstrained correlation matrix would be a nonstationary structure with $\mathrm{g}=\mathrm{n}-1$ (number of time points).

The second set of models uses GLS estimation. Compared with the GEE models, this method relaxes the restrictions of sameness within cross-section correlation matrices. Hence, it permits the estimation of heteroscedastic variances across sections, and the estimation of cross-
sectional specific autoregression (i.e. each country is allowed to have its own error variance and its own magnitude of autocorrelation). The models are restricted to autoregressive models of order 1.

Thus, the GEE models in STATA permit a greater flexibility in estimating error structures, but assume that these structures are constant for all countries. On the other hand, the GLS models in STATA allow the coefficients of autocorrelated residuals and the error variance to vary across countries, but are restricted to an autocorrelation of order 1 only. None of these models allows for testing of random coefficient models. Thus, the association between alcohol consumption and mortality is assumed to be constant across all countries. The same is true of variables to adjust for confounding, omitted variable bias and time trends (GNP and calendar time). Models were used with and without inclusion of calendar time.

The findings can be summarized as follows.

- Measurements within countries are highly correlated in such a way that accounting for correlations only at lags 1 or 2 were not sufficient (e.g. models with stationary or nonstationary structure up to order 2). Thus, the correlations of higher order remained significant. Better fits were obtained, for example, under the assumption of an autoregressive structure, i.e. exponentially decaying correlations with increasing time span between measurements. In general, point estimates of coefficients for the alcohol-mortality association increased with better control of this autoregressive structure, indicating that insufficient control would bias estimates of this association downwards.
- The inclusion of calendar time as a constant coefficient control variable acted in the same direction as controlling for autoregression and clearly performed better than controlling for nonstationarity alone; controlling for nonstationarity did not further improve the estimation of the alcohol coefficient when used in addition to calendar time. As a conclusion, the use of calendar time as a continuous variable is at least as good as other methods (e.g. differencing) to account for nonstationarity in the present context. However, inclusion of autoregression further improved estimation even when calendar time was included.
- Whether the autoregressive structure was estimated to be constant across countries or to be country-specific resulted in smaller differences than those between an autoregressive structure and a structure restricted to low-order lag correlations (nonstationary or stationary). It should be noted, however, that the estimation of higher order (>2) nonstationary structures (which allow more flexibility of the correlation matrix) did not converge to a solution. This was probably because of the number of parameters that needed estimation. For a
model with an autoregressive structure (e.g. of order 1), although correlations for higher lags can be significant, only 1 parameter must be estimated as it is assumed that correlations of time points with higher lag orders follow an exponentially decaying function of the correlation at lag 1. In nonstationary models, correlations with a higher lag order can vary freely and must be estimated separately.
- The inclusion of heteroscedasticity (unequal variances) did not improve models, or did so only marginally.

As already mentioned, it appeared that the better the error structure of time series was captured, the higher were the point estimates for the relationship between alcohol consumption and mortality. In none of these models, however, could varying coefficients for this relationship across countries be modelled. The underlying assumption of these pooled cross-sectional models is that there is a constant relationship and that pooling is used to increase sample size for efficient estimation, while adjusting for a more complex error structure than independence. However, tests for constant coefficients showed that there is significant variation across countries for both the coefficient of alcohol consumption and for calendar year, pointing to geographically differing and not altogether changing associations. Although the autocorrelated error structure could not be accounted for, random coefficient models yielded the highest association for alcohol consumption, pointing to the possibility that the use of random coefficient models better captured the data and the error structure than constant coefficient models accounting for autocorrelated residuals, by estimating a constant effect of alcohol consumption and a constant effect of calendar time. Clearly, random coefficient models including the autoregressive error structure may further improve estimation.

There is software that can in principle handle autocorrelation and heteroscedasticity in multilevel models (Bryk et al. 1996; Yang et al. 1999). It should be noted, however, that in the present study the inclusion of autocorrelated disturbances failed to converge. The possible reason for the nonconvergence might be that the model was already well specified with the inclusion of random coefficient time trends, and the additional inclusion of further parameters might therefore have resulted in colinearity problems. This seems to be a general problem in analysis of aggregate data in the alcohol field, where relatively low variability within series is coupled with relatively short series. It is, however, not likely that the omission of autocorrelated disturbances in random coefficient models may have greatly distorted the findings. Although including autocorrelation of errors resulted in further improvement, this improvement was relatively minor in pooled cross-sectional time series models with constant alcohol coefficients that adjusted for a constant coefficient of calendar time, compared to the improvement from random coefficients models. In addition, in random coefficient models without including autocorrelation
the impact of calendar year was not estimated as being constant across all countries, and might therefore further account for autocorrelation, as it separately adjusted in each country and therefore better captured the country-specific confounding than a country-averaged model.

The advantage of random coefficient models was that not only could the association between consumption and mortality vary across countries, but so could the associations with the control variable time. Thus, the adjustment of time could be analysed in a country-specific manner. Finally, none of the pooled cross-sectional time series models could analyse variations in the relationship between alcohol consumption and mortality as being moderated by patterns.

In conclusion, all sensitivity analysis performed indicated that multilevel modelling outperformed pooled cross-sectional time series models, although the autocorrelated error structure could not be taken into account directly. As estimation of such a structure was not feasible even for the longer time series in the field, there was no hope that this could be done when more countries with relatively short series (fewer than 10 data points) were added. On the contrary, adding other countries would increase the cross-country variability and reduce the impact of autocorrelation within country, especially as this may have little impact given the few data points.

### 3.3 CRITERIA FOR IDENTIFYING RELEVANT STUDIES

The criteria listed in Table 12.8 apply to all meta-analyses used to estimate the relationship between per capita consumption and specific diseases (English et al. 1995).

Alcohol-related consequences were thus identified by reviewing and evaluating large-scale epidemiological studies on alcohol and health, including epidemiological input into major reviews (Collins and Lapsley 1991; Corrao et al. 1999; Devlin et al. 1997; English et al. 1995; Gurr 1996; Harwood et al. 1998; Klingeman and Gmel 2001; Rice et al. 1991; Ridolfo and Stevenson 2001; Single et al. 1996, 1999a, 1999b; Stinson et al. 1993; U.S. Department of Health and Human Services 2000). Papers were collected primarily from the peer-reviewed international literature. As indicated above under the discussion on causality, we followed the accepted guidelines established in the first major review (English et al. 1995). All conditions for which evidence of a causal relationship was conclusive were included in the final list. Discussion of disease conditions where causality was not judged to be sufficient can be found in section 3.5.

### 3.4 Description of studies, including METHODOLOGICAL QUALITIES

More than 6000 studies were included in the different analyses on which the estimates for this chapter were based. For further descriptions we refer to the original publications of the meta-analyses (English et al.

Table 12.8 Exclusion criteria for studies used in determining the relationship between average volume of consumption and mortality/morbidity in CRA
$\left.\begin{array}{ll}\text { Reason for exclusion } & \text { Explanation and/or examples } \\ \hline \text { Restricted study population } & \begin{array}{l}\text { The study was carried out in a sample that was difficult to } \\ \text { generalize for the entire population (for example, a cohort } \\ \text { of persons suffering from a particular disorder) }\end{array} \\ \text { Inappropriate comparison } & \begin{array}{l}\text { The control group was contaminated by a high exposure to } \\ \text { the risk factor under consideration or other factors related } \\ \text { to the condition }\end{array} \\ \text { group } & \begin{array}{l}\text { Exposure was alcohol dependence rather than } \\ \text { alcohol consumption, or alcohol consumption was undefined } \\ \text { or had poorly defined nominal categories (for example, } \\ \text { "regular" vs "non-regular" drinkers) or was limited to } \\ \text { frequency of consumption (without considering quantity) or }\end{array} \\ \text { measure } & \begin{array}{l}\text { was measured in a manner not representative of general } \\ \text { exposure (for example, with meals or in the last 24 hours) }\end{array} \\ \text { A study was reported in more than one paper, and was }\end{array}\right\}$

1995; Gutjahr et al. 2001; Ridolfo and Stevenson 2001; Single et al. 1999a). Nevertheless, we provide here a general methodological description of the studies used and their assumptions.

Most studies reviewed used either a cohort or case-control design (Rothman and Greenland 1998b). For epidemiological studies on alcohol consumption using these designs, the following limitations generally apply.

- Alcohol use is mostly measured by only a few questions, either separating frequency of drinking and quantity per occasion or combining them into one modified frequency question in the tradition of nutritional epidemiology (e.g. Rehm 1998a, 1998b for further descriptions and a critique). Research has shown that such questions may lead to underestimates of true consumption. Also, data on the relationship
between patterns of drinking and health outcomes are limited, as typical questions in epidemiological surveys cannot be used to measure drinking patterns (Rehm 2000). Studies with more complete alcohol assessment are mostly cross-sectional, or the baseline assessment was carried out very recently so that no longitudinal results can yet be reported.
- The relationships between alcohol consumption and chronic disease outcomes are often based on outcomes assessed at follow-up, regressed on several variables from the baseline assessment. These procedures assume that the baseline variables are stable over time, or that they are somehow good indicators of the postulated theoretical relationship (e.g. Rehm et al. 1996). For example, in assessing the relationship between volume of consumption and liver cirrhosis, it must be assumed that heavy consumption persists after baseline and is a good indicator for overall tissue exposure, which is the theoretical determinant (Lelbach 1975, 1976). Work on the regression dilution bias has shown that the size of the real effect is often underestimated by using only the baseline assessment (Clarke et al. 1999) if the exposure is somewhat constant or preserves rank order over time. Moreover, there is evidence from longitudinal studies that individual drinking patterns are not stable over time (Fillmore 1988; Vaillant and Hiller-Sturmhofel 1996), which may obscure the apparent relationship even further.
- The relationship between alcohol consumption and outcomes must be assumed to be fairly constant across settings, in that results of epidemiological studies from a few countries are applied to others. While this may be justified with biologically based relationships (e.g. alcohol and breast cancer), ${ }^{18}$ such an assumption is more problematic with casualties and injuries as outcomes, since these are much more context-dependent.

All of these points indicate that the results of the meta-analyses on which our estimates are based will have limits with regard to precision. These limits are not captured by the CI for combined relative risks.

### 3.5 Relative risks and attributable fractions

Some conditions, such as alcoholic psychosis or alcohol dependence syndrome, are by definition causally related and wholly attributable to alcohol (i.e. they would not exist in the absence of alcohol consumption) (Table 12.9). For most conditions, however, alcohol is a contributory rather than a sufficient cause (Rothman and Greenland 1998a). Pooling of risk estimates for these diseases from individual studies was performed by means of precision-based weighting (English et al. 1995). Methods and results of the pooling procedure (meta-analysis) have been described in more detail elsewhere (Gutjahr and Gmel 2001).

In contrast, the alcohol-attributable fractions (AAFs) for acute consequences such as injuries are usually directly determined from the blood alcohol concentration (BAC) at the time of the injury. For example, road accidents are attributed to alcohol according to whether the driver responsible for the accident tested positive for alcohol and to what degree (e.g. BAC $\geq 0.05 \%$ ). ${ }^{19}$ In the case of traffic accidents we have relative risk estimates, based on case-control studies, for different levels of BAC (Ridolfo and Stevenson 2001; see also McLeod et al. 1999). But relative risk estimates are usually rare for acute consequences other than traffic injuries. Thus, for the purpose of the present study, AAFs from the international literature were used (English et al. 1995; Gutjahr and Gmel 2001; Ridolfo and Stevenson 2001; Single et al. 1996; Stinson et al. 1993).

To structure the presentation and discussion of results, alcohol-related health consequences will be categorized as follows.

1. Chronic harmful effects of alcohol consumption, excluding depression and IHD:

- wholly alcohol-attributable outcomes;
- cancers (neoplasms);
- cardiovascular diseases;
- liver cirrhosis;
- effects of prenatal alcohol exposure;
- neuropsychological conditions; and
- other chronic diseases.

2. Chronic beneficial effects of alcohol consumption, excluding IHD:

- ischaemic stroke; and
- other conditions (type II diabetes, gallstones).

3. IHD as a chronic condition where alcohol has harmful and beneficial consequences:

- depression; and
- acute adverse effects:
- unintentional injuries (motor vehicle accidents, poisonings, falls, drownings, other unintentional injuries)
- intentional injuries (self-inflicted injuries, homicide, other intentional injuries).

Table I2.9 Disease conditions that are by definition fully alcoholattributable $(\mathrm{AAF}=\mathrm{I})$

| ICD-9 code | Disease |
| :--- | :--- |
| 291 | Alcoholic psychoses |
| 303 | Alcohol dependence |
| 305.0 | Alcohol abuse |
| 357.5 | Alcoholic polyneuropathy |
| 425.5 | Alcoholic cardiomyopathy |
| 535.3 | Alcoholic gastritis |
| $571.0-571.3$ | Alcoholic fatty liver, acute alcoholic hepatitis, alcoholic cirrhosis of |
| 790.3 | liver, unspecified alcoholic liver damage |
| $980.0,980.1$ | Elevated blood alcohol level |
|  | Toxic effect of ethyl alcohol, toxic <br> effect of methyl alcohol |

### 3.6 Chronic harmful effects of alcohol consumption, EXCLUDING DEPRESSION AND IHD

## Wholly alcohol-attributable diseases

A number of diseases are by definition fully attributable to alcohol (AAF $=1$ ). These are listed in Table 12.9.

## DISEASES WITH A CONTRIbUTORY ROLE

## Cancer

Oropharyngeal, oesophageal and liver cancers. Alcohol has consistently been related to the risk of cancer of the mouth (lip, tongue), pharynx, larynx, hypopharynx, oesophagus and liver (Corrao et al. 1999; English et al. 1995; Gurr 1996; Single et al. 1999; U.S. Department of Health and Human Services 2000; WHO 2000). The relationship between average volume of alcohol consumed and cancer incidence is usually characterized as increasing almost monotonically (Bagnardi et al. 2001), but this may partially be an artefact of the methods used (Single et al. 1999). Evidence for the role of alcohol in these cancers has accumulated from case-control and cohort studies. Recently, much emphasis has been placed on investigating biochemical mechanisms in laboratory studies to explain the carcinogenic behaviour of alcohol (U.S. Department of Health and Human Services 2000). ${ }^{20}$

Female breast cancer. Much research has been conducted over the last decade on breast cancer. Prior to 1995, it was usually concluded that evidence of a causal relationship with alcohol was insufficient (English et al. 1995; Rosenberg et al. 1993; Schatzkin and Longnecker 1994). Recent studies and reviews have shown, however, that not only haz-
ardous or harmful drinking but also even moderate alcohol consumption can cause female breast cancer (Single et al. 1999a). A meta-analysis by Smith-Warner et al. (1998) found a clear linear relationship over the whole continuum of consumption. Other original studies supported this finding (Bowlin et al. 1997; Corrao et al. 1999; Nasca et al. 1994; Royo-Bordonada et al. 1997; Swanson et al. 1997; Van den Brandt et al. 1995; Wingo et al. 1997). In contrast to the weight of evidence, Zhang et al. (1999) concluded from their investigation that moderate intake did not increase the risk of breast cancer, and that a low level of drinking was associated with a protective effect. This finding, however, appears to be a notable outlier (Longnecker 1999) and, so far, has not been corroborated. Recent studies have focused on plausible biological mechanisms, including alcohol's effect on hormones and tissue, its contribution to the initiation, progression and promotion of breast cancer, and its interaction with nutritional factors (for an overview see Singletary and Gapstur 2001; Soler et al. 1998; U.S. Department of Health and Human Services 2000).

Cancers of the stomach, pancreas, colon, rectum and prostate. Many recent research projects have investigated whether these cancers are alcohol-related. Overall, evidence for a causal relationship between alcohol and cancer of these sites, if any was found, was weak and inconclusive (Bode and Bode 1997; Boutron et al. 1995; De Stefani et al. 1998; Gapstur et al. 1994; Harnack et al. 1997; Ji et al. 1996; Longnecker and Enger 1996; Lundberg and Passik 1997; Piette et al. 1998; Sarles et al. 1996; Seitz et al. 1998a, 1998b; Singborg 1998; Soler et al. 1998). On prostate cancer, again most studies did not report observing an increased risk (Breslow and Weed 1998; Ellison et al. 1998; Hiatt et al. 1994; Tavani et al. 1994), whereas two cohort studies (Ajani et al. 1998; Putnam et al. 1998) and one case-control study (Hayes et al. 1996) reported a small increased risk in men who consume even moderate amounts of alcohol. In conclusion, evidence for a causal relationship between alcohol and cancer of the stomach, pancreas, colon, rectum and prostate has not so far produced consistent results, especially with regard to physiological pathways. Thus, we did not include these cancers, even though some of them showed significantly elevated risks in a recent metaanalysis (Bagnardi et al. 2001).

Cancer of salivary glands, ovary, endometrium, bladder. It has been hypothesized that alcohol might constitute a risk factor for cancer of the major salivary glands (Horn-Ross et al. 1997; Muscat and Wynder 1998), ovary, endometrium (Bradley et al. 1998; Longnecker and Enger 1996; Newcomb et al. 1997; Parazzini et al. 1995) and bladder (Bruemmer et al. 1997; Donato et al. 1997; Longnecker and Enger 1996; Yu et al. 1997). For each of these sites, results were scarce or conflicting, and
the effects, if any, were not statistically significant. Moreover, there is no knowledge of physiological pathways for these sites.

There is an almost linear dose-response relationship between volume of drinking and the relative risk of alcohol-related cancers. Although there have been speculations about the impact of patterns of drinking, especially for breast cancer (Kohlmeier and Mendez 1997), the current state of knowledge does not suggest that these play an important role in the etiology of cancer. ${ }^{21}$ Thus, the alcohol-attributable burden for cancer will be modelled exclusively on average volume.

## Cardiovascular disease

The role of alcohol, as both a risk and protective factor for cardiovascular disease, has been studied extensively in the past decade. IHD has been the focus of most research and is discussed separately below. Most studies suggest that low-level consumption also offers some protection against ischaemic stroke, and this condition is therefore also discussed in the section below on the beneficial effects of alcohol.

In contrast, hypertension and other cardiovascular disorders such as cardiac arrhythmias, heart failure and ill-defined descriptions and complications of heart disease are adversely affected by alcohol (see e.g. Friedman 1998; Klatsky 1995; Puddey et al. 1999; Rosenqvist 1998; U.S. Department of Health and Human Services 1997; Wood et al. 1998). The weight of evidence suggests that daily consumption of more than 30 g pure alcohol for men (and presumably lower levels for women) causes hypertension (Beilin et al. 1996; Curtis et al. 1997; English et al. 1995; Grobbee et al. 1999; Keil et al. 1997; Klatsky 1996). Low-level intake, however, was not associated with hypertension in men, and may even confer a small protective effect in women (English et al. 1995). There are some indications that hypertension may be related to the pattern of heavy drinking occasions (Murray et al. 2002; Puddey et al. 1999; Wannamethee and Shaper 1991).

For haemorrhagic stroke, the weight of evidence suggests an increase in risk for males even at low levels of consumption (Berger et al. 1999; Jackson 1994; Sacco et al. 1999; You et al. 1997). For females, the most recent meta-analyses of Ridolfo and Stevenson (2001) suggested a protective effect for drinking categories I and II but an 8 -fold increased risk for drinking the equivalent of more than 40 g pure alcohol daily (see Table 12.10). Patterns of drinking not only play a role in any protective effects of alcohol on IHD but are also relevant for risk of stroke (Hillbom et al. 1998) and sudden cardiovascular death or cardiovascular death in general (Kauhanen et al. 1997a, 1997b; Kosarevic et al. 1982; Poikolainen et al. 1983; Wannamethee and Shaper 1992), with heavy drinking occasions and intoxication resulting in increased risk. Patterns of drinking should therefore be included in future estimates of harmful cardiovascular outcomes.

## Liver cirrhosis

Alcohol consumption has been identified as the leading cause of liver cirrhosis in established market economies (Corrao et al. 1997, 1998; English et al. 1995). Whereas the association with alcoholic liver cirrhosis is clear, with all cases being attributable to alcohol, debate remains as to whether this equally applies to unspecified liver cirrhosis. Several authors contend that, empirically, it is extremely difficult to separate alcoholic from unspecified liver cirrhosis, and that the term "unspecified liver cirrhosis" is applied when no specific etiological factor is reported or identified (English et al. 1995). Research in the United States and in Central and South American countries has indicated that an appreciable proportion of deaths from cirrhosis without mention of alcohol was in fact attributable to alcohol (Haberman and Weinbaum 1990; Puffer and Griffith 1967; Room 1972). ${ }^{22}$

On the other hand, applying AAFs of liver cirrhosis to other countries can be extremely misleading. In many countries (e.g. China and India), liver cirrhosis is mainly caused by other factors such as viral infections. The corresponding AAFs have been shown to vary between less than 10\% (China) and 90\% (Finland) (WHO 2000).

The relationship between alcohol consumption and liver cirrhosis seems to depend mainly on volume of drinking and is independent of pattern of drinking (Lelbach 1975, 1976). However, some research also indicates a potential effect of occasions of heavy drinking (Rhodés et al. 1993). Moreover, there is some indication that spirits are especially harmful in causing liver cirrhosis (Gruenewald and Ponicki 1995; Kerr et al. 2000; Longnecker et al. 1981; Schmidt 1991). The problem with this research is that it is almost entirely based on ecological studies and thus describes only correlations, which may have other causes (Morgenstern 1998; Rehm and Gmel 2001a).

## Effects of prenatal alcohol exposure

Today, there is ample evidence that alcohol consumption during pregnancy is related to various risks to the fetus, which include gross congenital anomalies and fetal alcohol syndrome (FAS) (Alvear et al. 1998; Church et al. 1997; Faden et al. 1997; Habbick and Snyder 1997; Larkby and Day 1997; Larroque and Kaminski 1996; Mattson et al. 1997; Passaro and Little 1997; Passaro et al. 1996; Polygenis et al. 1998; Roebuck et al. 1998; Shu et al. 1995; Windham et al. 1995). FAS has been characterized as a continuum, with minor physical malformations at one end and serious neurobiological dysfunctions, including mental retardation, at the other (Connor and Streissguth 1996). The prenatal teratogenic effects of alcohol also include lethal outcomes comprising spontaneous abortion, low birth weight, fetal damage, prematurity and intrauterine growth retardation (Abel 1997; Bradley et al. 1998; Windham et al. 1997). These can occur even at low average
volumes of consumption, particularly during the first trimester of pregnancy.

## Mental conditions

The co-morbidity of alcohol dependence with other mental conditions is high, both in clinical and in general population samples (e.g. Grant and Harford 1995; Merikangas et al. 1998). The crucial question in this respect is about causation. We have included depression in this review only where we believe the evidence to be sufficient to conclude a causal role for alcohol. Since this relationship is controversial, it is discussed below in a separate section.

## Other chronic conditions

Other risks of alcohol consumption currently discussed in the literature include epilepsy (see e.g. Jallon et al. 1998; Leone et al. 1997; Martin et al. 1995), acute and chronic pancreatitis and psoriasis. Whereas for pancreatitis the causal role of alcohol seems to be clear, Amman et al. (1996) and Skinazi et al. (1995) contend that the discrimination between acute and chronic pancreatitis is not justifiable, since the overwhelming majority of patients presenting with acute pancreatitis at the same time have an underlying chronic pancreatitis (Robles-Diaz and Gorelick 1997; Thakker 1998). On psoriasis, our search did not yield any recent studies. English et al. (1995) found that the results of the pooled estimates were consistent with a moderately strong and statistically significant effect of average volume of consumption.

Table 12.10 summarizes the relative risks at different levels of consumption for alcohol-related chronic consequences.

### 3.7 BENEFICIAL HEALTH EFFECTS OF ALCOHOL CONSUMPTION on disease

## ISCHAEMIC STROKE

Cerebrovascular disease (stroke) consists of several subtypes, the most common being ischaemic stroke and haemorrhagic stroke, which are affected differently by alcohol. For ischaemic stroke (the predominant type) the weight of evidence, including biological mechanisms, suggests effects similar to those for IHD, namely that low to moderate consumption may offer some protection (Beilin et al. 1996; Hillbom 1998; Keil et al. 1997; Kitamura et al. 1998; Knuiman and Vu 1996; Sacco et al. 1999; Thun et al. 1997; Yuan et al. 1997; Wannamethee and Shaper 1996). It seems that this protective effect is more pronounced in females (Table 12.11).

## Other beneficial health effects

Alcohol consumption may offer some protection against type II diabetes and cholelithiasis (gallstones) (see also Ashley et al. 2000 for a recent

Table 12.10 Relative risks for chronic harmful alcohol-related disease for different drinking categories (relative to abstainers)

overview on beneficial effects of alcohol). The Australian meta-analysis by English et al. (1995) concluded that there was some evidence that alcohol may protect against the onset of type II diabetes. Since then, the findings from a cohort of more than 40000 male health professionals showed that moderate alcohol consumption may reduce the risk of type II diabetes, perhaps through the effects of alcohol on insulin sensitivity (Rimm et al. 1995). In addition, findings from the British Regional Heart Study indicated a protective effect (Perry et al. 1995). Further, a followup of men enrolled in the United States Physicians Study revealed a marked negative association of incident type II diabetes with alcohol consumption (Ajani et al. 1999). In a recent prospective study, a U-shaped association was found between alcohol and type II diabetes (Wei et al. 2000).

On the other hand, Kao et al. (1998) found evidence (based on small numbers) of an inverse relationship between alcohol consumption and the risk of type II diabetes for women. This relationship was not found in men; indeed, men consuming more than 21 units of alcohol per week were at increased risk of type II diabetes. A protective effect of moderate alcohol consumption against type II diabetes may be mediated through the effects of alcohol on glucose tolerance and insulin resistance. Moderate alcohol drinking has been shown to increase insulin sensitivity (Facchini et al. 1994; Kiechl et al. 1996) and lower insulin resistance (Lazarus et al. 1997), even in young adult drinkers (Flanagan et al. 2000). Finally, there is some evidence that inflammatory processes may mediate alcohol-induced diabetes (Imhof et al. 2001; Pradhan et al. 2001). In summary, there is growing evidence from cohort studies that moderate alcohol consumption reduces the risk of diabetes and a plausible underlying biological mechanism has been identified. This was the reason for including this effect as a beneficial effect in subregions with beneficial drinking patterns (established market economies with best mortality pattern: AMR-A, EUR-A, WPR-A). For all other subregions, no effect was modelled for these drinking categories. However, evidence for the relationship between alcohol consumption and diabetes is far from conclusive at present.

There is evidence that alcohol consumption may offer some protection against gallstones (English et al. 1995; Holman et al. 1996). These findings have been substantiated by recent large-scale cohort and case-control studies, which reported an inverse relationship (Attili et al. 1998; Caroli-Bosc et al. 1998; Chen et al. 1999; Leitzmann et al. 1998). Table 12.11 gives an overview of diseases for which alcohol potentially has beneficial effects.

Table 12.1I Relative risks for chronic beneficial alcohol-related health effects for different drinking categories (compared to abstainers)

| Disease or condition | ICD-9 code | Relative risk |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |

### 3.8 IHD AS A CHRONIC CONDITION FOR WHICH ALCOHOL HAS HARMFUL AND BENEFICIAL CONSEQUENCES

## Epidemiology-average volume of consumption

$\mathrm{IHD}^{23}$ is one of the leading causes of death in the world (Murray and Lopez 1996a). The most important health benefits of alcohol in terms of IHD have been found at low to moderate levels of average volume of consumption (Beaglehole and Jackson 1992; Doll 1998; Edwards et al. 1994; Fuchs et al. 1995; Goldberg et al. 1995; Hillbom 1998; Holman et al. 1996; Jackson 1994; Rehm et al. 1997; Single et al. 1999a; Svärdsudd 1998). Only a few individual-level studies have failed to substantiate this association in men (Hart et al. 1999) or women (Fillmore et al. 1998; Maskarinec et al. 1998).

While some studies have suggested that alcohol may offer protection against IHD across the entire continuum of consumption (Camargo et al. 1997; Doll et al. 1994; Keil et al. 1997; Rehm et al. 1997 [males only]; Kitamura et al. 1998; Thun et al. 1997), they nevertheless show that most of the protective effect is gained at low levels of consumption, such as one drink every other day.

Overall, average volume of drinking and IHD show a J-shape relationship in the usual medical epidemiological cohort studies in established market economies (Corrao et al. 2000). Compared to abstinence, low to moderate average consumption of alcohol has been found to confer a lower risk of IHD incidence and mortality. For higher levels of average volume of consumption, the risk relationship is reversed (e.g. Corrao et al. 2000; Friedman and Kimball 1986; Rehm et al. 1997), with heavy average consumption being associated with a risk larger than that for abstainers. In the most recent meta-analysis Corrao et al. (2000) demonstrated the described J-shape, and also demonstrated several other characteristics from the literature on average volume of consumption and IHD.

- There was a pronounced sex effect, showing that women were less protected for a given level of consumption, with an earlier upturn of the curve.
- The beneficial effect of alcohol was less pronounced for fatal outcomes.
- The study results were inconsistent, especially with respect to relative risk for higher intake, indicating additional influencing factors not controlled for.
- The better quality studies placed the maximum beneficial effect at lower levels of average alcohol intake. The maximum protective effect was measured at 20 g pure alcohol per day; the relative risk $=1$ line, equivalent to abstainers' risk, was crossed at 72 g per day; and there was a significant detrimental effect over 89 g per day.
- More specifically, cohort studies, wholly adjusted studies, studies that compared drinkers with lifetime abstainers and those that excluded sick subjects at baseline showed less beneficial effects than case-control studies, unadjusted or partially adjusted studies, studies that compared drinkers with current abstainers and those that included sick subjects.
- Mediterranean countries showed more protective effects for the same levels of average consumption.

The epidemiological evidence that light to moderate average alcohol consumption protects against IHD is strengthened by substantial evidence concerning the biological mechanisms by which a protective effect could be mediated (Rankin 1994; Renaud et al. 1993; Single et al. 1999b; Svärdsudd 1998). First, moderate alcohol intake has been linked to favourable lipid profiles, especially an increase in high-density lipoproteins (HDL) (Baraona and Lieber 1998). It has been estimated that as much as $40-50 \%$ of the protective effect may be attributable to this mechanism (Criqui et al. 1987; Criqui and Ringel 1994; Suh et al. 1992). Second, moderate alcohol intake favourably affects coagulation profiles, particularly through its effects on platelet aggregation (McKenzie and Eisenberg 1996; Rubin 1999) and fibrinolysis (Reeder et al. 1996). Third, low to moderate consumption of alcohol has been shown to favourably affect insulin resistance (Kiechl et al. 1996; Lazarus et al. 1997; Rankin 1994). Fourth, it has been postulated that alcohol could protect against IHD through its effect on hormonal profiles, particularly its estrogen effects (Svärdsudd 1998). Fifth, the alcohol metabolite acetate has been postulated to protect against IHD by promoting vasodilation (U.S. Department of Health and Human Services 1997). Sixth, alcohol affects inflammation and, through this pathway, can influence IHD (Imhof et al. 2001; Jacques et al. 2001; Morrow and Ridker 2000; Ridker 2001). Finally, it is possible that some of the effect is mediated through the anti-
oxidative constituents of alcohol beverages, especially wine (Reinke and McCay 1996). Nevertheless, most of the protective effect appears to be linked to ethanol per se.

The protective effect of light to moderate consumption has been questioned on several grounds. The role of the comparison group has been questioned (Shaper 1990a, 1990b; Shaper et al. 1988), it being suggested that the abstainer group includes people who have stopped drinking because of health reasons and these are responsible for the elevated disease risk compared to light and moderate drinkers. Many subsequent studies controlled for this effect by taking lifetime abstainers as the comparison group (Rehm and Sempos 1995). Nevertheless, in most established market economies, where most of the research on alcohol and IHD has taken place, abstainers constitute only a minority of the general population and the possibility that they have other behavioural characteristics responsible for the elevated IHD risk cannot be excluded. No alternative explanation has ever been empirically demonstrated, however. For instance, social isolation has been theoretically claimed to confound the alcohol-mortality relationship (Skog 1996), but empirical research has not been able to substantiate this effect (Murray et al. 1999).

In conclusion, the relationship between average volume of drinking and IHD seems to be J-shaped. Light to moderate drinking is associated with a lower IHD risk than abstinence or heavy drinking. However, the results are inconsistent, indicating that factors other than those included in the study may also determine the relationship. One of the main factors may be pattern of drinking (i.e. the way in which the same average amount of alcohol is consumed). In this respect two patterns deserve mentioning: irregular heavy drinking and drinking with meals.

## EPIDEMIOLOGY—PATTERNS OF DRINKING

## Heavy drinking occasions

Heavy drinking occasions have been linked to adverse cardiovascular events for some time (Poikolainen 1983). However, many studies had used wider endpoints than IHD (Kauhanen et al. 1997b) or samples of problem drinkers or persons with alcohol-use disorders (Dyer et al. 1977; Rosengren et al. 1987; Rossow and Amundsen 1997), where heavy drinking patterns are confounded with volume.

Some of the more recent studies have controlled for (average) volume of drinking. A case-control study in Australia (McElduff and Dobson 1997) compared 11511 cases of acute myocardial infarction or coronary death with 6077 randomly selected controls. If people drank in binges (usually five or more drinks on an occasion for women, nine or more drinks on an occasion for men), there were no protective effects for coronary events and relative risks were mainly larger than 1 compared to abstainers (indicating higher risks for major coronary events). This
elevated risk was present even in groups with low overall volume of drinking. As expected, the authors also found a protective effect of daily drinking, which was most pronounced for regular light to moderate drinkers.

Similarly, Murray et al. (2002) evaluated the cardiovascular consequences of binge drinking (eight or more drinks at a sitting) and usual (non-binge) drinking of alcohol in a longitudinal, population-based study. Interview data from 1154 men and women aged 18 to 65 years in Winnipeg, Canada were linked to health care utilization and mortality records in an eight-year follow-up period. Cox proportional hazards regressions were estimated separately for men and women. The outcomes included first event for physician visits, and hospitalizations and deaths due to IHD, hypertension, or other cardiovascular disease. Binge drinking increased the risk of IHD in men (hazard ratio [HR] of 2.3, $95 \% \mathrm{CI}$ $1.2-4.2$ ) and women (HR of $1.1,95 \%$ CI 1.02-1.2) and increased the risk of hypertension in men (HR of 1.6, $95 \%$ CI 1.04-2.4) but not women. Binge drinking had no effect on the risk of other cardiovascular disease. All of these results were controlled for average volume of drinking. Again, the expected cardioprotective effects were confirmed in both men and women. The harmful effects of heavy drinking occasions on IHD morbidity and mortality could thus be disaggregated from the effect of average volume of drinking. Finally, Trevisan et al. (2001a) found in a case-control design that, after adjustment for average volume of consumption, weekend drinking by men was significantly related to risk of myocardial infarction compared to men drinking less than once a week (logistic regression: OR 1.9, 95\% CI 1.2-3.2).

In addition to the effect on IHD, there appears to be a relationship between irregular heavy drinking occasions and other forms of cardiovascular death, especially sudden cardiac death (Kauhanen et al. 1997b; Wannamethee and Shaper 1992; Wood et al. 1998). This is consistent with the physiological mechanisms of increased clotting and reducing the threshold for ventricular fibrillation after heavy drinking occasions, which have been reviewed by McKee and Britton (1998). Specifically, heavy drinking occasions have been shown to increase the blood level of low-density lipoproteins (LDL), which in turn have been linked to negative cardiovascular outcomes. Contrary to low or moderate steady drinking, heavy irregular drinking occasions are not associated with an increase in levels of HDL, which have been linked to favourable cardiovascular outcomes. In addition, irregular drinking is associated with increased risk of thrombosis after cessation of drinking (Renaud and Ruf 1996). Finally, irregular heavy drinking seems to predispose to histological changes in the myocardium and conducting systems, as well as to a reduction in the threshold for ventricular fibrillation. In conclusion, irregular heavy drinking occasions are mainly associated with physiological mechanisms that increase the risk of sudden cardiac death and other cardiovascular outcomes, in contrast to the physiological
mechanisms triggered by regular low to moderate consumption that are linked to favourable cardiac outcomes. Nevertheless, individual-level studies are still scarce and some studies show no effects (Murray et al. 1998).

## Drinking with meals

Trevisan et al. (2001b) reported on drinking with meals and IHD mortality based on the Risk Factor and Life Expectancy Study, a pooled series of epidemiological studies conducted in Italy with 8647 males and 6521 females aged 30-59 years at baseline and free of cardiovascular disease. Subjects were followed up for an average of seven years. Alcohol consumption showed a protective effect on IHD, and drinking wine with meals was linked to more positive outcomes than drinking wine outside meals. Compared to drinking with meals, drinking wine outside meals had a relative risk of $1.8,95 \%$ CI $0.97-3.5$ for IHD in males, adjusted for average volume of drinking and other potential confounders. There were not enough IHD cases to conduct a similar analysis for females, but the effects for all-cause mortality for females showed a five-fold risk for wine outside meals compared to wine with meals (relative risk of 5.0, 95\% CI 1.5-10.9).

Another study (Trevisan et al. 2001a), using a case-control design, examined 443 male myocardial infarction survivors and 922 healthy controls aged 35-69 years. Compared to non-drinkers the age, education and smoking-adjusted odds ratios for former drinkers and current drinkers were $0.67,95 \%$ CI $0.32-1.38$ and $0.47,95 \%$ CI $0.24-0.95$, respectively, confirming the overall cardioprotective effect of alcohol consumption (see above). Men who reported drinking without food at least $75 \%$ of the time had an odds ratio of $1.5,95 \%$ CI $0.96-2.3$ compared to those who drank mainly with meals and snacks, after adjustment for age, education and volume of alcohol consumed.

The potential mechanisms linking consumption of alcoholic beverages with meals to a lower IHD risk, compared to consumption between meals, remain to be fully clarified. However a few mechanisms have been hypothesized. A study by Trevisan et al. (1987) in a large sample of Italian men and women found a significant association between drinking between meals and higher prevalence of hypertension, compared to drinking with meals, even after adjustment for differences in alcohol consumption between these drinking pattern categories. These findings were recently confirmed in another study using a population-based sample in the United States (Wu and Trevisan 2001). Finally, Foppa et al. (1999) found in a controlled randomized trial that moderate consumption of wine with a meal reduced postprandial blood pressure. Drinking with meals has also been shown to positively affect fibrinolysis (Hendriks et al. 1994) and lipid levels (Veenstra et al. 1990).

Other potential physiological links between drinking with meals and these IHD risk factors include a reduced absorption of alcohol owing to
the presence of food in the gastrointestinal tract (Gentry 2000). Another physiological link may be that food increases the alcohol elimination rate (Ramchandani et al. 2001).

## AgGregate-LEVEL STUDIES ON PATTERNS AND AVERAGE CONSUMPTION

Given the described relative scarcity of individual-level studies, it is not surprising that much of the argumentation is based on aggregate-level studies, especially on Russian experience with the natural experiment of the Gorbachev anti-alcohol campaign. The Russian Federation is generally considered to be one of the countries with the highest rates of irregular heavy drinking (Bobak et al. 1999; Malyutina et al. 2001). Thus, if a heavy drinking style has an adverse impact on cardiovascular disease in general and on IHD in particular, such effects should have become evident at the population level in the experience of the anti-alcohol campaign during the last years of the Soviet Union. In the period 1984-1987, when estimated total alcohol consumption in the Russian Federation fell by about $25 \%$ (Shkolnikov and Nemtsov 1997), age-adjusted male deaths from circulatory disease fell by $9 \%$ (Leon et al. 1997). After the end of the campaign, the death rate rose again quite dramatically. The role of alcohol in the recent drastic increases in mortality in the Russian Federation, however, remains controversial, as many other changes occurred in the late 1980s and early 1990s (Bobak and Marmot 1999; Britton and McKee 2000; Leon et al. 1997; McKee et al. 2001; Notzon et al. 1998; Shkolnikow et al. 2001). There seems to be general agreement, however, that alcohol has played an important role in increasing mortality rates, although the level of impact is unclear.

There is another indirect line of research on the effect of heavy drinking on IHD. Countries with a tradition of heavier or binge drinking on weekends show proportionately high IHD or cardiovascular disease mortality on or immediately after the weekend (Germany, IHD: Willich et al. 1994; Moscow, cardiovascular disease events: Chenet et al. 1998; Lithuania, IHD events: Chenet et al. 2001; Scotland, IHD events: cf. Evans et al. 2000). Other aggregate-level research on per capita alcohol consumption and IHD have failed to find effects, even for countries with the best drinking pattern (i.e. drinking pattern $=1$ ) in a time series analysis with differenced data, controlling for tobacco (Hemström 2001). Finally, Skog (1983) also found no significant effects in a time series analysis on differenced data for Norway.

## Summary of The epidemiological evidence

In conclusion, the relationship between drinking and IHD is complex, and the epidemiological literature on it is evolving. There seems to be a clear beneficial effect, supported by biochemical evidence, of regular light to moderate drinking, but it is unclear how many people actually drink in a manner that will provide them with these benefits. Also, there are
indications that irregular bouts of heavy drinking are linked to physiological mechanisms, which are in turn linked to negative IHD outcomes, as well as to other negative cardiovascular disease outcomes. Better surveys are needed, including the measurement of biomarkers indicative of the relationships specified above. In these surveys, the relevant variables such as irregular heavy drinking or drinking with meals should also be included.

Many of the individual-level cohort studies on the relationship between average volume of drinking and IHD have been carried out on special populations such as nurses, doctors or other health professionals, mostly in established market economies, who have relatively regular and potentially beneficial drinking patterns. As a result, the effect of average volume of alcohol consumption may be overstated in the usual meta-analysis. Thus, the results of these analyses cannot be applied worldwide, since more detrimental patterns of drinking prevail in the majority of countries. Moreover, the impact of pattern of drinking has to be included, in addition to the effects of average volume of drinking.

Unfortunately, as described above, patterns of drinking cannot be modelled by meta-analysis owing to the scarcity of data on the relationship between exposure and outcome. Thus, we used the multilevel modelling approach described earlier to incorporate patterns of drinking into the estimates.

MEASURING THE EFFECT OF AVERAGE VOLUME OF CONSUMPTION AND DRINKING PATTERN ON IHD MORTALITY
The details of determining the impact of average volume and pattern of drinking on IHD are described earlier. The characteristics of the data set are given in Table 12.12.

Table 12.13 gives an overview of the most important results with respect to the differential impact of alcohol consumption on IHD mortality. As predicted, in countries with consumption pattern 1, alcohol had beneficial effects on the incidence of IHD. For countries with pattern 2, the impact on IHD varied around zero (i.e. no marked impact of alcohol). In countries with pattern 3, alcohol showed a detrimental impact on IHD for males only. For countries with pattern 4, the detrimental impact of alcohol was pronounced for both males and females. Assuming interval scales between the categories of the pattern variable, the models were estimated as in Table 12.14.

Again, in countries with pattern 1, beneficial effects appeared for both males ( -0.0214 ) and females $(-0.0376)$. These consumption models indicate that the overall effect of IHD at an average pattern level ( 2.51 in the sample used) is detrimental for males and not significantly different from zero for females. In other words, the results from individual-level studies could be replicated in this aggregate-level study. This means that for countries such as France and Italy we expect a beneficial effect of alcohol on IHD mortality; for countries such as Slovenia and the United

[^49]States there will be no overall effect; for countries such as the Republic of Korea and Ukraine we expect an overall detrimental effect of alcohol for males; and for countries such as the Russian Federation we expect a detrimental effect for both males and females. The results from this model are consistent with the finding that the anti-alcohol campaign in the Gorbachev era had such an impact on IHD mortality in the Russian Federation.

The model has limitations, however. Most notably, each country has been assigned one pattern value that is assumed to be stable over time. Whereas patterns have been found to be stable in the past (Room 1992; Simpura 2001), clearly this assumption is an oversimplification. Moreover, it is clear that in most countries there are people with different drinking patterns. Thus, future research should be based on distributions of patterns by sex and age, rather than on one pattern value per country.

The results of this model are not consistent with a recent ecological analysis by Hemström (2001), using a time series approach with differenced data. Hemström (2001) found a random distribution of insignificant negative (beneficial) and positive (detrimental) alcohol effect estimates. He used only per capita data without any control for drinking pattern. However, based on individual-level studies and the results of the present analysis, beneficial effects would have been expected for countries with a consumption pattern of 1 , such as France, Italy, Portugal and Spain. We can only speculate on the difference in results between the two analyses. Hemström's time series were relatively short (45 years per country), not allowing some of the tests for correct model specification (Rehm and Gmel 2001a). There also may have been some overdifferencing problems with co-integration or the joint use of differencing and taking the logarithm, which may have obscured the effect (Greene 2000; Hatanaka 1996; Yaffee 2000).

On the other hand, the present analysis draws on relatively limited time series in a wide range of drinking cultures, which increases the ability to generalize but which also has limitations. Our findings for the pattern- 1 subgroup have the strong advantage of convergent data from individual-level studies, supported by biological plausibility. We have therefore used our finding of a protective effect at the population level for the countries with beneficial patterns (pattern 1) as a current best estimate of effects (for comparison with results using coefficients from meta-analysis).

Given the limits of ecological analysis, individual-level data should always be given priority in judgements of causality, although not necessarily in terms of estimates of the overall effect of changes in a risk factor at the population level (Skog 1996). This applies to our analysis as well.

## Determining AAFs for IHD, including patterns of DRinking

To arrive at the AAFs, the results of the dummy regression were taken and only effects larger than $\pm 0.015$ were modelled. However, since the
multilevel analysis could only control for per capita GNP as a confounder, and since there are general limits in controlling for confounding in such analyses (Morgenstern 1998), the effects of alcohol indicators were halved in order to be conservative and to adjust for any other confounding. This approach, though arbitrary in the choice of halving, is consistent with that taken in risk analysis for other risk factors (e.g. tobacco) to avoid residual confounding.

Taking into consideration the distribution of patterns in all countries within the 14 subregions, and standardized mortality rates after 1994, the AAFs can be derived (Table 12.15).

Table 12.15 shows the effects of alcohol-attributable IHD mortality based on aggregate-level analysis, halving the effects to adjust for potential confounding. This can easily be done by using the respective values in the formulas above.

Alternatively, one may use the relative risks from the individual-level studies as a basis and apply them to the subregions AMR-A, EUR-A and WPR-A, as almost all of the studies come from these subregions. Such an approach leads to higher cardioprotective effects (see Table 12.16) and may well contain overestimates based on the usual cohort composition, where people with more regular drinking styles are overrepresented. However, individual-level studies are usually preferred to ecological studies both for establishing causality and for making estimates of impact (e.g. Morgenstern 1998). Further, with respect to overall disease burden attributable to alcohol, this provides a more conservative approach to estimating.

The resulting AAFs, using individual-level estimates of relative risk for AMR-A, EUR-A and WPR-A, would be $-0.11,-0.15$ and -0.15 , respectively. The cardioprotective effect estimated in this way is larger than that given above (see Table 12.15). We used these estimates for the final calculations. The numbers for EUR-B are given only for sensitivity analysis. Overall, the average patterns for this subregion (2.9) are much closer to the average pattern for EUR-C (3.6) than that for EURA (1.3). Thus, we did not feel justified in using the estimates based on studies almost exclusively from countries with beneficial patterns (A subregions).

### 3.9 Depression

## BACKGROUND AND EPIDEMIOLOGY

Alcohol is implicated in a variety of mental disorders that are not alcohol-specific. However, no major overview on alcohol-attributable burden of disease has yet included these disorders (English et al. 1995; Gutjahr et al. 2001; Rehm et al. 2001a, 2001b; Ridolfo and Stevenson 2001; Single et al. 1999). While the causality of the relation is hard to define, sufficient evidence now exists for us to include an estimate of the causal role of alcohol in depression, a major mental disorder.

a The estimates for AMR-A, EUR-A and WPR-A serve only as sensitivity analysis as the AAFs for these subregions will be based on individual-level studies (see Table 12.16 below).

In the general population, alcohol dependence and major depression co-occur over-proportionally, on both a 12 -month and a lifetime basis (Kessler et al. 1996, 1997; Lynskey 1998). Among alcohol consumers in the general population, higher volume of consumption is associated with more symptoms of depression (Graham and Schmid 1999; Mehrabian 2001; Rodgers et al. 2000). Compared to moderate drinkers, both higher

(Bjork et al. 1999) and lower (Rodgers et al. 2000) levels of depressive symptoms have been found among abstainers. Among patients under treatment for alcohol abuse and dependence, the prevalence of major depression is higher than in the general population (Lynskey 1998; Schuckit et al. 1997a). Similarly the prevalence of alcohol abuse and dependence is higher for patients under treatment for depression (Alpert et al. 1999; Blixen et al. 1997).

This suggests that alcohol abuse is linked to depressive symptoms, and that alcohol dependence and depressive disorders co-occur to a larger degree than expected by chance. However, it is not clear in the individual case whether depression caused alcohol problems, whether alcohol consumption or alcohol problems caused depression, or whether both could be attributed to a third cause (Vaillant 1993). The pathway from depression to problematic alcohol use and alcohol dependence has long been discussed under the heading of self-medication (i.e. the use of alcohol to alleviate depressive symptoms). In addition, a shared third cause could be certain neurobiological mechanisms (see Markou et al. 1998) or genetic predisposition. Moreover, all three pathways of causation may co-exist at the same time, with different proportions of the cooccurring morbidities being attributable to each, and of course some co-occurrence being simply due to chance.

## Establishing the causal Link between alcohol AND DEPRESSION

Causal relations in epidemiology are usually based on several criteria (Hill 1965; Rothman and Greenland 1998a). Using these criteria, we will review the evidence that part of the burden of depression is caused by alcohol. As indicated above, this does not preclude the possibility that part of the burden of alcohol dependence is also caused by depression, or that part of the co-occurrence is causally related to some third factor. Following the majority of the literature, we base our argumentation mainly on alcohol dependence rather than alcohol consumption per se. This is done mostly for reasons of data availability: depression and alcohol dependence are usually part of the same mental health surveys, and almost all estimates of co-occurrence stem from this kind of survey. It is not usual to include questions on alcohol consumption per se in this type of survey, nor is it usual to include a diagnosis of depression in alcohol surveys.

Prevalences of alcohol dependence or alcohol use disorders (i.e. alcohol dependence and harmful use of alcohol) were thus used as indicator of alcohol consumption drinking categories, assuming a constant relationship between the two variables. This indicator relationship was also made possible by the fact that alcohol use disorders by definition have an AAF of 1.0 -that is, under the counterfactual scenario (Murray and Lopez 1999) of no alcohol available at all, there would be no burden due to alcohol dependence. Moreover, in different regions of the world,
average volume of drinking and prevalence of alcohol dependence are correlated to a high degree ( $r=0.86$ ) (Rehm and Eschmann 2002).

## Temporal order

Causal factors must precede consequences. Logically, therefore, only that fraction of depression in which the onset of alcohol problems preceded the onset of depression can be caused by alcohol problems. The fraction in which alcohol problems came first is an upper bound for the proportion of depressive disorders caused by alcohol dependence. This upper bound is summarized in Table 12.17 for different forms of depression in several countries, based on the International Consortium in Psychiatric Epidemiology (ICPE) (Merikangas et al. 1998).

Clearly, in all areas (i.e. countries, provinces and cities) mentioned in Table 12.17, the proportion of depressive disorders preceded by alcohol dependence is higher for males than for females. This corresponds to the higher prevalence of alcohol dependence in these areas. In fact, the proportion of rates of depressive disorders and alcohol problems correlate to 0.80 (major depression) and 0.82 (other depressions) for these areas (Pearson correlations; alcohol dependence rates from World bealth report 2001 and Rehm and Eschmann 2002). This means that at least $64 \%$ of the variation in the proportion of depressive disorders in the various subregions can be statistically "explained" by the variation in alcohol dependence. Of course, the remarks made above on possible forms of causal pathway still apply. This relationship provides a basis for predicting such rates for other subregions where data are lacking (see below).

Another indicator of the role of alcohol dependence in causing some depressive disorders is the comparison between onsets for different mental disorders co-occurring with alcohol disorders. In the US National Comorbidity Survey (Kessler et al. 1996) the proportion of disorders preceded by alcohol dependence was higher for depression than for any other disorder.

## Consistency

Epidemiological studies are very consistent, both in the general population and in clinical samples, in showing that alcohol dependence and depressive disorders co-occur to a higher degree than might be expected by chance. This has been observed in several countries and regions (e.g. Merikangas et al. 1998; Swendson et al. 1998). In fact, we do not know of any study where alcohol dependence and depressive disorders did not co-vary to a larger degree than that expected by chance.

The co-variation between the proportion of people with depressive disorders with a preceding alcohol dependence and the prevalence of alcohol dependence is also consistent across countries (see above).

## Strength of association

It has been consistently found that alcohol-dependent individuals demonstrate a two- to three-fold increase in risk of depressive disorders (e.g. Hilarski and Wodarki 2001; Schuckit 1996; Swendson et al. 1998). This is an effect comparable in size with many other causal effects (Gutjahr et al. 2001) (Table 12.19).

## Reversibility (remission during abstinence)

Key evidence for a causal effect of alcohol dependence on depressive disorders comes from studies that analyse what happens to rates of depressive disorders when patients with clinical symptoms abstain from drinking. Most of these studies come to the conclusion that many depressive syndromes markedly improve within days or weeks of abstinence (Brown and Schuckit 1988; Dackis et al. 1986; Davidson 1995; Gibson and Becker 1973, Penick et al. 1988; Pettinati et al. 1982; Willenbring 1986). Of course, other things change within therapy, so not all of the
effect is necessarily due to the pharmacological effect of drinking. In addition, experimental studies have found that more symptoms of depression are reported during heavy drinking episodes (Isbell et al. 1955; Schuckit et al. 1997b; Tamarin et al. 1970; Weiner et al. 1971). In conclusion, there is sufficient evidence that abstinence substantially removes symptoms of depression in alcohol-dependent persons within a short time.

## Family patterns

Several studies have tried to separate alcohol-dependent persons with primary (sometimes called "independent") depressive disorders from those with secondary (sometimes called "induced") depressive disorders by examining different family patterns of both alcohol dependence and depressive disorders. For instance, Hesselbrock et al. (1983) and Schuckit et al. (1997b) found higher rates of depressive disorders, rather than alcoholism, in close relatives of alcohol-dependent patients with primary depression than in patients with secondary depression. Other studies, both in clinical samples and in the general population, did not find different rates of alcohol dependence or affective disorders based on the primary-secondary distinction (Grant and Pickering 1997; Hasegawa et al. 1991). Thus, the studies on genetic vulnerability suggest differences between primary and secondary transmission, but are not conclusive.

## Biological mechanisms

There are several plausible mechanisms by which alcohol dependence may cause depressive disorders (Markou et al. 1998), but research is not yet conclusive. It should be noted that there is a biological link via intoxication or heavy use rather than via dependence alone.

## Dose-response relationship

Merikangas et al. (1998) found that there is a continuum in the magnitude of co-morbidity as a function of position on the spectrum of substance use (use, problems, dependence). While there are relationships at the level of symptoms in the general population, the relationships are strongest between alcohol dependence and depressive disorders (see above).

## Potential alternative explanations

There may be other explanations for the co-occurrence of alcohol dependence and depressive disorders, either from genetic disposition or the environment. For example, Grant and Pickering (1997) suggested that alcoholism and major depression might be alternative manifestations of the same underlying disorder. Nevertheless, there is no explanation for the finding that depressive symptoms increase markedly during bouts of heavy drinking and disappear during periods of abstinence, even if no antidepressant medication is given. This is the strongest indication of a causal effect.

## Summary of evidence on causality

Overall, we find sufficient evidence of causality for the influence of alcohol dependence on depressive disorders. The evidence indicates that a clear and consistent association exists between alcohol dependence and depressive disorders and that chance, confounding variables and other bias can be ruled out with reasonable confidence as factors in this association. Consistent with the assessments for other disease and injury categories, most weight was placed on consistency across several studies, strength of the association, reversibility, temporal order and the fact that the effect was at least physiologically plausible.

## Estimating AAFs of depressive disorders

Quantitative estimates of the proportion of depressive disorders attributable to alcohol can be derived from the high correlation between alcohol dependence and the proportion of depressive disorders with preceding alcohol-use disorders (see above), using alcohol dependence rates in different subregions of the world (Table 12.18, columns 3 and 4).

The empirical data on proportion of depressive disorders with preceding alcohol-use disorders were regressed on survey results of alcohol dependence for the same subregions without a constant. The omission of the constant was due to the fact that in a situation without any alcohol dependence, the proportion of alcohol-attributable depressive disorders should also be zero. Thus, the regression line must pass through the origin. Since the relationship is quite close, the respective regression coefficients became highly significant even with few data points.

Clearly, the proportions in columns 3 and 4 of Table 12.18 are the upper limit of depressive disorders attributable to alcohol. In order to derive a realistic proportion of alcohol-attributable depressive disorders, we need to subtract the proportion of co-occurrences due to chance. In a situation of chance, the occurrence of alcohol-use disorders in depressed persons should be exactly equal to the occurrence of alcohol-use disorders in non-depressed persons (i.e. the general population). Thus, the prevalence of alcohol-use disorders was first subtracted from the upper limit to derive AAFs. The prevalence of alcohol dependence was taken from The world health report 2001, which itself was based on a pooled analysis of survey results. The relationship between alcohol dependence and alcohol abuse (i.e. harmful use in ICD-10) was derived from the US National Comorbidity Survey (Kessler 1998) and was assumed to be constant across subregions. This assumption was necessary as there were fewer data on alcohol abuse than on alcohol dependence, and as the diagnostic systems used vary considerably for this diagnosis.

To control for possible confounding, the effects were halved as has been done elsewhere (e.g. IHD analysis above) as well as for other risk factors (Peto et al. 1992 for smoking; see also chapter 11). The resulting estimates for AAFs of depressive disorders can be found in Table 12.18, columns 5 and 6.

a From World health report 2001, based on survey results (Rehm and Eschmann 2002) and then estimated consistently with DisMod, ${ }^{24}$ taking into account case fatality, duration and/or incidence.

These results show that AAFs of depressive disorders vary substantially in different subregions of the world. They reflect differences in rates of heavy alcohol consumption and alcohol dependence. Thus, AAFs are considerably larger for males than for females. They are highest in the

Russian Federation and its surrounding countries (EUR-C) and in North America (AMR-A), and almost nonexistent in Muslim-dominated areas (EMR-B and EMR-D).

## CONCLUSIONS ON ALCOHOL AND DEPRESSION

Based on standard criteria of causality, we conclude that there is sufficient evidence for a causal relation between alcohol-use disorders and depressive disorders. We suspect that careful examination would also reveal a relationship between heavy drinking and depressive disorders, although heavy drinking unfortunately is not usually measured as an endpoint in epidemiological cohort studies.

The status of alcohol abuse as a causal agent in depression is not as clear. There are co-occurrences between alcohol abuse and depressive disorders that are larger than chance (Kessler et al. 1996, 1997), but the relationship is weaker compared to the relationship with alcohol dependence. This may have to do with the less clear conceptual status of alcohol abuse, which is defined in the current version of the Diagnostic and statistical manual of mental disorders (DSM) (American Psychiatric Association 1994) nosology to include social and legal responses to the patient's drinking, and which is not a category of disorder in ICD. On the other hand, many studies found only one factor when analysing criteria of alcohol dependence and alcohol abuse, or a division of factors that did not correspond to the division between the diagnoses in DSM. Thus, the relationship between alcohol abuse and depressive disorders should be clarified in future research. It may have relevance, beyond burden of disease research, in helping to clarify the status of alcohol abuse in general.

### 3.10 Summary of relative risk for chronic diseases, using CRA disease categories

Relative risk estimates are summarized in Table 12.19.

### 3.11 Acute adverse health consequences

Alcohol use has been associated with increased risk of injury in a wide variety of settings, including road traffic accidents (involving vehicles, bicycles and pedestrians), falls, fires, injuries related to sports and recreational activities, self-inflicted injuries and injuries resulting from interpersonal violence (Cherpitel 1992; Freedland et al. 1993; Hingson and Howland 1987, 1993; Hurst et al. 1994; Martin 1992; Martin and Bachman 1997; U.S. Department of Health and Human Services 1997,2000 ). There is also some evidence that the presence of alcohol in the body at the time of injury may be associated with a greater severity of injury and a less positive outcome (Fuller 1995; Li et al. 1997).
Table I2.19 Relative risk for major chronic disease categories by sex and average drinking category

## Unintentional injuries

Alcohol consumption produces effects that are often perceived as positive, as evidenced by the widespread popularity of drinking. But it also leads to actions that result in unintentional injury and death. This section highlights research findings on causality of alcohol involvement and findings relevant to establishing dose-response relationships and drinking patterns. It focuses on traffic injuries, as most of the research has been conducted in this area, and traffic accidents are the most important component of unintentional injuries (Rehm et al. 2003b).

Studies relating average volume of drinking to risk of injury have found the risk of injury to be positively related to increasing average intake levels of alcohol, with the risk increasing at relatively low volumes of intake (Cherpitel et al. 1995). Two studies of injury among older adults reported a U-shaped relationship between alcohol use and occupational injury (Zwerling et al. 1996) and traumatic deaths (Ross et al. 1990). However, abstinence could be related to existing health problems or cognitive deficits that are, in turn, related to accident risk (Zwerling et al. 1996). Hence the higher risk among abstainers is likely to be purely spurious.

Several patterns of drinking have been related to risk of injury. Frequent heavy drinking and frequent subjective drunkenness are both associated with injury, particularly injury resulting from violence (Cherpitel 1996a). Frequency of heavy drinking has also been associated with a greater likelihood of death due to injury, relative to other causes (Li et al. 1994). One important line of research in this area has empirically defined a parameter of usual drinking pattern that is most closely associated with the risk of injury and drunk driving behaviour, after adjusting for other drinking pattern variables and characteristics of the drinker (Gruenewald and Nephew 1994; Gruenewald et al. 1996a, 1996b; Treno and Holder 1997; Treno et al. 1997). The greatest risk was found in individuals who consume relatively large amounts on some occasions, and whose highest amounts are markedly greater than their average amount per occasion.

Several retrospective studies have compared BAC in individuals who have experienced a collision or trauma, compared with selected individuals not involved in trauma, using a case-control design (Cherpitel 1992; Freedland et al. 1993; Fuller 1995; Hurst et al. 1994; Stoduto et al. 1993; U.S. Department of Health and Human Services 1997). One of the most influential case-control series was the Grand Rapids Study of 5985 collisions (Borkenstein et al. 1964; Hurst et al. 1994). Statistically adequate re-analysis of the Grand Rapids Study indicates that all levels of BAC are associated with an increased risk of crashes, relative to a BAC of zero, with an accelerating slope in which the risk of injury increases markedly with high BACs (Hurst et al. 1994).

There are clear reasons why alcohol is related to injury. Moderate doses of alcohol have been demonstrated in controlled experimental studies to have cognitive and psychomotor effects that are relevant to the risk of injury, such as reaction time, cognitive processing, coordination and vigilance (Eckardt et al. 1998; Kruger et al. 1993; Moskowitz and Robinson 1988; U.S. Department of Health and Human Services 1997). The comprehensive recent review by Eckardt et al. (1998) concluded that the threshold dose for negative effects on psychomotor tasks is generally found at around $40-50 \mathrm{mg} \%$ (equivalent to $0.04-0.05 \%$ ). The authors also stated, "injury can occur as a result of alcohol's disruption of psychomotor function in individuals at BACs of approximately 10 mM ", which is equal to a BAC of little less than $50 \mathrm{mg} \%$.

Dose-response curves observed in experimental data are not always monotonic. For example, a recent experimental study (Lloyd and Rogers 1997) assessed the effects of low doses of alcohol given with a meal, and found that 8 g of absolute alcohol (about 0.25 litre of beer) resulted in improved performance of complex cognitive tasks relative to no alcohol, but that 24 g of absolute alcohol produced impaired performance. Such J -shaped or U-shaped effects of low ethanol doses on task-specific performance are explicable pharmacologically (Eckardt et al. 1998). The Grand Rapids Study also found that dose-response curves varied somewhat between novices and frequent, experienced drinkers.

In summary, the evidence indicates that the amount consumed per occasion, and more specifically the blood alcohol content, is the critical feature in determining risk of injury. Blood alcohol concentrations as low as $40-50 \mathrm{mg} \%$ may cause psychomotor impairment, leading to increased risk of injury in circumstances such as driving or operating machinery.

Thus, despite methodological problems, there is evidence of causality for the most researched injury category (traffic accidents). Table 12.20 gives the AAFs for different kinds of injuries in four recent reviews. The reviews based their estimates on meta-analyses or other summaries of the relations found in published studies. It should be recognized that, while there are many such studies, they are mostly from a relatively small range of countries. Most of the AAFs were directly derived, for example from police statistics, although there are case-control studies as well (McLeod et al. 1999).

Causality, at least for traffic accidents, can be established since:

- alcohol is clearly associated with the outcome;
- there is a dose-response relationship: the higher the BAC, the higher the chance of injury;
- there is a biochemical explanation for the relationship; and
- with suitable interventions to reduce alcohol consumption, the outcome is reduced as well. Thus, in a meta-analysis, Shults et al.

[^50]Late effects of injuries by another
(2001) found random breath-testing programmes or selective breathtesting checkpoints to be effective in reducing mortality from traffic accidents by $18 \%$ and $20 \%$, respectively.

## INTENTIONAL INJURIES

Alcohol is strongly associated with violent crime (Graham and West 2001), although this association varies considerably across settings (Murdoch et al 1990; Room and Rossow 2001). Studies on violence have repeatedly shown that alcohol consumption precedes violent events, and that the amount of drinking is related to the severity of the subsequent violence. In addition, the experimental literature suggests that alcohol plays a causally contributing role ${ }^{25}$ in aggression. Meta-analyses of experimental studies suggest a small to moderate effect size of about 0.22 (Bushman 1997) in the overall relationship between alcohol consumption and aggression. Some effort has been made to separate pharmacological effects from expectations, ${ }^{26}$ but the general conclusion is that expectations form part of the "psycho-pharmacological" effects of alcohol (Bushman 1997; Graham et al. 1998), and neither can nor should be separated in attempting to understand the effects of alcohol. Alcohol bathes the brain in chemicals and it is likely that a number of different effects of alcohol contribute to the increased likelihood of aggressive behaviour. First, alcohol seems to have an effect on the serotonin (5HT) and GABA brain receptors, similar to that produced by some benzodiazepines (Pihl et al. 1993). The subjective experience of this effect may be a reduced level of fear and anxiety about social, physical or legal consequences of one's actions. This reduced fear or anxiety may result in increased risk-taking by some drinkers. This particular causal pathway has received support from animal research linking alcohol, GABA receptors and aggression (Miczek et al. 1993) and from experimental and observational research showing higher risk taking associated with alcohol intoxication (Graham et al. 2000; Pihl and Peterson 1993). Alcohol also affects cognitive functioning (Peterson et al. 1990), leading to impaired problem solving in conflict situations (Sayette et al. 1993) and overly emotional responses or emotional lability (Pihl et al. 1993). Other behavioural and attitudinal effects of alcohol related to aggression have been identified, although at this point not necessarily linked to particular pharmacological effects on the brain. These include a narrow and tenacious focus on the present (Graham et al. 2000; Washburne 1956), also described as "alcohol myopia" (Steele and Josephs 1990) and increased concerns with demonstrating personal power, at least for men (Graham et al. 2000; McClelland et al. 1972; Tomsen 1997).

Alcohol-related violence involves more complex issues of social interaction than would be relevant to drink-driving and other alcohol-related accidental injuries. In particular, the effects of alcohol are moderated by both the environment and the characteristics of the drinker (Chermack and Giancola 1997; Lipsey et al. 1997; Rossow et al. 2001; U.S. Depart-
ment of Health and Human Services 2000). For example, meta-analysis of experimental research on alcohol and aggression found that the effects of environmental manipulation to increase aggression were stronger for intoxicated than for sober participants. In another meta-analysis, Ito et al. (1996) found that the effects of alcohol were greater in situations characterized by greater anxiety, inhibition conflict and frustration, while differences between sober and intoxicated persons were smaller in situations involving high provocation or self-focused attention. Further, given sufficient disincentives for aggression the effects of alcohol on aggression can be reduced or even eliminated altogether (Hoaken et al. 1998; Jeavons and Taylor 1985).

As with alcohol-related accidents, some proportion of violence that occurs after people have been drinking might have occurred anyway, without the involvement of alcohol. Alcohol-related violence involves an interaction of the effects of alcohol on one or more people, the environment and the personality of the drinker (Graham et al. 1998). However, the environment for alcohol-related aggression is not independent of drinking. ${ }^{27}$ For example, in environments devoted to drinking (e.g. bars, pubs), it does not make sense to try to determine the proportion of violence that would have occurred even if the person had not been drinking, because this particular environment does not exist without drinking. Although a few incidents that occur in bars involve interpersonal conflict between friends or couples that might have occurred in another setting, almost all incidents of aggression that occur in bars are unplanned, emerge from the social interaction in the bar (Graham and Wells 2001) and often involve strangers. Therefore, it seems reasonable to assume that close to $100 \%$ of incidents of violence occurring in bars and other environments where drinking is the main activity should be considered attributable to alcohol, either directly through the pharmacological effects of alcohol or indirectly through the social norms related to drinking.

Estimating the proportion of violence in other settings that should be attributed to alcohol is more problematic. There are pharmacological effects of alcohol, as described above, that make aggressive interactions more likely. This is more likely to be the case if all those involved have been drinking, owing to the interaction of the effects of alcohol on each person (Leonard 1984). In addition, alcohol is known to increase the likelihood of the escalation of conflict (Martin and Bachman 1997; Sharps et al. 2001). On the other hand, marital violence, for example, often occurs when neither party has been drinking. Therefore, the assessment of the exact proportion of alcohol-related violent injuries and death that should be attributable to alcohol is often difficult, and needs to be assessed from different sources, such as time series analyses, natural experiments, case-control studies, emergency-room studies, general population surveys and experimental designs (Pernanen 2001).

## DERIVING THE AAFs FOR DIFFERENT SUBREGIONS FOR INJURIES (BOTH INTENTIONAL AND UNINTENTIONAL)

Injuries are also influenced by average volume of alcohol consumption and by patterns of drinking, especially by acute levels of BAC or intoxication. To model this relationship, a multilevel analysis identical to the one on IHD was used (for statistical derivation and specification of the model see section 3.2; for formulas see notes below Table 12.13). Table 12.21 gives an overview of the underlying data. Table 12.22 gives the main results of the analysis.

The effect of alcohol on injury at pattern 1 is 0.013 for males and 0.010 for females. The effect for pattern 2 populations is the same, as the coefficients did not significantly differ. For pattern 3, the effect is 0.056 for males and 0.014 for females. For pattern 4 , the respective effects are 0.196 for males and 0.027 for females.

The results can be summarized as follows.

- Average volume of drinking has a significant detrimental effect on risk of injury even at consumption pattern 1 , independent of sex. The impact is larger in males.
- The impact of per capita consumption on injury is different between different countries, as shown by the significant variance component.
- No significant difference in the effect of drinking on injury risk was found between patterns 1 and 2 .
- Pattern 3 has a significantly higher injury risk for both sexes, but the impact is much stronger in males (about 10 times).
- Pattern 4 has the highest injury risk for both sexes, and again the impact is much stronger for males.

To estimate AAFs for injuries we used the Australian AAFs, since these reflected the most up-to-date information (Ridolfo and Stevenson 2001). These were converted into odds ratios, ${ }^{28}$ which were applied to estimated exposure prevalence for all subregions, as with other diseases, multiplicatively adjusted by pattern weights from Table 12.22 and average volume of alcohol consumption. This procedure must be regarded as a crude approximation, yet the best attainable at present. Given the potential variation in the role of alcohol in casualties across settings, there is an urgent need for empirical studies of the relationship in different world regions, using a variety of methods. The WHO Collaborative Study on Alcohol and Injuries (www.who.int/ substance_abuse/topic_alcohol_injuries.htm) constitutes a step forward on this.

Appendix B gives an overview of the derived AAFs for mortality for major categories of accidental and intentional injuries, as defined for the CRA project.

Table I2.2I Characteristics of data set to calculate the relationship between per capita consumption, patterns of drinking and injury mortality

| Country | Injury mortality, males per 1000 | Injury mortality, females per 1000 | Average per capita alcohol consumption |  | Year of first data | Year of last data | Number of years |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |

Another point concerns the relation of alcohol with type of outcomemorbidity vs mortality. In general, more severe outcomes are more related to alcohol than less severe outcomes (Rehm et al. 2003b; Single et al. 1999b). Consequently, the AAFs for mortality should be higher than the AAFs for morbidity. Unfortunately, most research to determine AAFs for injury did not explicitly separate mortality and morbidity (see, e.g. Table 12.20). Ridolfo and Stevenson (2001) explicitly separated the AAFs for motor vehicle accidents, and for males found 0.328 for deaths and 0.247 for hospitalizations; they lacked sufficient data for females. Based on their work and that of Cherpitel (1994, 1996b), we determined the ratio of AAF for morbidity as two thirds of the AAF for mortality. The ratio for other kinds of injury is lower (Cherpitel 1994, 1996b). To
be conservative, these ratios were set at 0.44 (or two thirds of the ratio for motor vehicle accidents) (Cherpitel 1994, 1996b).

### 3.12 Quantitative and qualitative sources of uncertainty

Since most of the chronic disease relationships with alcohol depend on biochemical processes linked to average volume of consumption over time, their hazards have been fairly stable across countries (Corrao et al. 2000). On the other hand, injuries are context-dependent to a much larger degree. A good example is the difference between liver cancer and traffic accidents. Based on biochemical evidence, there are reasons to believe that the relationship between average volume of alcohol consumption and liver cancer is relatively stable across different countries and societies, even though epidemiological work tends to be concentrated in established market economies. The most notable exception for chronic disease has been IHD, where patterns of drinking play a decisive role in determining the impact of average volume of drinking. On the other hand, the number of accidents (and alcohol-related traffic accidents in particular) depends on many background variables, as illustrated above. Thus, the risk relations between injuries and alcohol are much less stable and their transferability is more questionable. Where it has to be done, it should carry wider CIs.

Based on the above considerations, the following pertain.

- For chronic diseases, estimates of relative risk are usually based on meta-analyses of more than 20 studies with relatively small CIs. The uncertainty introduced by cross-population transfer of data is not that large, as the relationships depend on biochemical mechanisms. It is therefore suggested that $\pm 15 \%$ of the point estimate be used as the standard in an uncertainty analysis. This applies to all chronic disease categories where AAFs are directly derived from prevalence and relative risk.
- In all cases where AAFs are derived in other ways (e.g. injury), these fractions are more influenced by contextual differences from one region to another and should thus be modelled with more uncertainty. We suggest $\pm 30 \%$ of the point estimate to account for additional assumptions.
- IHD is the notable exception. In this case, estimates differ considerably (see the heterogeneity in the meta-analysis of Corrao et al. 2000), with respect not only to the magnitude but also to the direction of the relation. To account for this uncertainty and the difference of estimates in different models, we suggest the values set out in Table 12.23.
Table 12.23 is based on the following assumptions.
- For AMR-A, EUR-A and WPR-A, the results from the individual-level meta-analysis (Corrao et al. 2000) were taken as best estimates. For

Table I2.23 AAF estimates and uncertainty intervals for IHD by subregion

|  | Best estimates |  |
| :--- | :---: | ---: |
| Subregion | Males |  |
| AFR-D | $0.02(-0.05,0.05)$ | Females |
| AFR-E | $0.07(0.00,0.09)$ | $0.00(-0.03,0.03)$ |
| AMR-A | $-0.13(-0.17,0.00)$ | $0.00(-0.03,0.03)$ |
| AMR-B | $0.16(0.00,0.21)$ | $-0.08(-0.12,0.00)$ |
| AMR-D | $0.08(0.00,0.12)$ | $0.02(-0.05,0.05)$ |
| EMR-B | $0.00(-0.03,0.03)$ | $0.03(-0.05,0.05)$ |
| EMR-D | $0.01(-0.03,0.03)$ | $0.00(-0.03,0.03)$ |
| EUR-A | $-0.16(-0.21,0.10)$ | $0.00(0.03,0.03)$ |
| EUR-B | $0.11(-0.13,0.15)$ | $-0.13(-0.17,0.04)$ |
| EUR-C | $0.15(0.10,0.20)$ | $0.00(-0.08,0.05)$ |
| SEAR-B | $0.01(-0.03,0.03)$ | $0.03(0.02,0.04)$ |
| SEAR-D | $0.04(-0.03,0.03)$ | $0.00(-0.03,0.03)$ |
| WPR-A | $-0.17(-0.23,-0.10)$ | $0.00(-0.03,0.03)$ |
| WPR-B | $0.01(-0.05,0.05)$ | $-0.13(-0.17,-0.07)$ |

a Best estimates derived from relative risk and not from multilevel estimates.
these subregions the results from the aggregate multilevel analysis were taken as upper limits, and $30 \%$ lower than the best estimate as lower limits.

- For EUR-B, the aggregate multilevel results were taken as best estimates, and the results from the individual-level analysis was taken as lower limit, and $30 \%$ higher than the best estimate as upper limit.
- For all other subregions, the aggregate multilevel analysis results were taken as best estimates and, based on pattern and volume of the subregion, uncertainty intervals were chosen as follows:
- $\pm 0.03$ in the case of low-volume drinking (average $<3 \mathrm{~g} /$ day) and average pattern values lower than 3.5;
- $\pm 0.05$ in the case of females for volumes $>3 \mathrm{~g} /$ day and average pattern values lower than 3.5 (this restriction for females was intended to account for the higher uncertainty of pattern values for females); and
- for all other estimates zero was taken as the lower bound, and the best estimate plus $30 \%$ as the upper bound (except for EURC, the only subregion with an average pattern value greater than 3.5).

A number of points need to be emphasized when interpreting these results. The underlying research for chronic disease is quite heterogeneous with respect to quality. In particular, measurement of alcohol provides limited information on patterns of drinking and for characteristics of abstainers. Most studies have just one time measurement of exposure. Often cohorts were selected with respect to minimizing loss to followup, and thus samples with more regular, low-to-moderate drinking styles were used. This constitutes a problem for estimating the effects of patterns of drinking, as well as for estimating the effects of continuous heavy drinking.

There is also a problem of measuring exposure with respect to acute consequences, although slightly different because often the BAC is given as the only indicator. Such a measure does not allow one to differentiate between the effects of pattern of drinking and average volume of alcohol consumption, as a heavy drinking occasion may be the exception or the norm. But for the population level, we need both types of information, as numbers of injuries will depend on both (see above). In addition, the BAC alone does not allow one to determine if alcohol was a contributing causal factor or not, only in combination with other information on control conditions, i.e. series of BACs in accident and non-accident conditions (Borkenstein et al. 1964). Unfortunately, such control conditions are lacking in most research (Gmel and Rehm 2003). Thus, with the exception of traffic accidents, the overall quality of the underlying research for most alcohol-related acute outcomes is of poor quality and derived AAFs may be subject to considerable error. This is reflected in the wide uncertainty margins suggested above.

### 3.13 Estimates of risk reversibility

Part of the risk from alcohol is immediately reversible: all acute risks can be completely reversed if alcohol is removed. Chronic diseases often depend on lifetime exposure, and thus risk is often reduced but not completely eliminated by removal of alcohol.

On the other hand, there are indications that a reduction of alcohol consumption in populations is associated with a fairly rapid decrease in chronic diseases such as liver cirrhosis. For example, time series analyses showed that decreases in per capita consumption were associated with considerable concurrent reductions in liver cirrhosis (e.g. Ramstedt 2001; Skog 1980; and especially Cook and Tauchen 1982).

Another example of a chronic condition with rapid, sometimes almost immediate remission is depression. In fact, most studies come to the conclusion that many depressive syndromes markedly improve within days to weeks of abstinence (Brown and Schuckit 1988; Dackis et al. 1986; Davidson 1995; Gibson and Becker 1973, Penick et al. 1988; Pettinati et al. 1982; Willenbring 1986).

It is not clear what effect alcohol removal would have on alcohol use disorders. Clearly, some criteria of both alcohol dependence and harmful
use of alcohol would no longer apply (e.g. continued use despite harmful consequences).

## 4. DISCUSSION OF ESTIMATES OF ALCOHOLATTRIBUTABLE BURDEN

### 4.1 Mortality

Alcohol-related burden of disease is considerable: $3.2 \%$ of global mortality and $4.0 \%$ of global burden of disease as measured in DALYs. In terms of alcohol-related mortality, almost half of the global burden $(46 \%)$ is related in acute causes, i.e. unintentional and intentional injuries (see Table 12.24; details in Appendix C). Within this mortality burden, for acute causes, unintentional injuries are by far the most important. The next important category is malignant neoplasms with $20 \%$ of the overall alcohol-related mortality burden, followed by cardiovascular diseases ( $15 \%$ of all alcohol-attributable deaths) and other noncommunicable diseases, a category almost entirely made up of liver cirrhosis ( $13 \%$ ). Cardiovascular deaths are a special case in that different patterns of drinking lead to beneficial and detrimental outcomes. Thus, the net result of $15 \%$ does not give a clear picture of the underlying structure. Going beyond the net result, alcohol was estimated to cause a total of almost 600000 cardiovascular deaths in the year 2000, exceeding even the alcohol-related burden of unintentional injuries. This figure was partly "offset" by the beneficial effects of alcohol on IHD and stroke. More males than females die of the effects of alcohol, with a ratio of about $10: 1$.

Table I2.24 Global deaths (000s) attributable to alcohol by major disease and injury categories, 2000

| Disease or injury | Males | Females | Total | Percentage of all <br> alcohol-attributable deaths |
| :--- | ---: | :---: | :---: | :---: |
| Conditions arising during the <br> perinatal period | 2 | 1 | 3 | 0 |
| Malignant neoplasms | 269 | 86 | 355 | 20 |
| Neuro-psychiatric conditions | 91 | 19 | 111 | 6 |
| Cardiovascular diseases | 392 | -124 | 268 | 15 |
| Other noncommunicable diseases | 193 | 49 | 242 | 13 |
| (type II diabetes, liver cirrhosis) |  |  |  |  |
| Unintentional injuries | 484 | 92 | 577 | 32 |
| Intentional injuries | 206 | 42 | 248 | 14 |
| Alcohol-related mortality (all causes) | 1638 | 166 | 1804 | 100 |
| All deaths | 29232 | 26629 | 55861 | In comparison, estimated |
| Percentage of all deaths that can | 5.6 | 0.6 | 3.2 | total for I990: I.5 |
| be attributable to alcohol |  |  |  |  |

The overall relationship between average volume of alcohol consumption and all-cause mortality is thus J-shaped in established market economies for age groups under 45 years, where benefits of light to moderate consumption on IHD apply (Holman et al. 1996; Rehm et al. 2001c). In countries with a predominant pattern of irregular heavy drinking, no J-shape can be expected and the shape between alcohol and all-cause mortality is expected to increase monotonically.

The estimated percentage of alcohol-attributable mortality (3.2\%) is more than double that estimated in the 1990 GBD study $(3.2 \%$ vs $1.5 \%)$. There are several reasons for this increase. First, alcohol consumption has increased overall, especially in the very populous SEAR-B, SEAR-D and WPR-B subregions, including China and India. In addition, in these subregions we do not expect benefits of drinking, unless the current patterns of drinking change to the positive. Second, the relative impact of injuries and chronic disease on overall mortality, both of which are related to alcohol, has increased over the past 10 years. Third, the methodologies are not comparable between the two estimates. The 2000 estimate differs in the following three major respects.

- It is much more disaggregated, with respect both to burden categories and to regional data. Thus, the present work has included adult per capita data for almost all countries, and much more survey-related data than available for the 1990 estimates.
- The present exercise explicitly includes quantifiable patterns of drinking for both IHD and injuries, whereas the 1990 estimates were almost entirely based on volume of consumption. This difference is most striking with regard to IHD, where the 1990 study considered only beneficial effects. The current exercise estimates both beneficial and detrimental effects, depending on patterns of drinking.
- The meta-analyses on average volume of consumption and different disease outcomes have become much more refined in terms of methodology (compare, e.g. Corrao et al. 1999, 2000 with the methodology of English et al. 1995).

Finally, the estimates in this work are restricted to GBD disease categories. Several diseases related to alcohol could not be accounted for, most notably cardiac arrhythmias and heart failure. In the GBD disease categories, cardiac arrhythmias and heart failure would be part of "other cardiac conditions". We had neither epidemiological studies on the hazards for various diseases in this broad category nor any data on the relative proportion of cardiac arrhythmias and heart failure among other cardiac conditions by subregion and sex, in order to separate these diseases. In addition, oesophageal varices, acute and chronic pancreatitis and several conditions occurring during the perinatal period could not be included for similar reasons. However, their alcohol-attributable mor-
tality burden would be likely to be minor compared to the "other cardiac conditions" mentioned above.

### 4.2 DALYs

Alcohol-attributable DALYs are summarized in Table 12.25. See Appendix D for details by subregion.

The biggest shift in the relative impact of disease categories compared to the pattern for alcohol-caused mortality is seen for neuropsychiatric diseases. Neuropsychiatric diseases are often disabling, but rarely fatal, and this is reflected in the markedly higher proportion of overall disease burden due to alcohol ( $38 \%$ ) in this category compared to alcohol-attributable mortality ( $6 \%$ ). Males have far more ( $>5$-fold) alcohol-related disease burden than females. The mortality and burden of disease figures presented here are net figures, where the alcohol-related beneficial effects on disease have been subtracted from its harmful effects. Therefore, the detrimental effects of alcohol on mortality, and disease burden in general, far outweigh the beneficial effects.

What are the most striking differences between subregions? Clearly alcohol-related burden is most detrimental in the developed world. Here $9.2 \%$ of the entire disease burden is attributable to alcohol, only exceeded by the burden attributable to tobacco and blood pressure (see Table 12.26 and WHO 2002). Here also, the ratio of males to females is lowest. However, as Table 12.26 indicates, alcohol also places a toll on health in the developed world, with relatively low mortality

Table I 2.25 Global burden of disease in 2000 attributable to alcohol according to major disease categories (DALYs in 000s)

| Disease or injury | Males | Females | Total | Percentage of all alcohol-attributable DALYs |
| :---: | :---: | :---: | :---: | :---: |
| Conditions arising during the perinatal period | 68 | 55 | 123 | 0 |
| Malignant neoplasm | 3180 | 1021 | 4201 | 7 |
| Neuro-psychiatric conditions | 18090 | 3814 | 21904 | 38 |
| Cardiovascular diseases | 4411 | -428 | 3983 | 7 |
| Other non-communicable diseases (type II diabetes, liver cirrhosis) | 3695 | 860 | 4555 | 8 |
| Unintentional injuries | 14008 | 2487 | 16495 | 28 |
| Intentional injuries | 5945 | 1117 | 7062 | 12 |
| Alcohol-related disease burden all causes (DALYs) | 49397 | 8926 | 58323 | 100 |
| All DALYs | 761562 | 693911 | 1455473 | In comparison, estimated total |
| Percentage of all DALYs that can be attributable to alcohol | 6.5 | 1.3 | 4.0 | for 1990: 3.5 |

Table I2.26 Burden of disease in 2000 attributable to tobacco, alcohol and drugs, by development status and sex

|  | $\begin{gathered} \text { High-mortality developing } \\ \text { subregions } \\ \text { (AFR-D, AFR-E, AMR-D, EMR-D, SEAR-D) } \end{gathered}$ |  |  | Low-mortality developing subregions <br> MR-B, EMR-B, SEAR-B, WPR-B) |  |  | Developed subregions <br> (AMR-A, EUR-A, EUR-B, EUR-C, WPR-A) |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | Males | Females | Total | Males | Females | Total | Males | Females | Total |
| Total DALYs (000s) | 420711 | 412052 | 832763 | 223181 | 185316 | 408497 | 117670 | 96543 | 214213 |
| Smoking and oral tobacco | 3.4\% | 0.6\% | 2.0\% | 6.2\% | 1.3\% | 4.0\% | 17.1\% | 6.2\% | 12.2\% |
| Alcohol | 2.6\% | 0.5\% | 1.6\% | 9.8\% | 2.0\% | 6.2\% | 14.0\% | 3.3\% | 9.2\% |
| Illicit drugs | 0.8\% | 0.2\% | 0.5\% | 1.2\% | 0.4\% | 0.8\% | 2.4\% | 1.2\% | 1.8\% |

patterns. Here the disease burden attributable to alcohol is the highest of all 26 risk factors examined in the CRA of the GBD study in 2000 (Ezzati et al. 2002). In high-mortality developing subregions, in Africa and parts of south-east Asia, alcohol is not yet one of the major risk factors. Here, the most important risk factors are underweight, unsafe sex, unsafe water, sanitation and hygiene, and other environmental factors. However, if past developments can help predict the future, we can expect that the alcohol-attributable burden will increase in these subregions along with economic development (see also section 5).

### 4.3 Conclusions

Alcohol causes a considerable burden of disease, in terms both of mortality and disability. While the total elimination of alcohol is not realistic, there are evidence-based policy measures that could substantially reduce the burden of alcohol. The recent review by Ludbrook et al. (2001) on measures to reduce alcohol misuse assessed the quality of evidence for four types of intervention aimed at reducing alcohol use and its consequences. Their findings coincide with a number of earlier reviews (e.g. Bruun et al. 1975; Edwards et al. 1994) and with the overview of Babor et al. (2003). In sum, the following measures were found quite effective:

- policy and legislative interventions, including taxation on alcohol sales, drink-driving laws, restricted licensing of outlets and advertising controls;
- law enforcement, for example random breath-testing of drivers;
- community interventions; and
- brief interventions.

On the other hand, mass media and awareness campaigns were not found to be very effective, although they seemed to be somewhat more popular with politicians and policy-makers.

Since these interventions exist and have been empirically shown to reduce the burden of both chronic and acute disease caused by alcohol, and also alcohol-attributable social harm, there is no justification for alcohol-related disease to remain at such a high level in many parts of the world.

## 5. Projections of the future

Quantitative projections regarding future exposure to alcohol are feasible only for average volume of drinking, since it is extremely difficult if not impossible to judge how drinking patterns will alter over time (see Figures 12.3-12.5).

Adult per capita consumption in EUR-A and EUR-B seems to be driven by long-term trends (Mäkelä et al. 1981; Simpura 1998). There

Figure I 2.3 Adult per capita consumption in litres of absolute alcohol for the AFR, EMR and EUR subregions

Figure 12.4 Adult per capita consumption in litres of absolute alcohol for the SEAR and WPR subregions

are indications that the current downward trend is levelling off. However, it is very hard to determine the period of long-term waves with short-term time series since 1960 or so. Thus, we predict a stable exposure for EUR-A and EUR-B at about the average level of consumption of the past 10 years. For EUR-C, the curve shows the most change. The dip at the end of the 1980s is due to the anti-alcohol campaign of the Gorbachev period in the former Soviet Union (White 1996). At the end

Figure I 2.5 Adult per capita consumption in litres of absolute alcohol for the AMR subregions

of the campaign, alcohol consumption rose again to former levels. Again, since there is no clear trend after the campaign, we predict about the same level of consumption as the average of the years after the end of the Gorbachev campaign. No trends are apparent for EMR-B, EMR-D and AFR-D. Therefore, the most reasonable projection of future alcohol consumption would be the level of current consumption. To obtain more stable estimates, the average of the 1990s has been used.

For the South-East Asia and Western Pacific subregions, the following predictions appear justified based on the trend data shown in Figure 12.4. For WPR-A, there was an upward trend that seems to have stopped at the end of the 1980s; thus, the average volume of the 1990s was used as the best projection. For WPR-B and SEAR-B, consumption clearly increased and we modelled future consumption by a linear upward trend. The upward trend in SEAR-D was less pronounced, but nonetheless present, and we therefore again used the linear upward trend.

In the Americas, there has been a long wave of increasing and then decreasing consumption for North America (AMR-A), almost parallel to the European consumption. For AMR-B and AMR-D there are slight downward trends. Since the long-term wave seems to turn upwards again, and since the downward trends did not reach significance, it seems prudent to model the future for all three subregions at about the same as the average of the 1990 s, as a stable estimate of the status quo.

Trends in drinking patterns have been studied in very special subsets of populations, such as youth in Europe (Hibell et al. 2000). But at the global level, for pattern of drinking, there is not even enough reliable data concerning the current situation, and thus quantitative predictions
are not possible. Therefore we assumed constant drinking patterns under a "business-as-usual" scenario. Projections of future adult per capita alcohol consumption are given in Table 12.27.

In three subregions (SEAR-B, SEAR-D and WPR-B) unrecorded consumption has to be added in order to predict burden, and these data need to be converted into drinking categories as above, based on surveys. Since we have neither survey data on the future nor any predictions for survey or unrecorded consumption, we suggest modelling future consumption as follows.

- For all subregions except SEAR-B, SEAR-D and WPR-B, predictions are based on 2000 data on proportions of drinking categories.
- Proportions of drinking categories II and III are increased by $2.1 \%$ over those for 2000 for SEAR-B and WPR-B, and by $0.7 \%$ for SEARD (Table 12.28). Of course, there are limits of linear increase, and we considered the current levels of consumption in the A subregions as upper limits.

In summary, the best estimates predict global increases in average consumption of alcohol, triggered by increases in developing and emerging economies in the South-East Asia and Western Pacific regions.

Table 12.27 Projections of adult per capita consumption by subregion, in litres of pure alcohol, excluding SEAR-B, SEAR-D and WPR-B

|  | Subregion |  |  |  |  |  |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: |
|  | AFR-D | AFR-E | AMR-A | AMR-B | AMR-D |  |
| Mean | 3.543 | 4.127 | 8.276 | 6.669 | 3.462 |  |
| 95\% Cl upper | 3.608 | 4.258 | 8.428 | 6.826 | 3.558 |  |
| 95\% Cl lower | 3.478 | 3.996 | 8.125 | 6.512 | 3.366 |  |
| SD | 0.085 | 0.171 | 0.197 | 0.204 | 0.125 |  |
| Trend | No trend | No trend | Long waves | No trend | No trend |  |
|  |  |  |  |  |  |  |
| EMR-B | EMR-D | EUR-A | EUR-B | EUR-C | WPR-A |  |
| Mean | 1.248 | 0.238 | 12.632 | 5.372 | 8.316 | 7.012 |
| $95 \% ~ C l ~ u p p e r ~$ | $I .355$ | 0.245 | 13.008 | 5.552 | 8.845 | 7.127 |
| $95 \%$ Cl lower | $I .142$ | 0.231 | 12.255 | 5.192 | 7.787 | 6.897 |
| SD | 0.139 | 0.009 | 0.490 | 0.234 | 0.688 | 0.149 |
| Trend | No trend | No trend | Long waves | No trend | No trend | Long waves |

Table 12.28 Projections of adult per capita consumption by subregion, in litres of pure alcohol, for SEAR-B, SEAR-D and WPR-B

|  | Subregion |  |  |
| :--- | :---: | :---: | :---: |
|  | SEAR-B | SEAR-D | WPR-B |
| Increase per year in litres <br> of pure alcohol after 2000 | 0.063 | 0.014 | 0.108 |
| $95 \% \mathrm{Cl}$ upper | 0.068 | 0.016 | 0.115 |
| $95 \% \mathrm{Cl}$ lower | 0.057 | 0.012 | 0.102 |
| Increase in adult per capita <br> consumption 2000 (\%) | 2.1 | 0.7 | 2.1 |
| Trend | Linear upward | Linear upward | Linear upward |
| Shared variation: year and 1960-1999a <br> consumption | $88.0 \%$ | $93.2 \%$ | $96.8 \%$ |

The shared variation or "explained variance" denotes a measure of strength of the relationship, i.e. how much of the variation of adult per capita consumption is explained by the linear trend.

## Acknowledgements

Parts of an earlier version of the contributions were made available on the WHO listserve for discussion, and we should like to thank all who responded. In addition, the authors would like to thank the following participants in the WHO expert meetings on alcohol as a risk factor for the burden of disease, held in Geneva on 29-30 January and 7-8 May 2001, for their valuable comments when revising prior versions: Mary Jane Ashley, Mary Assunta, Vivek Benegal, Susan Bondy, Ruth Bonita, Maximilian de Courten, Majid Ezzati, Oye Gureje, Wei Hao, Jennifer Hillebrand, Claudio Jeronimo da Silva, Håkan Leifman, Alan Lopez, Maria-Elena Medina-Mora, Zofia Mielecka-Kubien, Alexander Nemtsov, Ian B. Puddey, Margret Rihs-Middel, Leanne Riley, Kari J. Rummukainen, Shekhar Saxena, Raquel Shaw Moxam, Jussi Simpura, Bedirhan Üstün and Justin Willis.

Many people, too numerous to be listed here, contributed with data, and we wish to thank all of them for their help. Special thanks go to Ed Adlaf, Tom Greenfield, Wei Hao, Håkan Leifman, Maria-Elena MedinaMora and Tim Stockwell for conducting data analyses or data searches specifically for this exercise. Special thanks also go to Ron Kessler and his team, who provided specific estimates for the point on alcohol and depression, without which it would have been impossible to estimate alcohol-attributable burden on depression.

WHO, the Swiss Federal Office of Public Health (contract no. 00.001588), the Swiss National Science Foundation, the Addiction Research Institute in Zurich, Switzerland, the Swiss Institute for the Prevention of Alcohol and Other Drug Problems in Lausanne, and the

Centre for Addiction and Mental Health in Toronto, provided financial and/or technical support for this study.

Parts of the assessment of relations between alcohol and disease were undertaken for the report The social costs of alcohol consumption in Switzerland and received financial support from the Swiss Federal Office of Public Health (grant no. 98-000794/8120).

Several anonymous reviewers, as well as the members of the editorial committee (Majid Ezzati, Alan Lopez, Anthony Rodgers), deserve special thanks for their help in finalizing the text, as does Steve Vander Hoorn for the repeated burden calculations.

Finally, the authors would like to thank the staff at the Swiss Institute for the Prevention of Alcohol and Other Drug Problems in Lausanne and the Addiction Research Institute in Zurich, especially Irene Bosshard and Elisabeth Grisel, for technical assistance.

## Notes

1 See preface for an explanation of this term.
2 Social outcomes of alcohol consumption are defined as changes that affect the social behaviour of individuals, or their interaction with partners and other family members, or their circumstances (Rehm 2001). Social outcomes would include family problems, public disorder, or workplace problems (for overviews see Gmel and Rehm 2003; Klingeman and Gmel 2001). Social outcomes or consequences are not addressed in this chapter unless they are included in ICD-10. The majority of these problems are not covered by ICD-10, even though health is broadly defined by WHO to include well-being.

3 Intoxication and dependence are of course also influenced by biochemistry. However, since these two intermediate outcomes are central in shaping the effect of alcohol on many health and social outcomes, they are discussed separately. The other effects (e.g. on promotion of blood clot dissolution) are often specific for one disease or a limited group of diseases. Both intoxication and dependence are defined as health outcomes in ICD-10.
4 This is not to imply that there is no drinking to intoxication or occasions of heavy drinking in countries with established market economies; it is simply to say that this pattern of drinking is more common in countries with developing or emerging economies.
5 There are other ways of estimating unrecorded consumption, such as those based on available raw materials (see the estimates for the Russian Federation by Nemtsov 1998, 2000, 2002).
6 Surveys do not necessarily underestimate the recorded per capita consumption, even though the literature sometimes appears to imply it. For some countries, e.g. Mexico, adding up the figures from the survey may lead to higher estimates than the recorded per capita consumption.
7 This questionnaire can be obtained from the first author on request. It was finalized at a WHO expert meeting in Geneva, May 2001.

8 For comparison, a $75-\mathrm{cl}$ bottle of wine contains about 70 g of pure alcohol.
9 As part of the process of developing these ratings, an earlier list of derived and assigned pattern values as shown in Table 12.3 was made available on a WHO listserve to a large number of key informants for critical assessment. This process resulted in the identification of local surveys, which helped improve the estimates.
10 This reasoning was also behind the list of those invited to a WHO workshop on unrecorded consumption in May 2001, where experts from Brazil, China, India, Nigeria and the Russian Federation met with other experts on the methodology of estimating unrecorded consumption to discuss current estimates and develop a methodology to improve data gathering.

11 Ledermann had been the first to claim that the distribution of alcohol consumption among drinkers is log-normal. Subsequent research found the exact shape to be different but still approximately log-normally distributed (e.g. Duffy 1986 and rejoinders).
12 These analyses are sometimes also called hierarchical linear analyses (Bryk and Raudenbush 1992). Since the term "hierarchical" is ambivalent (in sociology it has also been used to describe stepwise regression), we exclusively use the term "multilevel" in this chapter.

13 In the statistical literature units are called sections, hence the method used is called cross-sectional time series analysis. In our case, countries are sections.

14 Europe was taken as a pilot as data are most available there. The current analysis included data from 81 countries for injuries and 74 countries for IHD, most of them outside Europe.
15 Year is only controlling for the linear part of the time structure. However, sensitivity analyses were carried out to estimate the performance of the method used.

16 "Random" does not mean that the underlying relationships are completely random. Effects may be partly deterministic owing, for example, to different policies. The term "random" here means that effects across sections or countries cannot be estimated without error, and the errors are assumed to have a random distribution.

17 If the patterns were estimated as deviations from mean patterns, then the value of $\gamma_{10}$ would reflect the average impact of adult per capita consumption.
18 Even for biologically based relationships, the relationship could be moderated by other factors such as diet (e.g. alcohol may be related to breast cancer through hormonal effects, but diet also affects hormonal levels and this may have an influence on the alcohol-breast cancer relationship). However, except for IHD, meta-analyses on alcohol and chronic disease have yielded fairly similar effects for different populations, so the assumption of applying the same effect for average volume of drinking is probably justified.
19 Such "categorical" attribution is quite different from the statistical estimation used in other epidemiological studies. For the usual derivation of alcohol-attributable fractions see Rothman and Greenland (1998b).

20 Type of beverage has been excluded so far from our consideration of patterns of drinking. While the evidence is not conclusive on the effect of beverage on all-cause mortality or on cardiovascular disease (e.g. Gruenewald et al. 2000; Kerr et al. 2000; Rimm et al. 1996), there are some indications that cancers of the gastrointestinal tract are differentially influenced by alcohol in higher concentration.
21 Part of this lack of an influence on patterns of cancer risk may be due to methodological reasons. Most epidemiological studies measure only volume of consumption and model only monotonically increasing trends, and thus could not detect any influence of patterns of drinking even if they were present.
22 In the Inter-American Investigation of Mortality, which studied 4000 deaths in each of 12 cities in 1962-1964, the final assignment of all deaths from cirrhosis "with mention of alcoholism" was $80.4 \%$ of all cirrhosis deaths. About half of these had been "without mention" on the death certificate. Only in Santiago and Mexico City was the final assignment for "with mention" less than twice the initial number. The study used searches of medical records and interviews with decedents' families and attending physicians to reassign deaths from the initial classification (Room 1972, based on Puffer and Griffith 1967).
23 IHD is used here for denoting all diseases with ICD-9 rubrics 410-414 (ICD10: I20-I25). The same categories have also been labelled coronary heart disease (CHD).
24 DisMod is a software tool that may be used to check the internal consistency of epidemiological estimates of incidence, prevalence, duration and case fatality for diseases. The latest version (DisMod II) is distributed by WHO: http://www3.who.int/whosis/burden/burden_dismod/burden_dismod_dismo d2.cfm?path=whosis,burden, burden_dismod,burden_dismod_dismod2\& language=english.
25 The notion of a causal contributing role is at the heart of the epidemiological concept of causality (Rothman and Greenland 1998). According to such standards, as explained in the text, the causal role of alcohol in intentional injuries is established. According to criteria used in criminology, this may not be the case.

26 Part of the effect of alcohol on aggression or on other more social outcomes is due to psychological variables. The term "expectations" denotes the individual predictions and expectancies of what will happen after consumption of alcohol. Experimental research has demonstrated that such psychological variables play a role in determining outcome.
27 Often traffic accidents are described as if the environment's effects are totally independent of the person's behaviour. However, tired drunk-drivers on the road at 03:00 might well not have been there if they had not been drinking. Intentionality (and alcohol's effects on it) forms part of what are called "accidents".

28 Odds $=\mathrm{p} /(1-\mathrm{p})$.

Appendix A: "Pattern of drinking" variables and their
Relative weights
Heavy drinking occasions
(Maximum of 11 points for this component)
Daily drinking
Less than $20 \%$ daily drinking for males: 1 point
Less than $10 \%$ daily drinking for females: 1 point
Frequency of getting drunk
Most male drinkers usually get drunk when they are drinking: 2 points
Most males drinkers often get drunk: 1 point
Most female drinkers usually or often get drunk: 1 point
Usual quantity per drinking session
Males: more than $60 \%$ typically consume four or more drinks per session: 2 points
Males: between $40 \%$ and $60 \%$ consume four or more drinks per session: 1 point
Females: more than $50 \%$ consume four or more drinks per session: 2 points
Females: between $35 \%$ and $50 \%$ consume four or more drinks per session: 1 point

Fiesta binge drinking
Males: fiesta drinking commonly occurs: 1 point
Females: fiesta drinking commonly occurs: 1 point
DRINKING WITH MEALS
(Maximum of 4 points for this component)
Males: rarely or never with meals: 2 points
Males: sometimes with meals: 1 point
Females: rarely or never with meals: 2 points
Females: sometimes with meals: 1 point

## Drinking in public places

(Maximum of 2 points for this component)
Males: common and everyday: 1 point
Females: common and everyday: 1 point
Scoring (Possible range: 0-17 POINTS)
Scoring by summation of individual questions: range $0-17$
10-17 points: assign a pattern value of 4
7-9 points: assign a pattern value of 3
4-6 points: assign a pattern value of 2
$0-3$ points: assign a pattern value of 1
Appendix B: Alcohol-attributable fractions (AAFs) for mortality from injuries
Note: AAFs for morbidity from injuries were derived by multiplying the mortality AAFs by two thirds for motor vehicle accidents and by four ninths for all other types of injury.

| AFR-D |  | Age group (years) |  |  |  |  |  |  |  |  |  |  |  |

## Chapter 13

Illicit Drug use<br>Louisa Degenhardt, Wayne Hall, Matthew Warner-Smith and Michael Lynskey

## Summary

Estimating mortality directly attributable to illicit drug use such as overdose death - the most tangible adverse heath effect of illicit drug useis difficult because of variations in the quality and quantity of mortality data. As a result, it is necessary to make indirect estimates, involving estimates of the prevalence of illicit drug use. However, it is difficult to make even indirect estimates because the use of these drugs is illegal, stigmatized and hidden. Nonetheless, efforts must be made to estimate the contribution that illicit drug use makes to the global burden of disease, because it is a pattern of behaviour that has a substantial adverse effect on the health of those who engage in it. In cohort studies of treated drug users the problematic use of illicit drugs has been associated with an increased overall rate of mortality, and with an elevated rate of a number of individual causes of death, four of which were estimated here: AIDS, overdose, suicide and trauma.

Definitions of the variable of interest are difficult because of deficiencies in the data collected by countries on illicit drug use, and by disagreements over what constitutes "problematic" illicit drug use. The definition used here was long-term regular injecting use of opioids, amphetamines or cocaine. Data on the prevalence of problematic illicit drug use were derived from a range of sources that used variable methods of deriving estimates.

A literature search was conducted of all studies that estimated the prevalence of problematic drug use. Available data on prevalence in countries with data were used to estimate the prevalence of problematic illicit drug use for subregions. ${ }^{1}$ A search was also completed for cohort studies of drug users that had estimated mortality due to the four individual causes of death, and to all causes of death. Data on the number of years of follow-up were extracted from each study and a weighted average annual mortality rate was calculated for each of the four causes
of death, and for their sum. A standardized mortality ratio (SMR) was also derived from previous estimates of the excess mortality from all causes attributable to illicit drugs. Estimates were made for some causes by applying an attributable fraction obtained from sources such as the Joint United Nations Programme on HIV/AIDS (UNAIDS) (for HIVrelated deaths) to estimates of total deaths for some causes. The median estimate of a range of estimates was used as the estimate for each subregion. Estimates were limited to persons aged 15-54 years.

In 2000, the median number of global deaths attributed to illicit drugs estimated by summing the four causes of death was 194058 . There were an additional 10000 deaths from overdose above and beyond those coded as drug use disorders (added to unintentional injuries) or when coded drug use disorder deaths were higher than estimated overdose deaths. The median 2000 estimate derived using the all-cause method was 197383 . Both estimates had wide uncertainty intervals around them ( 113494 to 276584 for sum of four causes; and 101751 to 322456 for all-cause estimates). When morbidity attributable to illicit drug use is added to the estimated mortality, this risk factor accounts for $0.8 \%$ of global disability-adjusted life years (DALYs). The distribution of numbers of deaths between subregions varied between the two methods. These variations in the estimates reflect the considerable uncertainty about prevalence of drug use in different subregions and uncertainty about the applicability of mortality data derived in developed countries to mortality among illicit drug users in developing countries.

The current estimates suggest that illicit drug use is a significant cause of premature mortality among young adults. This is an underestimate of total disease burden because: (i) there are deficits in data on mortality attributable to the use of some illicit drug (most notably cannabis and the newer synthetic drugs like MDMA ${ }^{2}$ ); (ii) there are differences across subregions in the quality of data available on the causes of mortality that were included in the current estimates; (iii) there is an absence of data that would permit estimates of some other causes of mortality and morbidity attributable to illicit drug use, such as hepatitis B and hepatitis C and violence. There is a need for better data on: the prevalence of illicit drug use in developed and developing countries, and on the mortality and morbidity attributable to problematic drug use.

## 1. Introduction

The use of legally proscribed psychotropic substances for non-medical purposes appears to be increasing in many parts of the world (Frischer et al. 1994; UNDCP 2000; UNODCCP 2000) but it is difficult to quantify the rate of increase. It is difficult to estimate the prevalence of this behaviour and its adverse health consequences in individual societies because this behaviour is illicit and therefore often hidden. Even estimating mortality related to illicit drug use, the most tangible adverse
heath effect, is difficult for reasons that are discussed below (Thorley et al. 1977). Nonetheless, efforts must be made to estimate the contribution that illicit drug use makes to the global burden of disease because it is a pattern of behaviour that has a substantial adverse effect on the health and well-being of those who engage in it, producing substantial loss of life and disability (Hulse et al. 1999).

The global burden of death and disability attributable to illicit drugs was first estimated by Donoghoe (1996), as part of the Global Burden of Disease (GBD) project (Murray and Lopez 1996). Donoghoe estimated that illicit drug use was responsible for 100000 deaths globally in 1990 , the majority of which ( $62 \%$ ) occurred in developing countries. Murray and Lopez (1996) pointed out that this estimate may be too low because of difficulties in reliably estimating the prevalence of illicit drug use and its adverse health effects. Donoghoe's estimate was based on the attributable fractions of various causes of mortality and morbidity attributed to illicit drug use by English et al. (1995), who reviewed all studies published up to 1993. The great majority of these studies, which were principally cohort studies, were conducted in the United States of America and Europe.

Since these estimates were made, there has been an apparent increase in illicit drug consumption in developed societies (Australian Bureau of Criminal Intelligence 2000; EMCDDA 2000; Frischer et al. 1994; UNODCCP 2000), and increased incidence of HIV contracted as a result of sharing of injecting equipment by illicit drug users in developing societies (Stimson 1993). This suggests that Donoghoe's 1990 estimates are likely to substantially underestimate the contribution that illicit drug use makes to the global burden of disease in 2000.

In this chapter, we have attempted to estimate the burden of disease due to illicit drug use by combining a range of sources of data on the prevalence of use and indicators of outcome. We also outline the definitions of the "exposure" variable used in making estimates, and outline the causes of burden considered in this chapter. As will become clear, estimates made of this cause of burden are difficult to make given: (i) paucity of data on the prevalence of illicit drug use around the world; (ii) the fact that data on causes of death related to illicit drug use are not well-recorded, so it is necessary to rely on indirect estimates derived from inaccurate prevalence estimates; and (iii) an absence of evidence on the risk of mortality and morbidity due to some causes among illicit drug users.

### 1.1 EXPOSURE VARIABLE

## Substances included

Illicit drug use includes the non-medical use of a variety of drugs that are prohibited by international law. These drugs include: amphetaminetype stimulants, ${ }^{3}$ cannabis, ${ }^{4}$ cocaine, ${ }^{5}$ heroin ${ }^{6}$ and other opioids, ${ }^{7}$ and MDMA (ecstasy). In order to estimate mortality and morbidity attrib-
utable to illicit drug use, we need to clearly define what is and is not included in this risk factor.

This chapter will focus on the burden attributable to amphetamines, cocaine and opioids. Other substances that are illegal in most countries, such as ecstasy, solvents and cannabis, have not been included in the present analysis as there is currently insufficient research information to quantify the health risks associated with these drugs. Thus, their exclusion should not be interpreted as meaning that the use of these drugs is safe. Rather, it reflects a paucity of research on the harm caused by their use.

Relationship to dose, frequency and route of ADMINISTRATION
The risk of premature mortality and morbidity from illicit drug use is dependent on dose, frequency and route of administration. Consequently it is necessary to define what is meant by "use" when defining the exposure variable "illicit drug use". The mortality risks of illicit drug consumption increase with increasing frequency and quantity of consumption (Fischer et al. 1997). Simple prevalence estimates of the proportion of the population that have ever used an illicit drug are likely to be associated with a low average risk since a single occasion of use and infrequent use, the most common patterns of use reported in population surveys, are associated with a small increase in mortality. More accurate estimates of the burden of disease attributable to illicit drugs require estimates of the prevalence of the most hazardous patterns of illicit drug use. These are found in highest prevalence among dependent drug users who typically inject drugs daily or near daily over periods of years. This pattern of use exposes users to the highest chance of fatal overdose (Warner-Smith et al. 2001) and of contracting bloodborne viral diseases (Ross et al. 1992).

The World Health Organization (WHO), following the International Classification of Diseases, defines problem drug use as "harmful drug use" and "drug dependence". Harmful drug use is defined by clear evidence that the substance use is responsible for physical (e.g. organ damage) and psychological harm (e.g. drug-induced psychosis). Drug dependence, as defined in the International Statistical Classification of Diseases and Related Health Problems, tenth revision (ICD-10), requires the presence of three or more indicators of drug dependence (WHO 1993). These include: a strong desire to take the substance; impaired control over the use; a withdrawal syndrome on ceasing or reducing use; tolerance to the effects of the drug; requiring larger doses to achieve the desired psychological effect; a disproportionate amount of the user's time is spent obtaining, using and recovering from drug use; and the user continuing to take other drugs despite associated problems. The problems should have been experienced for at least one month at some time during the previous year. The United Nations Drug Control Programme
(UNDCP) identifies "problem drugs" based on "the extent to which use of a certain drug leads to treatment demand, emergency room visits (often due to overdose), drug-related morbidity (including HIV/AIDS, hepatitis etc.), mortality and other drug-related social ills" (UNDCP 2000).

Most prevalence estimates vary with the assumptions made and the methodology employed. Data provided by the UNDCP do not have the same reliability as large-scale household surveys of the type generally conducted in developed countries. Unfortunately the expense of conducting such surveys makes their use in developing countries unfeasible. Even if such surveys were feasible in all countries, it is generally accepted that surveys underestimate harmful illicit drug use (Hall et al. 2000b).

The European Monitoring Centre for Drugs and Drug Addiction (EMCDDA) has invested considerable resources in developing methods for the collection of data on the prevalence of harmful illicit drug use that are both valid and comparable (EMCDDA 1997). While these standards have been developed for use within the European Union the global adoption of such standards may greatly improve estimates of drugrelated harm. The EMCDDA defines "problem drug use" as injecting drug use (IDU) or long duration or regular use of opioids, cocaine or amphetamines (EMCDDA 1999). The EMCDDA definition is the one that we have adopted in estimating mortality attributable to illicit drugs.

ILLICIT DRUGS NOT INCLUDED IN CURRENT ESTIMATES OF MORTALITY

## Cannabis

Cannabis has a high prevalence of use in many developed societies (Hall et al. 1999b) but there is a lack of well-controlled studies showing that its use increases mortality (Hall and Solowij 1998; WHO 1997). For example, we identified two cohort studies that have examined the effects of regular, prolonged cannabis use on risks of cancer. One of these reported no increase in overall cancer rates among cannabis users (although there were slightly increased rates of prostate and cervical cancer) (Sidney et al. 1997b). A case-control study found a doubling of the odds of aerodigestive cancers among heavy users of cannabis (Zhang et al. 1999) but it was difficult to disentangle the effects of cannabis smoking from those of tobacco smoking because many cannabis users also smoked tobacco (Andreasson and Allebeck 1990).

There are two prospective epidemiological studies of mortality among cannabis users. A Swedish study over 15 years of mortality among male military conscripts found an increased risk of premature death among men who had smoked cannabis 50 or more times by age 18 years (Andreasson and Allebeck 1990). Violent and accidental deaths were the major contributor to this excess. However, the association between mortality and cannabis use disappeared after multivariate statistical adjustment for alcohol and other drug use. Sidney et al. (1997a) re-
ported a 10 -year study of mortality in cannabis users among 65171 members of the Kaiser Permanente Medical Care Program aged between 15 and 49 years. The sample comprised $38 \%$ who had never used cannabis, $20 \%$ who had used less than six times, $20 \%$ who were former users, and $22 \%$ who were current cannabis users. Regular cannabis use had a small association with premature mortality (relative risk of 1.3) that was wholly explained by increased AIDS deaths in men, probably because cannabis use was a marker for male homosexual behaviour in this cohort. It is too early to conclude that cannabis use does not increase mortality because the average age at follow-up was only 43 years, and cigarette smoking and alcohol use were only modestly associated with premature mortality. For these reasons, we have not included any estimate of cannabis' effects on overall premature mortality.

Cannabis produces dose-related impairments in cognitive and behavioural functions that may potentially impair driving an automobile or operating machinery (Chait 1992). These impairments are larger and more persistent in difficult tasks involving sustained attention (Chait 1992). The most serious possible consequence of acute cannabis use is a motor vehicle accident if a user drives while intoxicated (Hall et al. 1994).

The effects of recreational doses of cannabis on driving performance in laboratory simulators and standardized driving courses have been reported as similar to blood alcohol concentrations between $0.07 \%$ and $0.10 \%$ (Hall et al. 1994). However, studies of the effects of cannabis on driving under more realistic conditions on roads have found much more modest impairments (Bates and Blakely 1999; Robbe 1994; Smiley 1999). This is probably because cannabis users are more aware of their impairment and less inclined to take risks than alcohol users (Smiley 1999).

Epidemiological studies of motor vehicle accidents have produced equivocal results because most drivers who have cannabinoids in their blood also have high blood alcohol levels (Hall et al. 1994, 2001). Studies with reasonable numbers of persons who have only used cannabis have not found clear evidence of increased culpability in these drivers (Bates and Blakely 1999; Chesher 1995). For these reasons we have not included any estimate of the contribution that cannabis makes to motor vehicle fatalities.

## Other illicit drugs

Estimating the contribution that MDMA (ecstasy), hallucinogenic substances and inhalants make to premature mortality presents similar problems to cannabis (Boot et al. 2000). While there are case reports of deaths associated with MDMA intoxication (Dowling et al. 1987; Henry et al. 1992; Parr et al. 1997) these appear to be rare by comparison with overdose deaths due to opioids and cocaine in developed societies with good mortality data, such as Australia (Ridolfo and Stevenson
2001). The illicit use of pharmaceuticals and anabolic steroids have also been excluded from further analysis because difficulties in measuring (i) the prevalence of their harmful use and (ii) mortality attributable to their use mean that it is not possible to calculate relative risks. Similarly, the failure to include solvents stems largely from a lack of good evidence on the prevalence and extent or harm attributable to their use.

The exposure variable for illicit drug use in this analysis is, therefore, injection or long duration of use of amphetamines, cocaine or opioids. The failure to include cannabis, MDMA, hallucinogens and inhalants in our estimates of burden of disease attributable to illicit drugs reflects our ignorance of their health risks; it does not imply that the use of these drugs is without risk to users.

## Counterfactual exposure distribution

The theoretical minimum counterfactual exposure distribution is zero illicit drug use. There may be countries in the world that can truly claim to have zero illicit drug use but there must be few of these now. Even countries that have the policy goal of achieving a drug-free society, such as Sweden, do not have zero illicit drug use. Arguably, once illicit drug use and dependence have appeared in a society, it is unrealistic to expect to be able to return to a zero level of illicit drug use. It may be reasonable to aim to reduce the prevalence of the most harmful types of illicit drug use and to minimize the harm that their use causes.

One approach to defining a plausible counterfactual exposure would be to use developed countries with the lowest prevalence of illicit drug use as the basis for the estimate. Countries like Finland and Sweden may be suggested as examples. The weakness with this strategy is that illicit drug use trends are dynamic and countries that currently have low rates may show increases in rates of use (as has recently happened in Sweden) as availability of illicit drugs increases and more favourable social attitudes develop towards illicit drug use among young adults.

It is also not clear what are feasible minimum counterfactuals. It is not clear whether prevention programmes, such as school-based and other intervention programmes, can prevent problem drug use (National Research Council 2001). These programmes have been most widely implemented and evaluated in the United States. After reviewing this evidence, the United States National Research Council recently concluded that the
effectiveness of most of these approaches for reducing substance use is unknown... Some prevention approaches are effective at delaying the initiation or reducing the frequency of tobacco, alcohol and marijuana use [but]...the magnitude of these effects are generally small... [and it] is not clear that preventing or reducing the use of gateway substances translates into a reduced use of cocaine or other illegal drugs (pp. 233-234).

These conclusions have been supported by a recent study of the likely impact of the most effective school-based prevention programmes, which concluded that they would have, at best, very modest effects in preventing cocaine use (Caulkins et al. 1999).

There is better evidence that some treatment programmes (e.g. opioid agonist maintenance treatment) can substantially reduce illicit opioid use and premature mortality from drug overdose ${ }^{8}$ among opioid-dependent persons (Warner-Smith et al. 2001). In the case of opioid-dependent persons, one could examine the effects that enrolling $10 \%$, $20 \%, 30 \%$, etc. of persons who were dependent on illicit opioids in opioid maintenance treatment would have on illicit opioid use, overdose deaths and disability produced by illicit opioid dependence. Similar estimates could be made of the expected reduction in HIV/AIDS among injecting drug users from the introduction of needle and syringe exchange and distribution programmes.

### 1.2 Data sources

To provide data on the prevalence and risks of illicit drug use, a series of extensive computer searches using databases listed below was conducted. The specific parameters of these searches are also listed.

## DATABASES SEARCHED

We carried out a citation search of Medline, Psychinfo and Web of Science, a search of reference lists of identified papers, including a literature search provided by English et al. (1995), which covered the literature published prior to 1993.

## SEARCH TERMS

1. Illicit drug, or substance use, or substance abuse, or drug use, or $d r u g$ abuse, or heroin, or opiates, or cocaine, or amphetamine—limited to human studies published in the English language.

## 2. Prevalence

3. Cohort, or case-control
4. Mortality
5. Morbidity
6. Suicide, or accidents, or HIV, or assault

Strategy: combine 1 and $2 ; 1$ and 3 and $4 ; 1$ and 3 and $5 ; 1$ and 3 and 6.

## 2. Risk factor exposure

### 2.1 Prevalence studies

Given the lack of reliable direct estimates of the health consequences of illicit drug use, it was necessary to make indirect estimates of burden. Hence, the first challenge in quantifying the burden of disease attributable to illicit drugs was to determine the prevalence of exposure to this risk factor. Illicit drug use differs from other risk factors in the GBD project in that one of its defining features, its illegality, makes it difficult to quantify. This presents two problems. First, illicit drug-using individuals are "hidden" and are thus difficult to identify. Second, even if all drug users can be located and interviewed, they may attempt to conceal their use of these drugs.

There are no well-tested and widely accepted "gold standard" methods for producing credible estimates of the number of people who make up the "hidden population" of such drug users (Hartnoll 1997). The preferred strategy is to look for convergence in estimates produced by a variety of different methods of estimation (EMCDDA 1997, 1999). These methods are of two broad types, direct and indirect. Direct estimation methods attempt to estimate the number of illicit drug users in representative samples of the population. Indirect estimation methods attempt to use information from known populations of illicit drug users (such as those who have died of opioid overdoses, and those who are in treatment or the criminal justice system) to estimate the size of the hidden population of illicit drug users.

A large number of studies purporting to be prevalence studies do not present credible prevalence data. Prevalence data reported in peerreviewed literature are scarce and often unrepresentative. In addition, the range of methodologies used makes comparisons between studies difficult. For this reason, other sources of data were sought to complement prevalence estimates reported in the peer-reviewed literature.

### 2.2 Prevalence of problematic illicit drug use

For the purposes of estimating global mortality, data collated by the UNDCP (2000) provides a convenient and comprehensive tabulation of the most recent international prevalence data. The aggregated prevalence data for subregions are displayed in Table 13.1. The principal advantage of using UNDCP data is that it provides a readily accessible set of estimates for the majority of countries in the world. The quality of the data collected and reported by the UNDCP varies across countries and regions from high quality national survey data to key informant and indicator data of uncertain validity.

In some cases, prevalence data provided by the UNDCP were supplemented by data from other agencies, such as the EMCDDA, and the Asian Harm Reduction Network (AHRN). In regions where these addi-
tional data were available, they were used in indirect estimation methods as an additional source of prevalence estimates, thus meaning that these regions had additional estimates of causes of mortality.

UNDCP 2000 DATA ON THE PREVALENCE OF 12-MONTH USE AMONG PERSONS AGED >15 YEARS

Table 13.1 shows the population estimates of each of the 14 subregions, as well as the UNDCP-derived prevalence estimates of problematic use of the three substances considered in current estimates. It can be seen that problematic cocaine use is largely restricted to the Americas, the European Union and the developed countries of Oceania. Conversely, opioid abuse appears to be restricted to Asia and eastern and central Europe, as well as the developed countries of Oceania, the European Union and North America. Patterns of use in developing countries appear to reflect proximity to production areas and trafficking routes that supply the drug markets of developed "consumer" countries.

A challenge when estimating the prevalence of illicit drug consumption is to avoid double counting individuals who use more than one substance. There is strong evidence (principally from developed countries) that few drug users use one drug exclusively (Darke and Hall

Table 13.I Prevalence (\%) of problematic illicit drug use in the past I2 months among persons aged >15 years, by subregion (UNDCP-derived estimates of prevalence) ${ }^{\text {a }}$

| Subregion | Population $>15$ years (000s) | Opioids | Cocaine | Amphetamine |
| :--- | :---: | :---: | :---: | :---: |
| AFR-D | 159577 | 0.09 | 0.26 | 0.31 |

| SEAR-D | 818521 | 0.15 | - | - |
| WPR-A | 129888 | 0.04 | 0.28 | 0.22 |
| WPR-B | 1131503 | 0.02 | - | 0.34 |

[^51]a Some estimates for subregions are based on data from a small number of countries in the subregion.

1995; Topp et al. 1999). Rather, most users nominate a drug of choice but regularly use a wide range of substances (Darke and Hall 1995; Klee et al. 1990). Thus combining estimates of the size of each population will overestimate the size of the drug-using population. Given that many opioid and stimulant users are polydrug users, and that these drugs are the most harmful illicit drugs, the simplest approach to this problem may be to use the prevalence of regular users of opioids and/or stimulants in each country as the prevalence estimate for problem illicit drug use.

In order to address this issue, a range of three prevalence estimates was derived from the above UNDCP data:

- a low estimate, which assumed that $50 \%$ of each of the prevalence estimates was unique and therefore additive;
- a medium estimate which assumed that $75 \%$ of each of the prevalence estimates was unique and therefore additive; and
- a high estimate, which assumed that the prevalence estimates were completely additive (i.e. that those who used opioids were a separate group from those who used cocaine and amphetamines).

In order to estimate the proportion of persons who had used these drugs problematically in the past year, data from the 1997 Australian National Survey of Mental Health and Well-Being were used. This survey was a structured diagnostic interview of a representative sample of Australian adults aged $\geq 18$ years (Hall et al. 1999d; Henderson et al. 2000). It assessed persons who had used opioids and stimulant drugs for symptoms of DSM-IV ${ }^{9}$ defined abuse and dependence. Of those who had reported using these drugs within the past year, $28 \%$ met criteria for DSM-IV abuse or dependence.

In the current calculations, therefore, it was assumed that $28 \%$ of those who had used these drugs within the past year were problematic users of these drugs.

It must be noted that prevalence estimates were not available for all countries in all subregions. In making estimates from UNDCP data, where countries had no reported prevalence estimates, subregional estimates of prevalence were used by deriving a weighted average prevalence rate from the data that were available from countries in the subregion. This weighted average rate was used in making subregional estimates. Some subregions therefore had estimates based upon only some countries within the subregion, which may make these estimates less representative:

- AFR-D: prevalence estimates based upon estimates provided for Cameroon, Chad, Ghana, Mauritius, Nigeria, Senegal and Sierra Leone;
- AFR-E: prevalence estimates based upon estimates provided for Ethiopia, Kenya, Namibia, Rwanda, South Africa, Uganda, the United Republic of Tanzania and Zimbabwe;
- AMR-D: prevalence estimates based upon estimates for Bolivia, Ecuador and Peru;
- EMR-D: prevalence estimates based upon estimates provided for Egypt, Morocco and Pakistan; and
- WPR-B: prevalence estimates based upon estimates provided for China, the Lao People's Democratic Republic, Malaysia, the Philippines, the Republic of Korea and Viet Nam.

## EMCDDA ESTIMATES OF "PROBLEM DRUG USERS"

These estimates were used to derive alternative estimates of prevalence in countries from EUR-A: Austria, Belgium, Croatia, Finland, France, Germany, Ireland, Italy, Luxembourg, the Netherlands, Norway, Spain, Sweden and the United Kingdom.

A weighted prevalence rate was derived from these estimates for the whole of EUR-A. The EMCDDA produced low and high estimates of "problem drug users" for countries in the European Union using a variety of estimation methods including capture-recapture and backprojection methods. Both these estimates were used to make lower and upper estimates of prevalence using these data. A median estimate was also calculated when making median estimates for each of the four major causes of mortality, and for all-cause mortality.

## AHRN estimates of IDU in the Asian region

Numbers from the AHRN were used to make estimates of the prevalence of IDU in these countries (IDU in this case was taken to represent the prevalence of "problem drug use" used in the other two estimates). Weighted prevalence estimates of IDU prevalence were only made in the subregion they were classified under if two or more countries reported (see www.ahrn.net). The countries were as follows:

- SEAR-B: Indonesia (no estimate made);
- SEAR-D: Myanmar (no estimate made);
- WPR-A: Japan, Singapore;
- WPR-B: Cambodia, China, Malaysia, Mongolia, the Philippines, the Republic of Korea and Viet Nam.

Table 13.2 shows the prevalence estimates produced from the EMCDDA and AHRN sources. Comparison with estimates in Table 13.1 reveals that the estimates are fairly similar.

In the current chapter, we have used all available estimates of prevalence to make a range of estimates of each cause of mortality. Hence, for

Table I3.2 Alternative estimates of prevalence of problematic drug use in three subregions

| Subregion | EMCDDA low <br> estimate (\%) | EMCDDA high <br> estimate (\%) | AHRN <br> $(\%)$ |
| :--- | :---: | :---: | :---: |
| EUR-A | 0.2 | 0.4 | NA |
| WPR-A | NA | NA | 0.3 |
| WPR-B | NA | NA | 0.01 |

NA Not applicable.
example, EUR-A has two sources of prevalence estimates: EMCDDA estimates (low and high) and UNDCP estimates (low, median and high). This approach was taken so as to make estimates based on as much of the available data as possible.

## 3. Health outcomes

### 3.1 Premature mortality

The major causes of premature death among illicit drug users are relatively directly related to their patterns of drug use. Evidence for these causes comes from studies of premature mortality among cohorts of illicit drug users who have been treated in Europe and North America. (It must be remembered that there is a range of issues surrounding the use of such cohort studies in deriving global estimates of mortality rates, which are discussed in section 6.2.)

Notwithstanding these issues, illicit drug users have elevated rates of four main causes of premature death by comparison with age peers who do not use illicit drugs, namely, drug overdose, HIV/AIDS, suicide and trauma.

## Overdose

"Overdose" refers to two ICD-10 classifications of cause of death: (i) accidental or intentional fatal poisoning caused by specific drugs, and (ii) poisoning deaths occurring among dependent drug users that are attributed to drug dependence. Despite the conceptual simplicity of drug overdose deaths it has been difficult to quantify the number of such deaths with any precision, even in developed countries, for reasons that are discussed below.

## HIV/AIDS

The connection between illicit drug use and HIV/AIDS largely arises from injection as the route of drug administration via drug users sharing
contaminated injecting equipment. This means that it is necessary to establish the prevalence of injecting drug use, rather than harmful drug use per se, in order to calculate the proportion of incident HIV cases that can be attributed to harmful drug use. This can be accomplished by extrapolating from data on the prevalence of injecting drug use among persons who are illicit drug users as indicated in studies in the peerreviewed literature. It can also be estimated by the proportion of HIV/AIDS cases that are attributed to IDU in each country. One issue that exists concerns a lack of data from some countries on the prevalence of AIDS cases that are attributable to IDU. In the current study, we have only used UNAIDS estimates of mortality attributable to injecting drug use.

## Suicide

Suicide is a cause of death in the ICD-10 but, as with overdose deaths, the reliability with which this cause of death is diagnosed may vary between countries depending on a number of variables. Cultural variations in attitudes towards suicide may influence coroners' and mortality registrars' willingness to classify a death as intentional (Domino and Lenaars 1989; Domino and Takahashi 1991).

## Trauma

Trauma includes homicide, motor vehicle accidents and other forms of accidental death. It is likely that this will be underestimated since few cohort studies report mortality rates from all forms of trauma and it is difficult to calculate attributable fractions for these causes because many trauma deaths in drug users may not be recognized as being drug-related.

## ALL-CAUSE MORTALITY

Several studies have calculated standardized mortality ratios (SMRs) for problem drug users. These studies indicated that problem drug users have substantially increased mortality rates, with typical estimates suggesting that they are approximately 13 times more likely to die than their peers (English et al. 1995; Hulse et al. 1999).

### 3.2 Likely sources of morbidity attributable to illicit drug use

Premature death is the most serious adverse health outcome experienced by problem drug users; it is also the best-studied health outcome in this population. Nevertheless, the contribution that illicit drug use makes to the burden of disease is not exhausted by premature death.

First, each of the major causes of premature mortality probably causes substantial morbidity. Second, drug dependence, which is highly prevalent among problem drug users, is also a cause of disability. Third, evidence suggests that the prevalence of hepatitis $B$ and hepatitis $C$ viruses (HBV and HCV) is high among injecting drug users (Alter et al. 1990;

Anderson et al. 1994; Levine et al. 1994; MacDonald et al. 1996, 2000). Both of these viruses are associated with substantial morbidity and premature death due to the sequelae of chronic infection (Alter et al. 1990; MacDonald et al. 1996, 2000).

However, there is little good evidence that allows quantification of the morbidity related to the use of illicit drugs, and it is not possible to make estimates of the burden of disease caused by morbidity resulting from illicit drug use. This means that current estimates of the burden of disease attributable to illicit drug use significantly underestimate the total burden of illicit drug use. An American analysis of the economic costs of drug use (National Institute on Drug Abuse 1992) revealed that problematic illicit drug use cost the United States an estimated US\$98 billion in 1992; of this, the figure for the impact of premature deaths was US\$ 14.6 billion. Health care expenditure cost an estimated US\$ 9.9 billion, and impaired productivity resulting from drug-related morbidity cost an additional US\$ 14.2 billion-clearly, costs from mortality attributable to drug use in the United States were a fraction of those attributable to morbidity. This means that our estimates are likely to underestimate the global burden of disease attributable to illicit drugs. Future estimates of the global burden of disease would be substantially improved by research into the total morbidity that is attributable to illicit drug use.

Outlined below are some of the major outcomes of illicit drug use that may be significant sources of morbidity. Future research is required to better document the nature and extent of morbidity attributable to the use of illicit drugs. In the absence of such data, we assumed that for each of the four causes included, the population attributable fractions for mortality could also be used to estimate the proportion of morbidity explained by that cause. Equivalently, we assumed that if illicit drug use causes a certain proportion of AIDS mortality, it does so by increasing its incidence, also increasing AIDS-related morbidity by a similar proportion. While uncertain, this assumption is closer to underlying mechanisms than assuming that illicit drug use contributed to none of AIDS-related morbidity. This approach cannot be used to estimate morbidity due to conditions that do not cause deaths, such as, neuropsychological impairment.

## NON-FATAL OVERDOSE

The prevalence of non-fatal overdose is not well studied in problem drug users apart from among opioid users in some developed societies, where non-fatal overdose is a common event (Darke et al. 1996; Gossop et al. 1996; Warner-Smith et al. 2001). An unknown proportion of these cases requires acute medical treatment and hospitalization and some of these may develop persistent medical sequelae as a result of non-fatal overdoses, such as cognitive impairment (Darke et al. 2000) and other medical problems (Warner-Smith et al. 2001). There are no good esti-
mates of the prevalence of these outcomes that would permit an estimate to be made of their contribution to the burden of disease. It should be a research priority to obtain better estimates of the prevalence of these forms of morbidity in future studies of illicit drug users so that the contribution that illicit drug use makes to the burden of disease can be better understood.

## AIDS

In developed societies, the widespread availability of anti-retroviral drugs has extended the life expectancy of persons living with HIV/AIDS (Donoghoe and Wodak 1998), with the result that HIV/AIDS may become a chronic condition. However, in these countries we rarely have data on the proportion of treated cases who acquired their infections as a result of IDU. We have assumed that the proportion of treated HIV/AIDS cases that are attributable to IDU is the same as the proportion of AIDS-related deaths that are attributed to IDU.

## Hepatitis B and C

Many injecting drug users in developed countries are infected with HCV. In Australian needle and syringe attendees, for example, the prevalence of HCV infection is estimated at between $50 \%$ and $60 \%$ (National Centre in HIV Epidemiology and Clinical Research 1998). Chronic infection has been estimated to occur in $75 \%$ of infections, and $3-11 \%$ of chronic HCV carriers will develop liver cirrhosis within 20 years. Given the large number of injecting drug users infected with HCV , and the more protracted complications arising from this infection, the net health and economic cost of HCV transmitted by injecting drug use may be as high as, or considerably higher than, those of HIV. Data on the prevalence of this infection among injecting drug users in developed countries is limited; it is non-existent in many developing countries.

Similarly, the prevalence of HBV has been documented as quite high among injecting drug users in developed countries. There is, however, a lack of good evidence on (i) the prevalence of HBV among illicit drug users; (ii) the risk of premature mortality caused by this disease; and (iii) the extent of morbidity that it causes. HBV has therefore not been included in current estimates for these reasons. It would be desirable in future to include estimates of morbidity and disability that HBV and HCV cause among illicit drug users.

## Attempted suicide

Recent studies in Norway (Rossow and Lauritzen 1999) and Australia (Darke and Ross 2000) have found high rates of self-reported suicide attempts among problematic opioid users (Darke and Ross 2000; Rossow and Lauritzen 1999). Survivors of such suicide attempts may require psychiatric and medical treatment and some suffer from medical sequelae. As with non-fatal overdose, there are no data that permit the
morbidity attributable to this cause among problem drug users, but estimates could be obtained by applying the same attributable fraction for suicide deaths to morbidity caused by attempted suicides.

## TRAUMA

In developed societies there are approximately 20 cases of severe injury for every death caused by a motor vehicle accident (MVA) (English et al. 1995). We could assume the same is true for problem drug users if we had a credible estimate of the proportion of motor vehicle fatalities that were attributable to problem drug use. In the absence of this data we estimated the proportion of MVA morbidity attributable to illicit drugs by applying the same attributable fraction for MVA deaths to morbidity caused by motor vehicle accidents.

## Psychiatric disorder

Studies of treated populations of opioid-dependent persons have found a high prevalence of major depression and anxiety disorders (Darke and Ross 1997). It is difficult to sort out cause and effect from these crosssectional data so it is unclear in what proportion of these cases psychiatric disorders preceded and contributed to the development of problem drug use or vice versa. Nor is it clear to what extent pre-existing psychiatric disorders have been exacerbated by problem illicit drug use or vice versa. It is accordingly difficult to estimate what proportion of these disorders are attributable to problem illicit drug use. For these reasons such estimates have not been included in this chapter. Better understanding of the causal relationships between the two is a priority for future research.

### 3.3 Causality

The main evidence for believing that illicit drug use is a cause of premature death, morbidity and disability comes from cohort studies and cross-sectional studies of illicit drug users.

## Mortality

The cohort studies have identified a number of causes of mortality that are more prevalent among problem illicit drug users than their peers, indicating an association between harmful illicit drug use and these causes of mortality. They have rarely been well controlled for potential confounders, such as social disadvantage, which is common among illicit drug users. English et al. (1995) have argued that the mortality excess among illicit drug users is too large to be wholly accounted for by social disadvantage. Moreover, there are good reasons for believing that the relationship is causal in the case of deaths caused by overdose and bloodborne virus infection. The major illicit drugs are known to have adverse effects in overdose that can be fatal. Opioids, for example, produce respiratory depression that can cause death, and this is especially likely to
occur if opioids are used in combination with other central nervous system depressant drugs such as alcohol and benzodiazepines (Darke and Zador 1996; Warner-Smith et al. 2001). Stimulant drugs, such as cocaine and amphetamines, can cause fatal cardiac arrhythmias and strokes (Goldfrank and Hoffman 1993; Platt 1997), which are very rare causes of death in young adults who do not use these drugs. Similarly, the viruses that cause HIV/AIDS, HBV and HCV infections are efficiently spread by contaminated blood in shared injection equipment (Donoghoe and Wodak 1998; MacDonald et al. 1996).

The case for illicit drug use being a contributory cause of suicide is less direct. Depression is a risk factor for suicide and it occurs at higher rates among illicit drug users. Intoxicating drugs like alcohol and opioids, and dependence on these drugs, have been shown in case-control and prospective studies to be risk factors for suicide (Beautrais et al. 1998, 1999). Opioid-dependent persons in treatment report very high rates of attempted suicide (Darke and Ross 2000).

The case for a causal connection between illicit drug use and trauma deaths is less direct still. Driving while intoxicated by alcohol is a well-known risk factor for fatal motor vehicle crashes (English et al. 1995) and the heavy use of alcohol is common among illicit drug users (Darke and Hall 1995; Darke and Ross 1997; Gossop et al. 1998). Opioids are also intoxicating substances that adversely affect driving, although they are much less commonly found in persons killed in fatal car crashes.

## Morbidity

The case for a causal connection between illicit drug use and morbidity caused by drug overdose, HIV/AIDS and HCV, suicide and trauma are the same as for mortality. To these must be added psychiatric disorders and drug dependence. By definition, drug dependence is caused by regular illicit drug use and most regular illicit drug users are dependent on one or more of the drugs that they regularly use.

The causal relationship between psychiatric disorder and illicit drug use is less clear. The two are associated in the general population and this is not attributable to confounding by social and demographic variables (Degenhardt et al. 2001). The direction of the causal relationship is less certain. Conduct disorders, depression and anxiety disorders that develop in early adolescence may predispose young adults to become dependent on illicit drugs. These disorders may also arise as a result of the adverse effects that illicit drug dependence has on the lives of those affected by it, or the rigours of regular illicit drug use may prolong preexisting depressive and anxiety disorders that may have resolved in its absence.

## 4. Risk factor-disease relationship

## $4.1 \quad$ Outcome studies

INCLUSION CRITERIA
The following inclusion criteria were used:

- cohort studies on the use of opioids, cocaine or amphetamines and mortality;
- studies in which SMRs were reported. SMRs are the ratio of observed numbers of deaths in the cohort to the expected number of deaths in people of the same age and sex distribution in the general population; and
- studies in which crude mortality rates (CMRs) could be derived from the available data in the article.

## Exclusion criteria

The following exclusion criteria were used:

- multiple reports of same data set;
- subsets of a cohort; and
- reviews, commentaries, letters and abstracts.

Table 13.3 shows those studies that were not included in the present analyses. CMRs were derived from data on the number of deaths, period of follow-up and number of participants. Where person-years were not calculated by the authors, persons lost to follow-up were assumed to be alive at the end of study period and included in our calculation of personyears observation (to maintain consistency with studies that did not report numbers lost to follow-up). Following previous research (Hulse et al. 1999) it was assumed that persons dying during the period of

Table 13.3 Outcome studies that were not included

| Reference | Reason for exclusion |
| :--- | :--- |
| Vaillant (I966) | Data are a subset of Vaillant (1973) |
| Watterson et al. (1975) | Series of cross-sections, not longitudinal |
| Thorley et al. (1977) | Data are a subset of Wille (198I) |
| Wiepert et al. (1978) | Poorly defined cohort |
| Ghodse et al. (1985) | Study of death register, not a predefined cohort |
| Selwyn et al. (1989) | No cohort defined |
| Frischer et al. (1993) | Retrospective |
| Fischer et al. (1999) | No mortality reported |

follow-up died in the middle of the period (when estimating the personyears at risk). CMRs are unadjusted, expressed as per cent mortality per annum.

### 4.2 Quantification of risk

In determining the risks associated with harmful illicit drug use, it is necessary to rely on the results of cohort studies that have conducted longterm follow-up of individuals identified as using illicit drugs. English et al. (1995) identified a total of 13 such studies investigating mortality associated with illicit opioid use up to 1993 (Barr et al. 1984; Bewley et al. 1968; Cherubin et al. 1972; Engstrom et al. 1991; Frischer et al. 1993; Ghodse et al. 1985; Haastrup and Jepson 1984; Hser et al. 1993; Joe et al. 1982; Perucci et al. 1991; Thorsen and Haarstrup 1975; Vaillant 1973). Through extensive literature searches we identified a further 16 studies that have been published since 1993, excluding studies which used previously published data (Capelhorn et al. 1996; Eskild et al. 1993; Friedman et al. 1996; Fugelstad et al. 1995, 1997; Galli and Musicco 1994; Goedert et al. 1995; Goldstein and Herrera 1995; Keenan et al. 1993; McAnulty et al. 1995; Oppenheimer et al. 1994; Orti et al. 1996; Robertson et al. 1994; van Haastrecht et al. 1996; Wahren et al. 1997; Zaccarelli et al. 1994). The studies summarized in Tables 13.4-13.8 were all studies identified that followed up cohorts of problem or injecting drug users.

The general limitations of cohort studies have been discussed elsewhere (Dart 1995; Feldman 1993; Freeman 1996). The particular limitations of the cohort studies that are most relevant to this project are, first, that these studies were conducted exclusively in developed countries (principally the United States with 11 studies, western Europe with 22 studies and the Western Pacific with two studies). Second, with one exception (McAnulty et al. 1995) these studies drew their samples from people receiving treatment for drug-related problems. Third, the majority of the studies have been done on opioid users, usually injectors. There is much less data on mortality among problem stimulant users. Finally, the majority of cohort studies were conducted in the pre-AIDS era. These limitations will be discussed in more detail later in this chapter.

In studies of all-cause mortality (Table 13.8), a total of 152432 subjects were included, which involved a total of 1035574 person-years of observation, during which time 11633 deaths were recorded. The weighted average all-cause mortality rate was $1.12 \%$ per annum. Pooled crude death rates from the specific causes of death identified by English et al. (1995) were calculated from data reported in these studies (see Tables 13.4-13.7).

### 4.3 OvERVIEW OF METHODS OF ESTIMATING THE MORTALITY burden of illicit drugs

Methods for estimating mortality attributable to harmful illicit drug use can be "direct" or "indirect". Direct methods count the number of deaths attributed to illicit drug use by applying attributable fractions to ICD-classified causes of death in national mortality registers. Indirect methods involve estimating mortality by multiplying measures of mortality risk (e.g. relative risk) by the prevalence of the risk factor in the population.

## DIRECT METHODS

The first method, which requires the greatest amount of data, uses the attributable fraction of mortality attributed to harmful illicit drug use calculated for a population for which direct measures of specific cause mortality data are available. This attributable fraction is then used to extrapolate the mortality attributable to harmful illicit drug use in another population.

This method has the advantage of excluding deaths in those exposed that are not due to the risk factor. The source of mortality data to use with this method is the All-Cause Mortality Database compiled by WHO. Attributable fractions for illicit drug use (which have been calculated in countries where direct estimates have been made) can be applied to these data.

In some countries direct measures of mortality are available from mortality registers. This is straightforward, in principle, for deaths caused by overdose, which has an attributable fraction of 1 . Aside from individual country mortality registers, other sources of directly measured mortality data include HIV/AIDS surveillance data available from agencies such as UNAIDS and the United States Census Bureau.

The difficulties involved in applying this method are exemplified by the case of "overdose" deaths. This is the only cause of death that is wholly attributable to harmful illicit drug use so all mortality due to this cause must be the result of the risk factor. It is the cause of death that should be the most easily quantified. However, the great many difficulties inherent in assigning any particular case to this cause of death have been well documented (Advisory Council on the Misuse of Drugs 2000; Danish National Board of Health 1997; WHO 1998).

In most United Nations Member States, cause of death is classified according to ICD-10 codes, which specify whether the cause of death was intentional poisoning (suicide), unintentional poisoning or dependence. Despite the existence of ICD-10 criteria for classification of cause of death, countries differ in the way that deaths are registered and causes of death are classified (Danish National Board of Health 1997; WHO 1998). For example there is one European country in which: ". . . it is well known that about $90 \%$ of drug-related deaths are coded
with the code for unknown cause of death" (p. 51) (Sanchez-Carbonell and Seus 2000).

A recent report by the Home Office has been critical of the system for recording drug-related deaths in the United Kingdom (Advisory Council on the Misuse of Drugs 2000). It noted that deaths may not be classified as drug-related if they are not referred to the coroner (as may happen when a certifying doctor is unaware that the deceased was a drug user) or the death is due to an indirect effect of harmful drug use, such as a viral infection. There also appears to be a great deal of variation between individual coroners in their preparedness to record deaths as drug related. The report notes that: "there are coroners working in areas of known high drug prevalence who never certify a death as related to drug misuse" (p. 80).

Other sources of variation identified in the British report were that neither post-mortem nor toxicological analysis are formally required for suspected drug-related deaths; that the verdicts available to the coroner are not mutually exclusive; that coroners do not have the necessary skills to distinguish between the verdicts available to them, most notably "dependence on drugs" and "non-dependent abuse of drugs"; and that there is no requirement of the coroner to identify the drugs involved (Advisory Council on the Misuse of Drugs 2000).

There are also variations between countries in how much information is gathered about the circumstances or cause of death (Danish National Board of Health 1997; WHO 1998). In Australia, for example, autopsy is routinely conducted on all suspected overdose deaths, making forensic and toxicological data the basis for the classification of cause of death. This, however, is a far from universal practice. In the United States, only $20 \%$ of drug-related deaths are subject to autopsy (WHO 1998). Similarly, the immediate cause of death is recorded in death registers but contributing factors may or may not (Danish National Board of Health 1997; WHO 1998). This can cause large differences in rates of drugrelated deaths based on death register data.

For causes other than overdose, where the attributable fraction is less than 1, the difficulties involved in attributing a death to illicit drug use are compounded. In addition to the caveats discussed above, the simple fact that there is a complete absence of such data in the majority of countries in the world necessitates the use of indirect methods to estimate mortality attributable to harmful drug use.

## INDIRECT METHODS

Indirect methods of estimating mortality can be used when directly recorded data are unavailable or unreliable. The estimates provided by these methods can be validated against direct methods in countries where reliable mortality data are available. For the vast majority of countries in the world, indirect methods provide the only indicator of the extent
of the health consequences of harmful illicit drug use, because of the absence of epidemiological data on drug-related mortality. Three indirect methods can be used to estimate the burden of mortality attributable to illicit drugs.

The simplest method is to multiply mortality rates in cohort studies by the estimated prevalence of problem illicit drug use in the country. This provides an estimate of deaths caused by illicit drugs for each of the causes of death that we have considered.

## KEY INFORMANT DATA

A final source of data is that which researchers in the drug and alcohol field can provide. The WHO Management of Dependence Project surveyed drug researchers in Member States and asked them to provide estimates of the prevalence of harmful drug use and resultant mortality in their country, using the best available data. The sources range in quality from large-scale population surveys to educated guesses based on clinical experience, but such consultations provide an independent source of estimates against which to check the sources outlined above.

Only 15 responses were returned and in most cases responses either reported on published data or data whose validity was difficult to evaluate. This source has not been included formally in current estimates. Future attempts to estimate the contribution that illicit drug use makes to global burden of disease may include such data.

Key informants may also be of use to judge the accuracy and validity of estimates of mortality attributable to the different causes of death. Such key informants are extremely invaluable and note has been made in the text of instances in which key informants reported that our estimates were likely to be underestimates.

### 4.4 Methods used for each cause of mortality <br> AIDS

UNAIDS estimates of death related to IDU were used. No upper and lower estimates were obtained.

## DRUG overdose

It should be noted that rates derived from research on opioid overdoses were included in these calculations and separate estimates of the number of persons dying from stimulant-related overdoses have not been made. There is a lack of good data on rates and/or risk of dying from stimulant-related overdoses. However, it is likely that in countries which have a higher prevalence of cocaine use, cocaine-related overdoses may account for a considerable proportion of all fatal drug overdoses. In the United States, for example, the Drug Abuse Warning Network indicated that in 1999, $28 \%$ of single-drug overdoses were due to co-
caine (National Institute on Drug Abuse, personal communication, 2002).

Our approach has been to assume that overdose rates derived from research on opioid overdose may be applicable to stimulant drugs. In estimates made of overdose deaths, rates of drug use (which include opioids, amphetamines and cocaine) were multiplied by the rate of opioid overdoses derived from cohort studies. Hence, it has been assumed that the same rate of overdose deaths applies to these other drugs as it does to opioid drug use. In the estimates derived from "allcause" rates in cohort studies, overdoses due to amphetamines and cocaine use will be included in this rate. Direct estimates made from the WHO Mortality Database included only deaths due to opioids so may be an underestimate.

In this chapter, data used to derive a number of estimates of the number of persons dying from overdoses were derived from the following sources.

## Direct estimates: attributable fractions combined with data from WHO all-cause mortality database

An attributable fraction was derived from EUR-A countries. This involved obtaining estimates of the total number of deaths coded in ICD as attributed to mental disorders and accidental poisoning due to opioids. The median attributable fraction of these countries was 0.1164 . This attributable fraction was applied to all other subregions to enable a direct estimate to be made.

Data were taken from the WHO all-cause mortality database on deaths attributed to mental disorders and accidental poisoning. Not all countries reported such data. In making estimates for subregions when some data were missing from countries in the subregion, an average overdose rate was calculated using the available data, and this rate was used to estimate the total number of trauma deaths in the subregion. It must be noted that many countries in some subregions did not report data in the WHO database, and some subregions had no countries that reported such data; the following subregions had estimates made from only few countries in the subregion, or had no estimates made:

- AFR-D: Mauritius;
- AFR-E: no estimate;
- AMR-B: Argentina, Belize, Brazil, Costa Rica and El Salvador;
- AMR-D: no estimate;
- EMR-B: Kuwait;
- EMR-D: no estimate;
- EUR-C: Armenia, Azerbaijan, Bulgaria, Kyrgyzstan, Poland, Romania and Slovakia;
- SEAR-B: Thailand;
- SEAR-D: the Democratic People's Republic of Korea;
- WPR-B: no estimate.

## Indirect estimates: cohort-derived mortality rate

A weighted average mortality rate was calculated from cohort studies (see Table 13.5 for included studies). The average was $0.43 \%$ per annum (to 2 decimal places). The upper and lower $95 \%$ confidence intervals of this rate were $0.25 \%$ per annum and $0.64 \%$ per annum.

## Suicide

Suicide was considered as a cause of mortality among illicit opioid users only. Hence, when making indirect estimates of deaths, only rates of opioid use were considered in analyses. Median estimates are reported. Where only one source of data was available in estimating a cause of mortality, then the median of this was used, and the lowest and highest estimate used for the range. If more than one source of estimates was available for a subregion, then the lowest and highest median estimates were used as the range.

## Direct estimates: attributable fractions combined with data from WHO all-cause mortality database

An attributable fraction of 0.09 was used to calculate the proportion of all suicides that were among opioid users. This attributable fraction was derived from an Australian study reported by English et al. (1995). Data were taken from the WHO all-cause mortality database on the number of deaths due to suicide by country, for persons aged $>15$ years. The year for which data were available varied. For those countries that had more than one year of data, the most recent year's data were used.

Not all countries reported such data. In making estimates for subregions in which some data were missing from countries in the subregion, an average suicide rate was calculated using the available data. This rate was used to estimate the total number of suicide deaths in the subregion. It must be noted that many countries in some subregions did not report data in the WHO database, and in some subregions there were no countries that reported such data. The subregions in which estimates were made from only few countries, or which provided no estimates are as follows:

- AFR-D: Mauritius;
- AFR-E: no estimate;
- AMR-B: Argentina, Belize, Brazil and Costa Rica;
- AMR-D: no estimate;

## Indirect estimates: cohort-derived crude mortality rates

The crude mortality rate due to suicide from cohort studies was also estimated (see Table 13.6 for included studies). The weighted average rate of death per annum due to suicide was $0.24 \%$ (shown here to 2 decimal places). In order to make a range of estimates around this average rate, the standard error of the rate was calculated and $95 \%$ confidence intervals constructed around the rate. These were used as the lower and upper ranges of the mortality rates due to suicide: these were $0.15 \%$ per annum and $0.33 \%$ per annum, respectively.

## Trauma

It must be noted that there are significant problems with estimates of rates/attributable fractions due to trauma, since cohort studies reported different sorts of trauma, and different numbers of causes. In the attributable fraction method of calculation, only road traffic accidents were used to calculate the number attributable to illicit drug use as it is unclear the extent to which homicides or other trauma deaths are due to illicit drug use.

Median estimates are reported. Where only one source of data was available in estimating a cause of mortality, then the median of this estimate was used, and the lowest and highest estimates were used for the range. If more than one source of estimates was available for a subregion, then the lowest and highest median estimates were used as the range.

## Direct estimates: attributable fraction combined with data from WHO all-cause mortality database

Data were taken from the WHO all-cause mortality database on the number of deaths due to motor vehicle or other road traffic accidents (ICD-9 codes E470-E474 and E479) by country. Not all countries reported such data. In making estimates for subregions when data were missing from some countries, an average trauma rate was calculated using the available data. This rate was used for estimating the total number of trauma deaths in the subregion. It must be noted that many countries in some subregions did not report data in the WHO database, and some subregions had no countries that reported such data. In the following subregions estimates were made from only few countries, or no estimates were made:
Table I3.6 Included outcome studies that examined rates of mortality due to suicide among problematic drug users

- SEAR-D: no estimate;
- WPR-B: the Philippines and the Republic of Korea.

The attributable fraction derived by Ridolfo and Stevenson (2001) of 0.015 was used to calculate direct estimates of trauma due to illicit drugs.

## Indirect estimates: cohort-derived crude mortality rates

Indirect estimates of the number of road traffic accident deaths due to illicit drug use were also made using pooled estimates of the rates of death due to trauma from cohort studies (Table 13.7). Rates of traumatic injury were also high in this group: the weighted average rate of death per annum due to trauma was $0.35 \%$. In order to make a range of estimates around this average rate, the standard error of the rate was calculated and $95 \%$ confidence intervals constructed around the rate. These were used as the lower and upper ranges of the mortality rates due to trauma: these were $0.23 \%$ per annum and $0.46 \%$ per annum, respectively (shown here only to 2 decimal places).

## ALL-CAUSE MORTALITY

Median estimates are reported. Where only one source of data was available in estimating a cause of mortality, then the median of this was used, and the lowest and highest estimate used for the range. If more than one source of estimates was available for a subregion, then the lowest and highest median estimates were used as the range.

## Direct estimates: attributable fractions combined with data from WHO all-cause mortality database

Data were taken from the WHO all-cause mortality database on the total number of deaths by country, for persons aged between 15 and 54 years. The year for which data were available varied so the data from the most recent year were used in those countries that had more than one year of data.

This age group (15-54 years) was chosen as the age group within which excess mortality rates would occur among problem illicit drug

[^54]users compared to non-users. After calculating mortality rates among this age group, an SMR of 13 was used to calculate the rate of all-cause mortality death among problematic illicit drug users. This was taken from previous studies estimating the excess rates of mortality in this group (English et al. 1995; Hulse et al. 1999). It was assumed for these calculations that the resulting rate of death applied to all illicit drug users. This will underestimate the mortality rate among the minority of illicit drug users who are older than 54 years.

Some countries did not have any death data included in the WHO database. For these countries no individual estimates were made. However, in making calculations for subregions, a weighted average of the all-cause mortality rates was calculated using the data from countries that were included. It was assumed that the countries for which no data were available had the average rate of the other countries in the subregion from which they came. Some subregions, however, had no countries which had appropriate estimates. Those subregions in which there were few or no countries for which estimates could be made were as follows:

- AFR-D: Mauritius;
- AFR-E: South Africa;
- AMR-B: Argentina, Belize, Brazil, Costa Rica, El Salvador and Paraguay;
- AMR-D: no estimate;
- EMR-B: Kuwait;
- EMR-D: no estimate;
- SEAR-B: Thailand;
- SEAR-D: no estimate;
- WPR-B: the Philippines and the Republic of Korea.

## Indirect estimates: cohort-derived crude mortality rate

Crude all-cause mortality rates were also derived from cohort studies included in this project (see Table 13.8). A weighted average all-cause mortality rate was calculated ( $1.12 \%$ per annum), with a $95 \%$ CI of the average rate estimated as between $0.78 \%$ per annum and $1.46 \%$ per annum.
Table I3.8 Included outcome studies that examined rates of all-cause mortality among problematic drug users

## 5. Estimated mortality attributable to ILLICIT DRUG USE, 2000

### 5.1 Burden of mortality attributable to specific causes

Table 13.9 shows the median indirect estimates of the number of deaths attributed to illicit drug use in 2000 for each of the 14 subregions (Table 13.10 also shows low and high range estimates around these medians).

## AIDS

The second largest individual cause of death was AIDS, with a global median estimate of 59000 deaths. The largest proportion of these deaths was estimated to have occurred in WPR-B (17000). The other two subregions in which the greatest number of deaths from AIDS related to illicit drug use were EMR-D (11000) and SEAR-B (11000).

There is some indication that the estimates for some subregions may be too low. The United States Centers for Disease Control and Prevention reported that in 1999, 5932 AIDS-related deaths occurred in the United States that were attributed to IDU (see http://www.cdc.gov/hiv/ stats/hasr1202.htm). Similarly, reports from UNAIDS experts indicate that estimates for EUR-C may also be too low, with reports that in the Ukraine alone, approximately 3440 deaths occurred due to AIDS in 1999 (UNAIDS, personal communication, 2001). While some reviewers commented that South-East Asian estimates were higher than they expected, recent work has indicated that the number of AIDS deaths in Thailand (one of the countries in this region) was higher than previously estimated (A. Lopez, personal communication, 2001). Recent work in the SouthEast Asia Region is consistent with the possibility that AIDS-related deaths have been underestimated in this region (Reid and Costigan 2002).

## Overdose

Opioid overdose was the next largest cause of death among illicit drug users, with a median estimate of 69152 deaths globally. The two subregions that accounted for the largest number of opioid overdose deaths were SEAR-D (22 989) and EMR-D (12 852), followed by EUR-C and AMR-A.

The estimates may be too low for some subregions. For example, WPR-A, which includes Australia, had a median estimate of 825 deaths, with a high and low estimate of 954 and 696, respectively. Data from the Australian Bureau of Statistics indicates that in 2000, a total of 737 deaths occurred among persons aged 15-44 years (National Drug and Alcohol Research Centre 2000).

## Suicide

Suicide among opioid users was estimated to account for 32216 deaths in 2000. SEAR-D accounted for the greatest proportion of these deaths

Table 13.9 Median indirect estimates of mortality attributed to illicit drug use, by subregion

| Subregion | AIDS | Opioid overdose | Suicide | Trauma |

| Total (median) |  |  |  | 33689 |

Note: There were an additional 10000 deaths from overdose above and beyond those coded as drug use disorders (added to unintentional injuries) or when coded drug use disorder deaths were higher than estimated overdose deaths.
(14 982), with EUR-C accounting for the next largest. A similar number of deaths were estimated to be due to trauma (34 184). WPR- B had the largest numbers of deaths due to this cause (9295), followed by AMRA (4057).

### 5.2 All-CAUSE mortality attributable to illicit drugs

Table 13.11 compares two methods of calculating the total mortality attributable to illicit drug use: (i) adding the above four causes; and (ii) using estimates of "all-cause" mortality derived from cohort studies and attributable fractions. There are some reassuring similarities between the two sources, and some noteworthy discrepancies.

Overall, the global estimates were remarkably similar ("all-cause" estimate 197383 vs "sum" estimate 194058). Of note was the fact that the subregions that had discrepant estimates were largely developing subregions, and not the subregions from which the majority of cohort studies and attributable fractions had been derived. One of the subregions that accounted for the slightly lower estimates using the all-cause mortality method was SEAR-D, whose all-cause estimate (around 11000 ) was only $23 \%$ of its sum estimate. In general, however, for most other subregions, estimates were within close range of each other, or the all-cause estimates were higher. The overall rate of death per 1000

a Sum of the median estimates of the following four causes: AIDS, opioid overdose, suicide via opioids and trauma.
b Median estimates of all-cause mortality derived from SMR analyses and pooled CMRs.
persons aged $\geq 15$ years due to illicit drug use, on a global level, was estimated at 0.5 per annum. The highest all-cause mortality rate was estimated to have occurred in AMR-A ( 0.16 per 1000 persons aged $\geq 15$ years), followed by AFR-D ( 0.12 per 1000 persons aged $\geq 15$ years). The lowest rates using all-cause estimates occurred within SEAR-D (0.01 per $1000)$, WPR-B (0.03) and SEAR-B (0.03).

The discrepancies between the two sources of estimates for developed societies suggested that in general (with the exception of AMR-A), the consistency between the two was reasonable. If anything, the all-cause method produced a higher estimate, which is consistent with the fact that the "four cause" method does not include an exhaustive list of all possible causes of death.

In some developing subregions (such as SEAR-D) there was marked discrepancy between the two sources of estimates. This could be due to higher rates of AIDS-related deaths among injecting drug users in these subregions, which were not adequately assessed by using the all-cause method (in which some cohort studies were carried out before AIDS became an issue).

### 5.3 Age and sex breakdowns

Our ability to make reliable and valid estimates of the age and sex breakdowns of deaths attributable to illicit drug use is extremely limited. Not only are estimates of the prevalence of drug use according to these characteristics limited (or absent) in many countries, it is also the case that evidence on the characteristics of persons dying from the causes examined here are limited. The estimates made below have been made with reference to limited data on the age and sex breakdowns of persons dying from AIDS, overdose, trauma and suicide.

## SEX

We made the following estimates of the sex breakdown. This was completed by using estimates of the proportion of tobacco users who were males in each of the 14 subregions. These had been calculated in each subregion from the smoking risk factor for the GBD project. Table 13.12 shows the estimates for proportion of deaths among males in each of the subregions. Table 13.13 shows the resulting numbers of deaths attributable to illicit drugs by subregion and sex. Table 13.14 provides estimates of the total DALYs attributable to illicit drugs by subregion and sex.

## Age groups

Similarly to the sex breakdowns, the age breakdowns are based on limited data concerning the age distribution of persons dying from the

four main causes of death considered here. It was assumed that no persons aged $<15$ years and no persons aged $>54$ years were problematic users of illicit drugs; the 15-54-year age group has typically been found to contain the vast majority of problematic illicit drug users (Anthony and Helzer 1991).

It was assumed that two-thirds of overdose deaths occurred among the $25-44$-year age group, with on-sixth each occurring in the 15-24and 45-54-year age groups, in line with previous research suggesting the bulk of deaths occur in such a pattern (Hall et al. 1999c, 2000c). Deaths related to illicit drug use that were due to trauma were assumed to be disproportionately distributed among younger age groups, with smaller proportions among those aged 35-54 years (see Table 13.15). With the knowledge that AIDS-related deaths usually occur years after contracting HIV, we assigned the deaths the same age distribution as the total HIV/AIDS deaths in each subregion.

## 6. Discussion

### 6.1 Methodological caveats

A number of potential sources of inaccuracy need be acknowledged in our estimates. First, there are a number of factors that determine the proportion of cases of any particular cause of mortality that are attribut-

Table 13.15 Estimated distribution of causes of death attributed to illicit drug use, by age

|  | Age (years) |  |  |  |  |  |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: |
| Cause of death | $<15$ | $15-24$ | $25-34$ | $35-44$ | $45-54$ | $>54$ |
| Overdose | 0 | $1 / 6$ | $1 / 3$ | $1 / 3$ | $1 / 6$ | 0 |
| Suicide | 0 | $1 / 3$ | $1 / 3$ | $1 / 6$ | $1 / 6$ | 0 |
| Trauma | 0 | $1 / 3$ | $1 / 3$ | $1 / 6$ | $1 / 6$ | 0 |
| Total $^{2}$ | 0 | 0.13 | 0.34 | 0.29 | 0.24 | 0 |

a Weighted average of the three causes.
able to harmful illicit drug use. These include environmental, cultural or behavioural factors, which are also likely to interact. The risk of contracting HIV/AIDS through injecting drug use, for example, is greatly reduced by providing sterile injecting equipment, and the use of such equipment will be affected by attitudes towards needle sharing. In countries with needle and syringe programmes the attributable fraction of HIV due to injecting drug use is likely to be relatively small compared to similar countries that do not have needle and syringe programmes, even assuming a similar prevalence of other risk factors for HIV transmission in both countries (Hurley et al. 1997). An illustration of this was provided by Lurie and Drucker (1997) who assessed the impact of needle and syringe programmes on the development of the HIV epidemic in Australia and the United States. They estimated that between 10000 and 25000 HIV infections in the United States could have been prevented if needle exchange programmes were implemented as they had been in Australia.

Second, the availability of drug treatment programmes, medical care and a host of other factors that differ between otherwise similar countries may produce differences in the attributable fractions in those countries. For example, van Ameijden et al. (1999) compared mortality in cohorts of heroin users in Amsterdam and Baltimore. They found Amsterdam drug users had an overdose/suicide mortality rate approximately twice that of their counterparts in Baltimore. This was despite the fact that a greater proportion of users in Amsterdam were in methadone maintenance treatment, which has been shown to reduce the risk of overdose. This finding contrasts with a previous finding of the same research group, which attributed lower mortality rates from infectious disease in Amsterdam to drug users having better access to primary health care in Amsterdam than in New York (Mientjes et al. 1992). The variation in mortality rates that result from differences in the complex interactions
of determinants of mortality makes comparisons of cohort studies conducted in different countries problematic.

Third, attributable fractions can only be reliably calculated in countries that collect accurate mortality data. These data are most likely to be found in developed countries vs developing countries (Muller 1982). Caution is required in applying fractions estimated in developed countries to developing ones.

### 6.2 Limitations of cohort studies

As mentioned earlier, the cohort studies of problem illicit drug users have a number of major limitations when used for the purpose of estimating the contribution of problem illicit drug use to the global burden of disease.

## TREATMENT POPULATIONS

The vast majority of cohort studies of mortality among illicit drug users have included people seeking treatment for problem drug use. A small number of studies have compared mortality of drug users while in and out of treatment (Capelhorn et al. 1996; Fugelstad et al. 1995; Gronbladh et al. 1990; Sanchez-Carbonell and Seus 2000; Zanis and Woody 1998). These studies have found that the relative risk of death while in treatment varied from less than 0.2 to 0.8 , with a mean of approximately 0.4 . These studies can be used to produce more accurate estimates of mortality by applying different mortality rates for proportions of users who are and are not in treatment.

## ILLICIT DRUGS USED

Injecting opioid users are over-represented in the cohort studies by comparison with cocaine and other stimulant users. The few studies that report separate data on problem illicit opioid and stimulant use suggest that mortality is higher among opioid users (Engstrom et al. 1991), probably because of the greater risk of fatal overdose from opioids. Stimulant users, by contrast, may be at higher risk of contracting diseases from bloodborne viruses such as hepatitis $B$ and $C$ from sharing injection equipment because they inject at a high frequency when bingeing on their drug of choice (Bux et al. 1995; Chaisson et al. 1989). They may also be more likely to engage in sex for drugs (Chiasson et al. 1991; Darke et al. 1995; Edlin et al. 1994).

## Extrapolation across subregions

Applying direct measures of mortality from cohort studies in developed countries to populations in developing countries is problematic. Developing countries generally have all-cause mortality rates that are significantly higher than the developed countries in which most cohort studies are conducted (WHO 2001). Thus it may be that there is less of a dif-
ferential in mortality rates between the general population and problem drug users in developing countries. Applying the relative risks from developed countries to developing ones may therefore overestimate the mortality attributable to illicit drug use in the latter.

## HIV/AIDS

The majority of cohort studies identified for this project were conducted before the HIV/AIDS epidemic began to affect mortality among injecting drug users. Changes in the epidemiology of HIV and other drugrelated conditions since these studies were conducted may reduce the validity of using prevalence or incidence data to predict mortality. In some developed nations, for example, the incidence of HIV and AIDS may be declining but the large number of prevalent cases may still produce a high burden of mortality (CDC 2001; UNAIDS 2001). Conversely, countries that are still in the early stages of the epidemic may have a high incidence of HIV/AIDS cases that have not yet begun to contribute to mortality. In either case mortality estimates based on the number of incident cases may be inaccurate, for very different reasons. However, in the absence of better data on this issue, UNAIDS data on the number of AIDS deaths in the year 2000 have been used to estimate mortality, since there are significant problems with making estimates from incident cases.

Despite the limitations of cohort studies, they present the most robust epidemiological evidence on the relationship between problem illicit drug use and mortality. When quantifying the burden of mortality attributed to illicit drugs, therefore, cohort studies provide the best basis on which to estimate risk and identify mortality outcomes.

In terms of estimating risk, as we have described above, the use of annual mortality rates derived from studies of illicit drug users in developed countries may underestimate mortality in developing countries. By contrast, applying SMRs from the cohort studies to developed societies may overestimate the mortality rate of drug users in developing countries (which already have higher mortality rates in general), since it is probable that the higher the general mortality rate in any given country, the lower will be the SMR for illicit drug users in that country (Muller 1982). We have used UNAIDS estimates in the current study.

Other data sources can be used to validate estimates of risk derived from cohort studies in some developed societies. In populations where reliable mortality data are collected the attributable fraction of mortality due to a range of conditions that may be related to problem illicit drug use can be calculated. These fractions can then be applied to estimates of mortality in other countries using the WHO all-cause mortality database. The main weaknesses of this method are: that it does not take into account variations in the prevalence of the risk factor; it assumes homogeneity between the population from which the attributable fraction was derived and the population to which it is being applied;
and that cohort studies are representative of the population at risk. It is nonetheless an independent method of calculating mortality that can be used to check estimates of mortality derived by multiplying measures of risk by prevalence estimates.

### 6.3 Summary and conclusions

In summary, in this work we have attempted to estimate the extent of global mortality and morbidity attributable to illicit drug use in 2000. This required estimates of both the global prevalence of problem illicit drug use and the mortality attributable to it. Ideally, such data would include estimation of the numbers of problem, or dependent users, as these are the individuals at greatest risk for drug-related harm. Currently, there are poor data on the prevalence of problem illicit use in many developing countries and there is no consensus on the definition and operationalization of "problem drug use". UNDCP data, supplemented by other sources, provide the best available data, although these have major limitations.

Similarly, there is a considerable amount of data from cohort studies of individuals identified as problem illicit drug users that can be used to estimate the relative risks of death among this group. Unfortunately, most of these studies have been conducted in developed countries on problem opioid users and many were conducted prior to the AIDS pandemic among injecting drug users. A priority for future research must be to assess mortality among illicit drug users in developing countries and, in particular, to examine the extent to which the findings of studies conducted in developed countries are applicable to developing countries.

Furthermore, much of this research has been based on samples of people entering treatment for drug-related problems. Further work is needed to quantify mortality among problem drug users who are not in treatment. Nonetheless, it is clear from the existing cohort studies that problem illicit drug users have a greatly elevated risk of premature death from drug overdose, HIV/AIDS, suicide and trauma.

By comparison with the extensive literature on the health effects of tobacco and alcohol use, very little is known about the adverse health effects of illicit drug use. This situation reflects at least three factors: the recent history of illicit drug use in many countries; the low prevalence of its use in the population compared to alcohol and tobacco; and the fact that its illicit nature encourages users to conceal or deny their drug use, hence inhibiting research on its effects on mortality and morbidity.

In 2000, the median of the two methods of estimating the number of global deaths attributed to illicit drugs was 195721 . Estimates produced by both methods had wide uncertainty intervals around them (113494 for sum of four causes; and 101751 to 322456 for all-cause estimates). When morbidity attributable to illicit drug use is added to the estimated mortality this risk factor accounts for $0.8 \%$ of global DALYs. The distribution of DALYs between subregions varied, reflecting variations in
drug use and death rates, with considerable uncertainty about the applicability of mortality data derived in developed countries to mortality among illicit drug users in developing countries.

Nonetheless, the current estimates suggest that illicit drug use is a significant cause of premature mortality among young adults in the developed and developing world. Our estimate is certainly an underestimate of total disease burden because: (i) there are deficits in data on mortality attributable to the use of some illicit drugs (most notably cannabis and the newer synthetic drugs like MDMA); (ii) there are differences across subregions in the quality of data available on the causes of mortality that were included in the current estimates; and (iii) there is an absence of data that would permit estimates of some other causes of mortality and morbidity attributable to illicit drug use, such as hepatitis B and C and violence.

Given public concerns about the effects of illicit drug use, and indications of a worldwide increase in the production and use of illicit drugs, better research must be done on the adverse health effects of their use. With that in mind we include a list of research priorities.

### 6.4 Research priorities

- There is a need for more rigorously designed prospective studies of mortality and morbidity among problem illicit drug users in developing countries, especially ones which have high rates of HIV/AIDS infection among injecting drug users, and which have experienced substantial increases in rates of such problem drug use in recent years.
- There is also a need for cohort studies of injecting drug users who are not in treatment, since there is evidence that rates of mortality are higher among this group.
- There is a need for better studies of morbidity attributable to nonfatal overdoses, bloodborne viral diseases such as hepatitis B and C, suicide attempts, and trauma among problem illicit drug users in both developed and developing countries.
- There is a global need for better surveillance systems to collect data on key drug-related consequences.
- There is a need for better prevalence estimates of problem illicit drug use in developed and developing countries, especially where there are indications of increased illicit drug use because of proximity to source countries.
- Other specific data collection needs include the following:
- improving the comparability and quality of data on the prevalence of drug use across regions;
- improving methods for accurately estimating the prevalence of, and burden associated with, illicit drug use among non-institutionalized populations;
- improving estimates of the number of "problem drug users" per se, to take into account polydrug use using consistent definitions of "problem drug use";
- obtaining mortality and morbidity data from developing regions from which more accurate methods to estimate the burden of illicit drug use can be derived for those regions;
- improving data on drug use among psychiatric patients, and data on psychiatric morbidity among drug users;
- developing more comparable and accurate mortality data by improving the consistency of procedures used to identify and register drug-related deaths across subregions, for both developed and developing subregions;
- systematic monitoring of mortality by drug type to provide data on mortality associated with non-opioid drugs, especially in the context of developing countries and countries with high HIV prevalence; and
- measurement of the coverage and nature of services in place to reduce burden, especially those aimed at reducing the transmission of bloodborne viruses.

## 7. PROJECTIONS OF ILLICIT DRUG-RELATED HARM

There are a number of indications that rates of illicit drug use and illicit drug-related harm have risen in the past decade. First, developed countries with reasonable mortality data have shown steady increases in drugrelated deaths, especially drug overdose deaths, over the past decade, for example, in Australia (Hall et al. 1999a); Spain (de la Fuente et al. 1995); and the United Kingdom (Hall et al. 2000c). Estimates derived from back projections of both overdose deaths and treatment entry in Australia have shown an increase in estimated number of dependent opioid users (Hall et al. 2000a, 2000b). Second, illicit drug use and drug-related harm such as overdoses and HIV/AIDS have been reported in an increasing number of countries where it was previously rare, such as in eastern Europe, the former Soviet Union, Asia and Africa (UNAIDS 2001; UNDCP 2000; UNODCCP 2000).

Despite indications that drug-related harm is increasing, it is difficult to predict future patterns of illicit drug use and drug-related harm for the following reasons.

First, there is a lack of good time series data on the prevalence of illicit drug use and data on drug-related harm may not be comparable over
time, even in countries with good mortality data systems, because of changes in classification systems (such as successive iterations of the ICD classification system), and because of improvements (and deterioration) in the quality of data that are collected.

Second, although the general trend has been for drug-related deaths to increase during the 1990s, there have also been a number of countries in which drug-related deaths have fallen sharply, often after various policy initiatives have been introduced. In France (Lepere et al. 2001) and Switzerland, for example, drug-related deaths have fallen markedly in the later half of the 1990s, probably in response to a marked expansion of opioid substitution treatment in both countries. In the past two years, Australia has also seen a substantial drop in opioid overdose deaths, after a steep rise from the early 1990s until 1999 (Degenhardt 2002). In this case, some of the early decrease may have been attributable to expanded treatment and educational initiatives to reduce overdose among opioid users. Since the beginning of 2001, the major driver of reduced overdose deaths in Australia has been a substantial drop in the availability of heroin (Weatherburn et al. 2001).

Third, there have been changes in the scale of illicit drug production and in the choice of drugs for illicit manufacture. For example, restrictions on opioid production in Afghanistan in the late 1990s may have reduced heroin supply to Europe, while the supply of cocaine and amphetamine type stimulants (ATS) increased (UNODCCP 2000). The net effect of these changes on drug-related harm is difficult to predict because the effects of ATS on mortality are less well studied and understood than that of opioids (Darke et al. 2000a).

### 7.1 Options for projection

A conservative option may be to assume that: (i) the current global problem will remain at about the current level, but that (ii) the distribution of burden will shift between developed and developing countries with declines in drug-related deaths in developed countries (resulting from expanded opioid substitution treatment) being offset by increases in drug-related deaths in developing societies.

A less conservative option would be to assume that in developed countries, rates of opioid use and opioid-related deaths will continue to rise, but at a slower rate (e.g. $50 \%$ ) than that observed during the 1990s, because of expanded treatment availability. In developing countries, the rate of increase could be projected to follow the same pattern and magnitude as that observed in developed countries like Australia, which have reasonable time series data on trends in opioid-related deaths over the period when illicit opioid use was first introduced and spread (Hall et al. 2000b).

Substantial uncertainty intervals would need to be placed around these estimates to indicate our ignorance of underlying trends and to empha-
size the need to undertake better epidemiological research to improve our estimates of the global burden of disease attributable to illicit drug use.

## Notes

1 See preface for an explanation of this term.
2 MDMA: 3,4 methylenedioxymethamphetamine, a synthetic drug that is used as a stimulant.

3 Amphetamine-type stimulant (ATS): one of a class of sympathomimetic amines with powerful stimulant action on the central nervous system.
4 Cannabis: a generic term for psychoactive preparations (e.g. marijuana, hashish and hash oil) derived from the cannabis sativa plant.
5 Cocaine: an alkaloid central nervous system stimulant drug that is derived from the coca plant.
6 Heroin: an opioid drug derived from the opium poppy.
7 Opioids: generic term applied to derivatives from the opium poppy, their synthetic analogues, and compounds synthesized in the body, which act upon the opioid receptors in the brain. They have the capacity to relieve pain and produce a sense of euphoria, as well as cause stupor, coma and respiratory depression.

8 Drug overdose: the use of any drug in such an amount that acute adverse physical or mental effects are produced. Overdose in this chapter refers to cases in which death is the outcome.

9 DSM-IV: American Psychiatric Association's Diagnostic and Statistical Manual of Mental Disorders, 4th edition.

# Chapter I4 

Unsafe sex<br>Emma Slaymaker, Neff Walker, Basia Zaba and<br>Martine Collumbien

## Summary

The risk factor "unsafe sex" has been defined here as sex between a susceptible person and a partner who has a sexually transmitted infection (STI), without taking measures to prevent infection. Unsafe sex cannot therefore be defined a priori (because sex is only unsafe with respect to the context in which it occurs), or measured directly from reported behaviours. A set of behaviours was defined as "risky sex" and the prevalence of various behaviours was estimated for 57 countries. The prevalence of risky sex as defined here is given by the proportion of the population who have had sex in the last year with a non-co-resident partner, and who did not use a condom on the last occasion with that partner. For the comparative risk assessment (CRA) estimates, the prevalence of risky sex between men and women was the primary focus.

The main outcome considered was infection with HIV, which is responsible for the majority of the burden of mortality and morbidity associated with STIs. Infections with Chlamydia trachomatis (chlamydia), Neisseria gonorrhoeae (gonorrhoea), human papillomavirus (HPV) and Treponema pallidum (the causative agent of syphilis; hereafter referred to as "syphilis") were considered in less detail because the information available for these infections is inadequate for detailed analysis.

Infection with HIV/AIDS is the fourth leading cause of mortality in the world. Currently, most ( 29.4 million) of the 42 million people globally who are infected with HIV are concentrated in Africa, but epidemics elsewhere in the world are growing rapidly. Prevalence is increasing most swiftly in eastern Europe and central Asia (UNAIDS/WHO 2002). Most of the infections prevalent in 2001 were acquired through heterosexual sexual intercourse. Most people infected with HIV do not know they are infected, making prevention and control difficult. The other STIs included in the burden estimates, C. trachomatis, N. gonorrhoeae, HPV
and T. pallidum (syphilis), cause morbidity in all regions of the world. Infection with some of these agents can lead to infertility (e.g. C. trachomatis) or cancer (HPV), and an acute STI may enhance the transmission of and susceptibility to HIV.

To estimate the prevalence of sexual risk behaviours, suitable studies were located and, where possible, the data produced by these studies were analysed to create a set of standard indicators for different aspects of sexual behaviour. The prevalence of different sexual behaviours and characteristics varies greatly between countries and between subregions. ${ }^{1}$ The levels of risk behaviour did not vary in a predictable manner, and variations in reported behaviour at the aggregate level do not correspond to differences in HIV prevalences. A literature search was also carried out to identify reported risk factors for HIV infection and estimates of the risk associated with each factor. Since the outcomes are infections transmitted from person to person, the relative risk of infection changes with the prevalence of the infection, and changes in prevalence affect incidence.

Two different approaches were used to estimate the avoidable burden of HIV/AIDS attributable to unsafe sex. For countries in sub-Saharan Africa where the prevalence of HIV/AIDS in adults is high and the epidemic is largely driven by heterosexual sex, a mathematical projection model (the Epidemic Projection Package [EPP]) was used to estimate how many infections were attributable to unsafe sex, and how many were potentially avoidable. For countries where adult prevalence is lower and the spread of HIV/AIDS is confined to specific subgroups, a different approach was used whereby current estimates of HIV/AIDS and projections were based on estimates of sub-epidemics related to the mode of transmission (e.g. injecting drug use, men who have sex with men, heterosexual transmission). For these countries the risk associated with unsafe sex was the percentage of all infections that were sexually acquired. The other STIs were assumed to be entirely the result of unsafe sex and therefore $100 \%$ of the burden caused by these STIs is avoidable.

The modelling exercise suggests that there would not have been an HIV epidemic in Africa had there never been any sexual transmission since of the cases of HIV infection prevalent in 2001, >99\% were associated with a sexually acquired infection at some point in the chain of transmission. In the rest of the world, the estimated percentage of the HIV infections prevalent in 2001 that were attributable to unsafe sex ranged from $25 \%$ in eastern Europe (EUR-C) to $95 \%$ in parts of Latin America (AMR-D). Using these estimates, the mortality attributable to unsafe sex ranged from 4000 deaths in EUR-C to 1632000 in AFR-E. Globally, 2444000 deaths and 75783000 disability-adjusted life years (DALYs) were attributable to this risk factor. If unsafe sex were to cease, most parts of the world would see a substantial drop in the number of new HIV infections.

## 1. Introduction

A variety of infectious agents can be transmitted through sexual contact, including HIV, chlamydia, gonorrhoea, HPV and syphilis). While having sex (which in this chapter refers to vaginal sexual intercourse, unless otherwise stated) may place a person at risk of being infected by one or more of these agents, it is difficult to assess the magnitude of this risk. Sex can only be defined as "safe" or "unsafe" if something is known about the context in which it takes place and with whom. Having sex does not place a person at risk of contracting a disease unless that person's partner has an infection, which they can transmit. Therefore, unlike many other risk factors, which are independent of the situation in the broader population, or with respect to other individuals, unsafe sex cannot be uniquely defined by the set of actions of an at-risk individual. Rather, a definition must be based on an analysis of the individual's actions in light of the background prevalence of disease. The principal health outcome considered in this chapter is the number of adults aged 15-49 years who become infected with HIV as a consequence of unsafe sex, and the number of these infections that is potentially avoidable. Infections in children resulting from vertical transmission were not included since these are not caused directly by unsafe sex, but by infection via the mother, together with a lack of pre- and postnatal treatment of mother and child. The other STIs (chlamydia, gonorrhoea, HPV and syphilis) were considered separately and in less detail because they contribute to a lesser degree to the burden of disease and mortality, and because of the limited amount of information available regarding the prevalence and current transmission dynamics of these infections in different subregions. A thorough review of the epidemiology and importance of these STIs was given in previous burden of disease work (Rowley and Berkley 1998).

The relationship between the risk factor unsafe sex and the disease outcomes, which contribute to the global burden of disease, cannot be described using the standard epidemiological tradition of constant, extrapolable hazards. This is owing to the fact that the outcomes considered in this chapter all relate to infections which are transmitted from person to person. The relative risk of being infected by any one of these diseases is therefore dependent on the prevalence of the disease.

### 1.1 Definitions of unsafe sex

In this chapter, STIs were the only negative outcomes of sexual contact considered. Other potentially deleterious outcomes, such as an unwanted pregnancy or the psychological consequences of sexual violence, are considered elsewhere in the CRA (see chapters 15 and 23). It is important to define the group of people who share a common risk factor for contracting an STI in order to be able to carry out a risk assessment. The risk factor has been called "unsafe sex", but this term does not
immediately suggest a clearly defined characteristic of either an individual or a population that can be used to determine how many people are affected by the risk factor. "Safe" sex has previously been defined as follows:

> Consensual sexual contact with a partner who is not infected with any sexually transmitted pathogens and involving the use of appropriate contraceptives to prevent pregnancy unless the couple is intentionally attempting to have a child. (Berkley 1998)

This definition is not useful for the purposes of this chapter, since many of the ways in which the above definition can be negated would not put an individual at risk of acquiring an STI. For example, sex with an uninfected partner without using contraception does not pose a risk of infection and nor would sex with an infected partner if a condom was used properly.

Therefore, before defining unsafe sex we must first consider what type of classification would be suitable to describe the degree of risk experienced by an individual or population. The risk of contracting an STI depends both on the individual and on the population. Individual behaviours determine whether or not it is possible for infection to occur. The prevalence of infection in the population determines whether or not the individual becomes exposed to an infectious agent. Therefore an ideal measurement of this risk would include both individual and population characteristics.

If it were possible to measure this risk at the individual level, a gradation across the population would be observed. Risk gradation suggests the possibility that a continuous index of risk could be constructed by combining several factors. However, many if not most behavioural factors do not retain a simple dose-response relationship when considered in combination with others. For example, consider a person who is not infected with HIV at a particular instant in time. The frequency of this person's sexual relations with a regular partner could show a dose-response relationship relative to the risk of acquiring infection, but only if the partner were infected. Similarly, the rate at which this person acquired new partners could also show a dose-response relationship, but only if each partner were infected. Past partner history would not be relevant, unless the individual had contracted another STI which could enhance the dose-response relationships between risk of infection and both coital frequency and partner acquisition rate. The conditionality of these interactions makes it practically impossible to quantify and construct a continuous measure of risk.

Individuals must therefore be categorized into static groups based on average levels of risk. This can be done so as to allow for the important effect of STI prevalence if the definitions of risk are based on probability of contact with cases, rather than on reportable behaviours. These
definitions will be valid at an instant in time, or for a very short time period; it is important to realize that such distinctions may be very short-lived since sexual networks are dynamic. The following definitions provide a way of thinking about the true distinctions.

## Unsafe Sex

Unsafe sex occurs if a susceptible person has sex with at least one partner who has an STI, without taking measures to prevent infection. Susceptible people are not yet infected, either because the infectious agent has not been successfully transmitted, or because the agent has been transmitted but infection has not yet been established. Such susceptible people form the group which is truly exposed to infection and they are at a very high risk of becoming infected. For intervention and prevention purposes, this group is not as important as that defined below, because it is too late to prevent the members of this group from being exposed to infection. However, this group is the most relevant in terms of predicting the number of new cases of STIs.

## Hazardous sex

The group of people engaging in hazardous sex are those susceptible persons who either engage in unprotected sex but who have not yet encountered a partner who has an STI, or who have had sex with at least one partner who has an STI, but have taken measures to prevent transmission. These people have the potential to be exposed to infection, either by encountering an infected partner, or if the measures taken to prevent transmission are ineffective (e.g. condom failure). This group of people is important for prevention efforts; a change in the size of this group has the most potential to change the number of new infections occurring in the future.

These two definitions ("unsafe" and "hazardous" sex) would provide a way to allocate people to risk groups if membership of the two groups could be measured. However, there is currently no way by which this can be measured and so it is necessary to use a definition based on reportable behaviours, i.e. "risky sex", as a proxy.

## RISKY SEX

The people who have risky sex share a certain set of behaviours; these can be different in different epidemic situations, but are likely to include having many sexual partners and not using condoms. This classification is based on individual reports and will include infected as well as susceptible people, because infection status is not known from such reports. Ideally, we seek to identify reportable behaviours so that the group identified as having risky sex would include those having unsafe sex and those having hazardous sex but exclude others (those having "safe" sex or no sex).

Figure 14.1(a) shows the relationship between groups of infected and susceptible people in terms of those who have unprotected sex, those who have sex with an infected partner, and those who report a "risk behaviour". The reported risk behaviour is the measurable component of an individual's sexual behaviour.

From this figure it is possible to see why classifying people into risk groups on the basis of reported behaviours is not necessarily a good measure of exposure to infection. Some people will be wrongly classified as at risk because they report risk behaviours, but actually they are already infected. Others will be wrongly classified because they report behaviours which have not exposed them to infection, as they did not behave in exactly the way they reported. Some people will be wrongly classified as not at risk because although they have had a sexual contact which could potentially have led to infection, they did not report this behaviour. This could be deliberate, because they do not wish to admit to "undesirable" behaviour, or unintentional, because the behaviour has been forgotten. People will also be misclassified if the risk behaviour they are asked to report is not the best predictor of the actual risk experienced. For example, in a population of married women this could happen if risk were classified on the basis of reporting sex with nonmarital partners, but the main source of infection was in fact the women's husbands.

Figure 14.1(b) shows where the groups defined above (unsafe sex and hazardous sex) fall in this schematic. The black section shows the group having unsafe sex: the susceptible people who have unprotected sex with a partner who has an STI. By definition, this group falls wholly within the group of susceptibles and includes some of the people who report risk behaviours and some of the people who are classified as having hazardous sex. The group which has hazardous sex is shown in the light grey and dark grey sections and is composed of those who either have unprotected sex or who have protected sex with a partner who has an STI. This includes people who do report risk behaviours and some who do not. Again, by definition, this group includes only susceptible persons. Some members of the group who report risky behaviour, shown in white, are not included in either the group having hazardous sex or the group having unsafe sex.

### 1.2 Estimating levels of risky sex in a population

If there were no STIs, then there would be no unsafe and/or risky sex. In areas where there is a high prevalence of STIs, a larger number of sexual behaviour patterns will be dangerous than in places where very few people are infected with a sexually transmitted pathogen. A pragmatic definition of a specific behaviour, or group of behaviours, (e.g. sex without a condom) as "risky" can be useful, providing it is understood that the degree of risk associated with this behaviour will not be the same in different populations, or at different times in the same population.

Figure I4.I Venn diagram illustrating the relationship between three ways of defining unsafe sexual behaviour
(a) Components of risk behaviour

(b) Correspondence between the components of risk behaviours and definitions of unsafe, risky and hazardous sex

With this caveat in mind, the question arises as to how best to describe populations with different levels of risk.

Aggregate measures of sexual behaviour will inevitably be less informative than more local measures. However, even country-level indicators cannot capture the more subtle variations in sexual mixing patterns, such as partnership concurrency. The level of risk attached to a particular behaviour changes with the prevalence of the infection; if prevalence is high, there are more infected people in the population and so a susceptible person has a greater chance of choosing an infected person as their next sexual partner. In each subregion, the prevalence of STIs and
of certain behaviours varies between the countries. Within the different countries, STI prevalence and sexual behaviour can vary between urban and rural areas, age groups and sexes, socioeconomic classes, religious groups, between people of different sexual orientation and according to other factors such as proximity to transport links and health services. Personality and physiology play a significant role in determining a person's sexual behaviour and, in the case of the latter, susceptibility to infection. The impact of these determinants cannot be measured at the population level, but they are of great importance in determining how many people are exposed to STIs and how many people become infected.

The effect of heterogeneity in sexual behaviour on the ability to measure the level of dangerous exposure is more subtle. When sexual behaviour is measured in a survey, data are only collected regarding the respondents' behaviour. However, the behaviour of the sexual partner is as important a predictor of risk as the behaviour of the respondent. A respondent who has a large number of sexual partners is probably at a high risk of contracting an STI. However, if all of these partners have never had sex with anybody else, the respondent is perfectly safe. Therefore in a population where people vary greatly in the number and frequency of their sexual contacts, a one-sided measure of "sexual behaviour" is difficult to interpret. It is known that in most populations men and women have very different patterns of sexual behaviour. Most populations also have a subset of both men and women who are distinguished by high levels of sexual activity. Both of these imbalances make it difficult to quantify risk based on reported behavioural data from surveys.

The level of risk, to oneself and one's partner, is illustrated assuming different patterns of partnership and condom use in three different epidemic situations in Figure 14.2. The epidemic states correspond to those defined in WHO/UNAIDS (2000). A low-level epidemic is one in which, although HIV infection may have been present in the population for some time, it has not spread outside defined groups at a high risk of infection, and the prevalence among these groups has not exceeded $5 \%$. A concentrated epidemic is one in which HIV infection has spread within defined groups and prevalence has exceeded $5 \%$ in at least one of these groups, but prevalence among pregnant women in urban areas remains below $1 \%$. A generalized epidemic is one in which HIV infection has spread throughout the general population, as indicated by a prevalence of infection of greater than $1 \%$ among pregnant women.

A partnership is mutually monogamous if both partners only have sex with each other for the duration of the relationship. Lifetime mutual monogamy is always safe, regardless of the prevalence of STIs in the population. One-sided lifetime monogamy is safe for one of the partners in this type of relationship: individuals who have sex with a partner who has never had sex with anyone else do not place themselves at risk of infection from this partner, but may themselves present a risk to this partner if they have also had sex with other people. Serial monogamy is

Figure 14.2 Risk matrices: the level of risk to an individual and their partner is illustrated assuming different behavioural patterns in different epidemic situations

Low-level epidemic

## Key to risk levels

defined as a succession of monogamous relationships. These relationships are monogamous from the individual's standpoint, but no assumptions can be made about the behaviour of the partner. Partnerships of this sort may last for days or years. The frequency with which partnerships are dissolved and reformed will affect the risk of acquiring an STI and this will also be affected by the prevalence of STIs in the population. If an individual has sexual partnerships that overlap, such partnerships are said to be concurrent. STIs can be spread more easily if people have sex with several partners within a short space of time. Therefore although having concurrent partnerships is associated with the greatest risk of contracting an STI, serial monogamy with very short intervals between successive partners also places the partners at high risk.

## 2. DATA SOURCES

The data used to calculate levels of risky sexual behaviour came from general population surveys designed to be nationally representative. More than 300 surveys were identified that could potentially have been used in this analysis. Many of these had been carried out under the auspices of the Demographic and Health Surveys (DHS) programme conducted by Macro International. The focus of these surveys was family formation and fertility, and only more recently have questions on sexual behaviour been incorporated. Most DHS data are from African countries, but some surveys have been carried out in South America and Asia. South American countries are also covered by the Centers for Disease Control and Prevention (CDC) Reproductive Health Surveys (RHS) which asked questions about sexual behaviour. CDC has also carried out some surveys in Asian and eastern European countries. Other organizations, such as Population Services International (PSI), also carry out surveys which provide suitable information.

Most of the established market economy countries have carried out their own surveys of sexual behaviour, many of which date from the late 1980s and early 1990s, a time when policy-makers began to be concerned about the potential for the spread of HIV in these populations. For example, the data from the United Kingdom of Great Britain and Northern Ireland used in this analysis date from 1990; the survey was repeated in 2000 but the data were not yet available. The problem of standardization is greater for established market economy countries' surveys because they have been carried out by many different organizations, each of which sought different information to address different concerns.

### 2.1 Search strategy

The scientific literature was searched for information on the prevalence of different sexual behaviours and the relationship between risky sex and STIs. Information dating from after 1990 was used wherever possible.

Identifying survey data sets and or reports which incorporated information on sexual behaviour was not straightforward since these terms are not indexed in the major bibliographic databases. Therefore the use of a formal search strategy alone would not have been adequate. Suitable surveys were located in several ways:

STEP 1: WEB SITES OF SURVEYING ORGANIZATIONS
Organizations that carry out surveys that include information on sexual behaviours provide lists of these on their web sites; this was the first source of information for the majority of surveys. These organizations are:

- Demographic and Health Surveys (DHS), Macro International and Measure, USA (http://www.measuredhs.com) and (http://www. measureprogram.org)
- Reproductive Health Surveys (RHS) carried out by CDC, Atlanta, USA (http://www.cdc.gov/nccdphp/drh/gp_surveys.htm)
- Population Services International (PSI), USA (http://www.psi.org/)
- Family Health International (FHI), USA (http://www.fhi.org/)
- Global programme on AIDS (GPA) listed on http://www.unaids.org/ publications/documents/epidemiology/determinants/Survey_Sexual_ Behaviour.doc

## Step 2: SEARCH OF PUbLISHED MATERIALS

Medline, Popline and Web of Science databases were searched for appropriate publications. Other databases providing qualitative information (such as Psychinfo) were not used because quantitative information was considered more important for this work.

## Step 3: Contact with other researchers

This turned out to be the most efficient strategy because researchers involved with one survey frequently knew of other existing surveys.

## Step 4: Internet search using Google

The Google Internet search engine was used, the principle search terms employed being the names of authors of surveys known to have been carried out and the names of institutes likely to have been involved in suitable surveys. It is not useful to carry out Internet searches using keywords related to sex.

## Search terms

- Popline

Search terms used were "sex behaviour", "condoms, male" "condoms, female" "population" "HIV infections". This yielded 709 references, of which 75 were selected.

- Medline

Search terms employed were sexual behaviour, risk, ratio, odds, changes, sexual behaviour, incidence or prevalence, change*, reduction or lower or decline, HIV.

- Web of Science

Search terms used were sexu* and country name. If a search term returned a large number of hits, it was narrowed by adding "risk".

All the databases were searched for information from countries where there was no DHS, CDC, PSI or national (state) survey available.

### 2.2 Prevalence studies: HIV and other sexually TRANSMITTED INFECTIONS

Data on the prevalence of HIV are generally from national surveillance systems. In most countries, women who attend antenatal care clinics (ANC) are tested for HIV anonymously and these data are taken to be representative of the general population in these countries. Other sources of surveillance data include blood donors, STI clinic patients and military recruits. Only ANC clinic prevalence data were used in this work. These data are collected by the United States Bureau of the Census and at the Joint United Nations Programme on HIV/AIDS (UNAIDS) in Geneva, from which the information is disseminated. The quality, coverage, history and competence of national surveillance schemes vary enormously (Walker et al. 2001). Consequently, prevalence data from some areas are more reliable than from others and more recent estimates are generally more reliable than older ones.

WHO collects the available STI prevalence data on a regular basis. However there is a lack of time-series data, which means that mathematical projection models cannot be used to make projections of future prevalence.

### 2.3 Prevalence studies: sexual behaviour

As described above, it is not clear which types of behaviours best define the group of people who are at risk of contracting an STI. Therefore information was collected on all behaviours which might be important in defining this group.

## Measuring sexual behaviour

## Target population

Many surveys of sexual behaviour have focused on high-risk groups within a population. In countries with concentrated epidemics, most STIs occur within these groups, which are often composed of people such as commercial sex workers or men who have sex with men. Unfortunately, the size of these groups relative to the total population is rarely known.

Information from surveys of groups at a high risk of infection cannot be extrapolated to the general population without an accurate estimate of the overall size of the group. General population surveys are unlikely to find a representative sample of members of groups at a high risk of infection and therefore underestimate the prevalence of risk-associated behaviour in a population. Data from groups at a high risk of infection have not been used directly in this work because sufficient information is rarely available to be able to use these data in the context of aggregate national estimates of risk behaviour. Therefore the estimates of the level of exposure could be too low in countries where STIs occur mainly within groups at a high risk of infection.

## Methods of data collection

Sexual behaviour surveys are a fairly recent activity and the best methods for obtaining the required information have not been established. The most appropriate reference period for information on the number and characteristics of sexual partners is not known. There is no reliable method for comparing data collected for different periods of time. For example, somebody who reports having had one partner in the last month has not necessarily had twelve in the last year, but may well have had more than one partner in this time. Asking people for information from a longer time period will introduce a recall bias. This bias could be a problem because people might be more likely to recall partners of longer duration than those with whom contact is more short-term. This could lead to underestimates of the number of more risky sexual contacts.

If sexual behaviour patterns are changing over time, a cross-sectional survey will not give a good estimate of the cumulative lifetime exposure to risk, because the risk exposure of the youngest age groups at the time of the survey will not reflect the risk that the older age groups experienced when they were young. Ideally, current state measurements should therefore be supported by life course measures, even if we have to rely on recall data for the latter.

Surveys which only collect information on the respondent's own behaviour will misclassify some individuals with respect to their risk of acquiring an STI. They will systematically underestimate risk because people who are at a low risk because of their own behaviour could be put at risk by the behaviour of their partner. If people who are at a low risk always chose low-risk partners, then surveys could accurately estimate the proportion of those who are at risk. There is evidence from selected DHS with a couple subsamples that this is not the case, and that there is substantial misclassification of women as at a low risk based on their own behaviour, but who are in fact at risk through their husbands. This is illustrated in Figure 14.3 and supported by the results of other studies (e.g. Rwanda and Kenya, Chao et al. 1994; Hunter et al. 1994).

Figure 14.3 The proportion of married couples in which at least one partner reports having had extramarital sex during the last year, by country

Source: Data from selected DHS.

The accuracy of survey instruments in correctly evaluating people's behaviour is unknown. In studies where cross-sectional household surveys have been validated with in-depth interviews, it has been found that people tend to under-report "undesirable" behaviours (Konings et al. 1995). The age, sex and personal characteristics of the interviewer may also influence the reporting of sensitive information (Malamba et al. 1994), which is likely to include the behaviours of interest. Many surveys find that the number of partners reported by men greatly exceeds the number reported by women. Two factors contribute to this: general population surveys may fail to include the few women who have a large number of partners, and women may consistently under-report how many partners they have had (Glynn et al. 2001).

In choosing which data to use for the risk assessment, the first criterion was that the survey sample should be representative of the general population. Some surveys, mainly those with a demographic focus, only interviewed women, and some were concerned only with ever-married women (women who are currently married or who have been married at some stage in their lives). The latter samples were generally carried out in countries where it is not possible to discuss sexual behaviour
openly and consequently they provide only a limited amount of information. The age range of persons included in the surveys also varied. If a survey was limited to a narrow population in terms of sex, age or marital status, it was only analysed in the absence of a suitable alternative. This was the case for several countries. The surveys used, the populations covered and the data sources for each are listed in Appendix A. The type of information available and the number of countries and subregions covered are listed in Table 14.1.

The surveys referred to in Table 14.1 were carried out between 1989 and 2001. In general, the most recent survey available was used for each country. Individual-level data were required to calculate values for most of the sexual behaviour indicators because these were not usually given in a suitable format in published reports. In some cases, the data used to calculate the estimates presented in this chapter did not come from the most recent survey because such data were not available at the time of writing.

There were very few countries for which more than one survey was suitable for calculating sexual behaviour indicators. If more than one eligible survey for a country existed, the survey providing the most information was used first. Data from different surveys were not combined when calculating any one indicator for a particular country, but the full set of indicators for a country were not always derived from the same survey. The estimates for each indicator were rated according to how directly each indicator could be calculated from the information elicited by the survey questions and the number of assumptions which had to be made in the calculation. In cases where two estimates were available for one indicator, the estimate that was considered better was used.

The responses received in a survey may have been influenced by the manner in which the questions were phrased. The data presented here were derived from responses to several differently-phrased questions and this may have distorted the results. Within subregions this should not be of concern, beyond increasing the uncertainty of the measurement, as it seems unlikely that this error should vary with respect to exposure to STIs. However, a bias may well be introduced when making comparisons between subregions with different styles of questions because questionnaire styles are generally more similar within subregions.

Most general population data only cover heterosexual behaviour. Those surveys which discuss sex between men are generally carried out only among men who have sex with men and the number of these individuals in a population is rarely known. Therefore the behavioural measures collected for this analysis focussed entirely on heterosexual sex. For some subregions where sex between men plays a key role in the epidemic, this is an important omission. However, data are rarely available on behaviour in homosexual men in the subregions with the greatest burden of STIs, and the focus of this chapter has been largely dictated by the epidemic in these countries. As will be explained in more detail below,
Table I4.I Indicators of sexual behaviour and the number of countries and subregions for which relevant data are available, by

| Indicator of sexual behaviour | Denominator | Numerator ${ }^{\text {a }}$ | Information available ( $n$ ) |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  |  |  | Countries |  | Subregions ${ }^{\text {c }}$ |  |

whilst homosexual men are not included in the exposure estimates, they are included in the estimates of attributable and avoidable infections as a result of the modelling approach taken.

## Flow of data

Having identified a suitable survey, the questionnaire (if available) was assessed to ensure that the data would be suitable for inclusion in this analysis. If suitable, the data were obtained and converted (if necessary) for analysis using Stata version 7.0. Variables were created for as many of the standard indicators (those listed in Table 14.1) as was possible for each survey. These were then used to calculate the weighted numbers of people in each category, and the results were exported to a Microsoft Access database.

## Survey design issues

There is no standard survey questionnaire. Even those carried out by the same organization, such as DHS, differ slightly from country to country and from year to year. DHS use a standard questionnaire for each survey round, but countries do not necessarily use all of, or only, the standard questions in their surveys. The standard questionnaire for the round four DHS has departed from the previous standard in the AIDS module and now asks about the previous three partners, in contrast to the prior rounds which asked about marital and non-marital partners. Other surveys have differently-worded questions and a different structure and order of questions. Therefore the data had to be standardized in some way.

Two major problems emerged while trying to compile the responses to different questionnaires to allow comparison. First, the reference period for questions on sexual behaviour varied. The majority of surveys asked about behaviour in the year prior to the survey but a few used different timescales. It is difficult to relate the responses to questions with one reference period to those with another reference period and therefore some of the data could not be used to calculate the standard indicators. Second, questions relating to condom use followed two styles. One style asked about condom use on the last occasion (with a particular partner). The other asks whether condoms were always, sometimes, or never used (with a particular partner). The latter question is impossible to compare between different surveys since it would be necessary either to quantify "sometimes" or to get an estimate of consistency of condom use with different partners. A significant amount of data on condom use could not be included here for this reason. Work has been done on methods for comparing responses to different types of questionnaire design; however, to do this effectively for this analysis would have required many assumptions to be made, and would thus have introduced another possible source of error.

## Standardization of questionnaires

Given the differences in question wording and questionnaire structure, it was not possible to define a set of rules for this process. Table 14.2 shows some of the questions used in constructing the same indicator for different countries.

### 2.4 Outcome studies: sexual behaviour and HIV/AIDS

## Estimating the relative risk of HiV infection in exposed vs nonEXPOSED PEOPLE

The relative risk or odds ratio for various indicators of sexual behaviour has been assessed in a number of general population studies listed in Table 14.3. The accuracy of these estimates is influenced by the following factors.

## Methodological issues

The time at which a person became infected is an important piece of information because it is their behaviour at around that time which is the most relevant when estimating relative risk. People do not usually know that they are infected, let alone when this occurred, so behaviour is seldom measured for the relevant period of time. This could reduce the chances of detecting a real association. Studies which attempt to find risk factors for STIs, in particular HIV, face problems because of cultural unease about discussing STIs. Other problems include a lack of laboratory resources and expertise in geographical areas with high prevalence, as well as the ethical issues involved in serological testing.

The studies which estimate the risk associated with particular behaviours are mostly cross-sectional. If sexual behaviour patterns are changing over time then these surveys, which look for patterns of association between estimates of exposure and prevalence, could produce misleading results. The behaviour reported by HIV-positive people who have been infected for some time, and whose behaviour has changed between the time of infection and the time of the survey, will not reflect their behaviour at the time of infection. The degree to which people are misclassified in this way will depend on the stage of the epidemic (because in the early stages more infections are recently acquired) and on the reference period used in the survey.

This effect could be mitigated if life course measures were also considered. Comparison between life course and the more recent measures could show if behaviours have changed. Some indicators of behaviour are known to correlate with others. For example, age at which the individual first has sex has been shown to correlate with number of extramarital partners later in life (White et al. 2000) and so inconsistencies in this relationship, where this has been previously documented, could point to changing patterns of behaviour.
Table 14.2

| Name of survey | Question asked | Mode |
| :---: | :---: | :---: |
| Number of people who have ever had sex |  |  |
| NEM European Group | Have you ever had sexual intercourse? | FTF |
| NATSAL 1990 (United Kingdom) | How old were you when you first had sexual intercourse with someone of the opposite sex, or hasn't this happened?" | FTF |
| DHS Zambia 1996 | Married: When was the last time you had sexual intercourse with (your husband/the man you are living with)? Not married: When was the last time you had sexual intercourse (if ever). | FTF |
| DHS Kazakhstan 1999 | How old were you when you first had sexual intercourse (if ever)? | FTF |
| PSI Rwanda 2000 | Avez-vous jamais fait l'amour avec une personne de sexe opposé? | FTF |
| Number of people who had sex in the year before the survey |  |  |
| NEM European Group | With how many persons of the opposite sex have you had sex over the last 12 months, even only once? | FTF |
| NATSAL 1990 (United Kingdom) | When, if ever, was the last occasion you had vaginal sexual intercourse with a (man/woman)? | SAQ |
| DHS Zambia 1996 | Married: When was the last time you had sexual intercourse with (your husband/the man you are living with)? Not married: When was the last time you had sexual intercourse (if ever) | FTF |
| DHS Kazakhstan 1999 | When was the last time you had sexual intercourse? | FTF |
| PSI Rwanda 2000 | Quand avez-vous fait l'amour la dernière fois? | FTF |
| Number of men who had sex with a commercial sex worker in the year before the survey |  |  |
| NEM European Group | Have you ever had sex with a person you paid to have sex? If yes: |  |
|  | When was it for the last time? | FTF |
| NATSAL 1990 (United Kingdom) | Have you ever paid money for sex with a woman? If yes: <br> When was the last time you paid money for sex with a woman? | SAQ |
| DHS Zambia 1996 | Have you given or received money, gifts or favours in return for sex at any time in the last 12 months? | FTF |
| DHS Kazakhstan 1999 | Have you ever paid for sex? <br> If yes: <br> How long ago was the last time you paid for sex? | FTF |
| PSI Rwanda 2000 | Au cours des douze derniers mois, avez-vous reçu de l'argent ou des cadeaux en échange des rapports sexuels ou bien avez-vous payé quelqu'un pour faire l'amour avec vous? | FTF |
| Key: FTF, face-to-face; SAQ, self-administered questionnaire. |  |  |

## 3. <br> Estimating levels of sexual Risk behaviour

### 3.1 FACTORS WHICH DETERMINE THE INCIDENCE OF A SEXUALLY TRANSMITTED INFECTION

Worldwide, there is great variation in the prevalence of STIs and in patterns of sexual behaviour, but there is little concordance in the variation between the two. Figure 14.4 shows schematically some of the factors which theoretically determine the incidence of an STI, using the example of HIV. The first box shows societal factors which determine general patterns of sexual behaviour and sexual mixing. The second shows the characteristics which influence whether the sexual contact is potentially infectious, i.e. whether a person is exposed to infection. The third shows the mediating factors, which affect the potential for transmission of infection from the infected partner. The fourth box shows those factors which determine whether or not the contact results in a new infection.

Table 14.3 shows some of the factors which have been found to be associated with HIV infection in the general population in a variety of studies. ${ }^{2}$ The Ugandan samples are from cohort studies, which were designed to elucidate some of these relationships. Table 14.4 shows some of the behavioural changes which have been reported at the same time as observed HIV prevalence has decreased, as has happened in some countries, most noticeably Uganda and Thailand. Changes in HIV prevalence can be attributed to changes in behaviour if incidence has also decreased, but it is difficult to establish if this is the case because prevalence can decline due to excess mortality among people already infected with HIV.

Distal determinants of behaviour

## Age

Age is correlated with whether or not someone is sexually active and the likelihood that their sexual partner is their spouse. In countries where the HIV epidemic is of recent origin, older age groups may have a lower cumulative exposure to infection because most of their past sexual

Table 14.4 Changes in behaviour which have been observed concomitantly with a decline in HIV prevalence or incidence

exposure occurred at a time of low prevalence. The association of HIV infection with young age was not seen in all the studies listed in Table 14.3, and where an association was found it was not always in the same direction and was sometimes different for men and women.

Sex
In most cultures, men and women initiate sexual activity at different ages. The typical age difference between partners may be different for men and women. Societies may condone some sexual behaviours for men and not for women. In countries with generalized epidemics, prevalence is usually higher in women than men, especially in younger age groups.

Travel, place of residence, workplace
Factors such as travel, area of residence and occupation or place of work have been measured differently by the various studies. In those studies where these factors were associated with HIV infection (Auvert et al. 2001a; Nunn et al. 1994; Quigley et al. 1997; Seed et al. 1995) they could be acting as proxy measures for potential contact with infected sexual partners. These factors will all influence the number of sexual partners and proportion of available partners who are infected.

## Religion

In the studies which found religion to be associated with HIV infection, the comparison was between Muslims and non-Muslims (Malamba et al. 1994; Nunn et al. 1994; Quigley et al. 1997). There are two characteristics of Muslims which may be relevant to HIV infection: the customary practice of male circumcision and the requirement to abstain from alcohol. The use of alcohol and other mood-altering substances is an independent risk factor in other studies (Auvert et al. 2001b, 2001c; de Gourville et al. 1998; Gregson et al. 2001). The social values incorporated in the Muslim faith may also cause people to have risky sex less frequently.

## Marital status

Married people usually have sex more frequently than unmarried people. In most countries, being sexually active outside of a co-resident (cohabiting) relationship is associated with an increased incidence of HIV infection. Sex between co-resident partners usually carries a lower risk of infection than sex with other types of partner, so prevalence may be lower among married people. This may depend on how much extramarital sex is taking place: the proportion of people who have sex outside marriage varies between countries (see Figure 14.5). In countries where HIV prevalence is high, the surviving partners of people who died of AIDS will tend to have a higher prevalence of HIV infection than the group of people who are still married. However, in some places being currently married has been shown to increase the risk of HIV infection. This may be because married people gain an additional sexual partner at the time of marriage (Auvert et al. 2001b) compared to their nevermarried peers. The increased frequency of (unprotected) sex within marriage may also increase the risk of HIV transmission.

## Contraceptive method mix

Condoms may be used to prevent unwanted pregnancies but many couples choose to use non-barrier methods. In many cultures, condoms are not seen as appropriate for use within marriage or in a long-standing relationship. A pattern commonly seen in developed countries is that initial condom use with a new partner is followed by a switch to oral contraceptives after a few months, e.g. France (Commissariat Général du

Figure 14.5 The proportion of married men and women who report having had sex with someone other than their spouse in the last year, by subregion

Note: The figure shows the range of values, within a subregion, for the national estimates of the proportion of married people who report extramarital sex. The line across the middle of the box represents the median value, the box itself spans the interquartile range and the lines extend to the adjacent values at either end of the interquartile range (only shown where the adjacent values fall outside of this range). Data points which fall outside this range are plotted separately. There are no suitable data for AMR-A, EMR-B and EMR-D, EUR-B and SEAR-D.

Plan: Observatoire régional de santé d'Ile-de-France and Agence Nationale de Recherches sur le SIDA 2001). In some populations, negative attitudes towards condoms may lead to lower levels of use.

## EXPOSURE

## Prevalence of HIV

The proportion of people infected with HIV in the population is the main factor influencing the probability of having sex with somebody who is infectious for HIV.

## Sexual mixing patterns

Partner selection would be described as completely assortative if people always chose partners who were similar to themselves in all the measured respects. However, the way in which people select their sexual partners is usually incompletely assortative, that is, people tend to choose partners who are similar to themselves in most, but not all respects. The
differences may be predictable and some mixing patterns can have significant influence over the spread of STIs. For example, age-mixing in sexual relationships (older men with young women) is thought to be an important factor in accelerating the spread of HIV (Anderson and May 1991).

Traditional STI epidemiology defines "core" and "non-core" groups. The incidence of infection is high in the core groups, and most transmission occurs within these groups. The core group is composed of people who have a large number of sexual contacts compared to the rest of the population. Core groups tend to be small, and as long as infection remains confined to these groups, the population prevalence will remain fairly low. Since mixing patterns are incompletely assortative with respect to frequency of partner change, there will be occasional contacts between members of the core group and the rest of the population. The people involved in these sorts of partnerships are known as "bridge" groups and provide the route by which an infection moves from the core group to the general population. An example of this would be married men who visit commercial sex workers: married men are mostly members of the non-core group, commercial sex workers are members of a core group and the subset of married men who visit the sex workers is the bridge group. Simple measures of partner change and proportions exposed in either group fail to capture variation in density of exposure which arises from non-random mixing (Anderson and Garnett 2000).

## Number of partners

If condom use is not widespread in the population, then having a greater number of sexual partners means being exposed to a greater risk of infection. This is probably not a linear relationship because in many countries a disproportionate number of STIs occurs among the small group of people who have numerous partners. Most of the surveys listed in Table 14.3 found an increasing risk of infection (Auvert et al. 2001b; Chao et al. 1994; Hunter et al. 1994; Quigley et al. 1997; ter Meulen et al. 1992) and seroconversion (the detection of antibodies to HIV in a person who has not previously produced such antibodies, indicating recent infection with HIV) (Gray et al. 2000) associated with increasing numbers of partners. The reference periods were not the same in these surveys so it is not possible to compare the magnitude of the increased risk; this pattern was not clear in all studies. In the Masaka cohort in Uganda, the effect of the number of partners seemed to be modified by age. There was a greatly increased risk associated with having more partners for those aged $<25$ years, but no clear pattern among older people (Malamba et al. 1994). In the Four Cities study, women reporting a greater number of lifetime partners had a significantly increased risk of being infected with HIV in Kisumu (Kenya), Ndola (Zambia) and Yaoundé (Cameroon) but not in Cotonou (Benin) (Auvert et al. 2001b). Only in Ndola (Auvert et al. 2001b) was an increased chance of being HIV-positive observed among men reporting a higher number of lifetime partners.

In Uganda, a reduction in the number of partners does not appear to have been necessary for a decline in prevalence to occur (Asiimwe Okiror et al. 1997; Kamali et al. 2000). In Zambia, localized decreases in the prevalence of HIV among young women attending antenatal care clinics were observed between 1994 and 1998, and the proportion of people reporting large numbers of sexual partners in the same area in coincident general population behavioural surveys was also seen to decline (Fylkesnes et al. 2001).

## Commercial sex

Contact with sex workers, a group that often has a high prevalence of HIV infection, seems mainly to be important outside of Africa. Commercial sex is difficult to define in a meaningful way across cultures because the exchange of money or gifts may generally accompany sex in some cultures, but this may not mean that the woman has a great many partners, or that she is demanding the payment in return for sex.

## Duration of relationships

Sex within a relationship that has been established for a long time is thought to carry a lower risk of HIV infection than sex with a more recently acquired partner. Logically, this would only be the case if both the partners were mutually monogamous throughout the duration of the relationship. It may be that mutually monogamous partnerships last longer than others and that the observed association is a selection effect.

## MEDiating factors

## Male circumcision

In Africa, male circumcision is associated with a lower probability of male HIV infection (Auvert et al. 2001c; Gray et al. 2000; Hunter et al. 1994; Seed et al. 1995; Weiss et al. 2000). There is a plausible biological mechanism for this (Glynn et al. 2001; Royce et al. 1997), although its importance outside of Africa remains to be measured. It is also unclear whether a circumcised, infected man is less likely to transmit the infectious agent to a female partner than an uncircumcised man.

## Sexually transmitted infections

HIV infection is likely to be associated with a history of infection with another STI because these agents share the same mode of transmission. Being infected with an STI indicates that a person has had a sexual contact which could also have led to HIV infection, if their partner was infectious for HIV. However, it has been found that, in addition to providing a marker for this type of contact (Obasi et al. 1999), the presence of another active disease increases the risk of both HIV transmission and infection (Mbopi Keou et al. 2000). In the studies summarized in Table 14.3, relevant information was collected for different diseases in differ-
ent ways. This is because the locally important STIs vary and the setting of the studies imposes restrictions on the information collected. However, in all the studies, having ever had another STI clearly increased the chance of being infected with HIV.

## Condom use

The efficacy of condoms in preventing the transmission of HIV and other STIs has been established (Weller and Davis 2002). However, only one of the studies listed in Table 14.3 (a study carried out among men attending an STI clinic in India (Rodrigues et al. 1995) found a protective association between reported condom use and HIV infection. The reason for this may be that in African countries condom use is actually a marker for risky sex. That is, condoms are only used by those who (rightly) perceive themselves to be at risk of infection. In this case, condom use would only be protective if condoms were properly used at every risky encounter. Condom use would only be revealed as protective in a statistical analysis if this could be confined to those who indulge in risky sex, or if the propensity to have risky sex could be controlled for. If members of groups at a high risk of HIV infection were initially more likely to use condoms, a protective effect would only become apparent as condom use became more widespread in the general population. The availability and acceptability of other methods of contraception might affect the chances of a couple using a condom.

## Sexual practices

Anal sex, both in homosexual male and in heterosexual couples, carries a higher risk of transmission than other practices. It has been suggested that drying the vagina before sex, and having sex during menses also increase the risk of HIV infection in women. However, this has not been clearly demonstrated (Auvert et al. 2001b; Buve et al. 2001a; Malamba et al. 1994).

## Susceptibility

There is a high incidence of HIV infection among young women who have become sexually active at an early age. A partial explanation for this observation may be that young women are particularly vulnerable to HIV infection because the immaturity of the genital tract renders them physiologically susceptible. This is a complex issue, as demonstrated by the results of the Four Cities study, which showed that the high prevalence of HIV infection among young women was not fully explained by behavioural factors (Glynn et al. 2001).

In Europe, transmission from males to females has been observed to be more efficient than vice versa (Anonymous 1992) but this was not confirmed in Rakai (Uganda) (Quinn et al. 2000). This pattern of differential transmission probabilities between the sexes is inconsistent in the rest of the world (Mastro and Kitayaporn 1998).

### 3.2 Choice of indicators of potentially hazardous SEXUAL BEHAVIOURS

Sexual behaviour can be summarized by a variety of different measures and, as described above, many of these measures have been found to be associated with HIV infection. However, it is also clear that these associations are not found in all populations, nor are they consistent in direction and magnitude across those populations in which an association has been observed. The most appropriate indicators of potentially hazardous behaviour were judged to be those which have been associated with HIV infection in different settings, and which:

- are available and relevant for all age groups, both sexes and all subregions;
- describe an important aspect of behaviour in all subregions; and
- are associated with the risk of acquiring HIV infection, or with being already infected with HIV.

First, an empirical approach was used to identify this subset. Popula-tion-level estimates are available for many of these behavioural indicators and estimates of HIV prevalence are also available for many countries. However, it is well known that there is no simple relationship between observed HIV prevalence and reported sexual behaviours at the population level. In many African countries with generalized epidemics, the national prevalence estimates are based on fitting a mathematical model of the HIV epidemic to observed HIV prevalence data acquired from among women attending antenatal care clinics. An estimate of the model parameter representing the fraction of the population that is at risk of contracting HIV infection was extracted from the model and a regression analysis was conducted to examine the association between this estimate and various indicators of sexual behaviour. The model, known as the Epidemic Projection Package (EPP), is described in detail in section 4.

Estimates for the behavioural indicators were calculated for all countries with data, as described in Table 14.1. Suitable model fits were available for 16 countries, and a complete set of indicators and model fits were available for nine countries. Each country contributed an urban and a rural estimate, bringing the sample size for the regression analysis to 18.

All analyses were carried out in Stata version 7.0. Correlation coefficients were calculated for each combination of model parameter and behavioural indicator. The results of these correlations governed which behavioural indicators were included in a linear regression model. This model also included another parameter, which describes the force of infection, as an instrumental variable. It was not possible to quantify a relationship between the behavioural data and the model parameter using this method. The analysis was hampered by the small sample size
and the associations that did emerge as statistically significant were not easy to interpret. Some indicators whose effects would be expected to be similar (such as age at first sex and the proportion of the population who had ever had sex), when included in the same regression model produced opposing coefficients. A robust analysis would require a much larger sample size than was available, given the large number of behavioural indicators and the high degree of correlation between these indicators.

The failure of our work, and that of other groups, to find a suitable quantification suggests that there may be no single relationship between any one measure of sexual behaviour at the aggregate level and the incidence of HIV infection in the general population. Rather, data at the level of individuals and their partners before infection may be required. The choice of which indicators to present was therefore governed by which indicators were commonly found to be associated with HIV infection in observational studies and the measures recommended by UNAIDS (2000), even if the nature of the association with HIV infection was not clear.

### 3.3 Prevalence of potentially hazardous sexual behaviours

Different sexual behaviour patterns are summarized here by three measures: lifetable median age at first sex; mean number of sexual partners in the last year; and the proportion of adults in the subregion who have had sex with a non-co-resident partner within the year preceding the survey, and who did not use a condom the last time they had sex with this partner. All the indicators were calculated for individual countries and the subregional estimates were created by weighting these estimates by the total population size of the country relative to the subregion. The number of countries and sample size used for each estimate are given in Table 14.5.

No subregions were completely described and there were no data at all for some subregions. Values had to be estimated for the missing categories by extrapolation of the results from other subregions; this was based primarily on the values of the available estimates. If no estimates were available for a subregion, the values were extrapolated from the subregion with the most similar proportion of people currently married (Figure 14.6). Throughout the results, extrapolated estimates are shown in the shaded cells as explained in the footnotes of the tables.

## Median age at first Sex

The median age at which people first had sex is presented in Table 14.6. This was calculated from the reported age at first sexual intercourse, or current age for people who have not yet had sex. Lifetable techniques were used to calculate this measure to allow for the inclusion of those people who had not yet had sex. The age of sexual debut is important because it affects the duration of exposure to STIs. There is evidence that
Table 14.5 Numbers of people and countries on which the estimates for the behavioural indicators considered were based, by

| Subregion ${ }^{\text {a }}$ | Ever had sex |  |  |  |  |  | Had sex in the last year |  |  |  |  |  | Sex with non-co-resident partner in last year ("higher-risk" sex) |  |  |  |  |  |  |

Figure I4.6 The proportion of people who are currently married, by age and subregion

Note: The lowest proportion of older women who are currently married is found in EUR-A, despite the fact that EUR-A falls in the middle of the range for the two younger age groups. This could be due to a larger proportion of women who never marry, or a higher incidence of marital dissolution in this subregion compared to the others.
young women are more susceptible to HIV infection and that people who start to have sex at a younger age may have more risky behaviour over a lifetime than those who delay the first time they have sex. Values for AMR-A were extrapolated from Australia and New Zealand. These values were used instead of those for the WPR-A subregion as a whole because the latter subregion is very heterogeneous and AMR-A is very similar to Australia and New Zealand for the other indicators, where there are data. The values for the EMR-B and EMR-D were extrapolated from EUR-C.

## SEX WITH NON-CO-RESIDENT PARTNERS

The proportion of all people who report having had sex within the last year, with a partner with whom they do not live, and who did not use a condom the last time they had sex with that partner is perhaps the closest measure of unsafe sex that it is feasible to calculate and is our working definition of risky sex. Sex outside of a cohabiting (co-resident) partnership (within the last year) without using a condom is thought to carry a greater risk of HIV infection than marital sex. As shown in Table 14.7, there are striking variations in the levels of this indicator across the subregions, but they do not follow the pattern of HIV prevalence.

## Mean number of partners during the last year

Table 14.8 shows the mean number of sexual partners in the preceding year in the adult population (aged 15-59 years), regardless of the relationship to any of the partners. Again, there are clear differences between the subregions.

Table 14.7 The proportion of the adult population (aged I5-59 years) who report having had sex with a non-co-resident partner in the last year, without using a condom on the last occasion

## 4. RISK FACTOR-DISEASE RELATIONSHIP

### 4.1 HIV

HIV infection is known to be sexually transmitted. Some sexual practices with an HIV-positive partner carry a greater risk of infection than others. In some populations, there are groups of people who can be identified as having a greater likelihood of being infected with HIV. The factors that govern whether a susceptible person chooses one of these people at a higher risk of being infected as a sexual partner will influence their own risk of infection. Sexual behaviour and its determinants are not easy to measure, and can vary in several dimensions, all of which may be pertinent for HIV transmission.

It is hard to model the impact of changes in exposure for an infectious disease with person-to-person transmission because the risk associated with exposure will change with changes in the prevalence of the infection. A sexual contact is only an exposure if one partner is infected with HIV and the other is not, and the likelihood of this occurring will change as the prevalence of infection changes. The social perception of risk may feedback to behaviour and further contribute to change. There-

fore a relative risk measured for a particular population at a particular point in time is meaningless for another place or point in time, unless the overall prevalence, the epidemic maturity and the degree to which infected and susceptible people mix are almost identical.

An alternative way to predict the future prevalence of an infection which is transmitted from person to person is to use a recursive mathematical projection model to account for the increase in incidence caused by the increase in the number of prevalent cases. Simpler approaches, based on a static risk of infection, will not adequately capture the dynamics of infection over a period of time if prevalence is high, because the risk of infection will change as the prevalence of infection changes.

If prevalence is low, a simpler approach can be justified because the error introduced in the estimates of the number of new infections by ignoring changes in prevalence is much smaller. The size of the error that results from using an approach based on a static level of risk in a highprevalence situation will depend on the prevalence of the infection, the speed at which prevalence changes and the period of time considered. To illustrate the scale of errors introduced by ignoring the nonlinearities of epidemic dynamics, we note that in a population with an

HIV prevalence of $20 \%$, with a concurrent infection rate among HIVnegative people of approximately $3.5 \%$ per year, over a five-year period the prevalence could increase by $2 \%$ or fall by $3 \%$ without any changes occurring in risk behaviour, but depending on the maturity of the epidemic at the time when the HIV prevalence of $20 \%$ was reached. Currently, UNAIDS estimates that the prevalence of HIV in nine African countries is in the order of $\geq 20 \%$ among women attending antenatal clinics in urban areas (and in four countries the prevalence of HIV is $>20 \%$ among women attending clinics in rural areas) (UNAIDS/WHO 2002). The estimates of avoidable infections presented here are for a fiveyear period. To determine the range of probable outcomes, it is essential that a suitable mathematical model be used to derive estimates of new infections for these subregions, both for the "business-as-usual" scenario, and to estimate what may happen under the different counterfactual scenarios.

## Methods for estimating HIV prevalence over a period OF TIME

UNAIDS/WHO make country-specific estimates and projections of HIV infection worldwide and the UNAIDS Epidemiology Reference Group has developed a model to make projections of HIV prevalence. The model has been implemented in a program known as the Epidemic Projection Package (EPP) (The UNAIDS Reference Group on Estimates Modelling and Projections 2002). EPP is designed to represent the evolution of generalized epidemics and so its use for prediction is confined to countries in which generalized epidemics have developed. In this chapter, EPP was used to calculate estimates for the two African subregions (AFR-D and AFR-E) (Table 14.9).

## Reasons for using the EPP model

There are a number of models which could have been used for the CRA, but the EPP model, currently used by UNAIDS, was deemed to be the most appropriate. The other available models include deterministic models, such as AVERT (Rehle et al. 1998), but most of these make no allowance for behaviour change. The GOALS model (http://www.futuresgroup.com), developed by WHO and the Futures Group models the impact of interventions concerning behavioural change, primarily from a programme manager's or policy-maker's perspective, with the focus on the cost-effectiveness of different interventions. This model requires a much larger amount of input data than EPP and is not appropriate for longer-term projections. Most of the models designed to explore the effects of different interventions are more complex than EPP. Additional assumptions (such as profiles of commercial sex work) would have been needed for such models to be used, as sufficient data are not always available.

Table 14.9 Countries for which an EPP model fit is available

$\checkmark$ Available.

- Not available (insufficient data points to fit the model; no generalized epidemic in the smaller countries).

Stochastic models are also available, the prime example being STDSIM (Korenromp et al. 2000; van der Ploeg et al. 1998), which is a complex model requiring detailed specification of a range of demographic, biological and behavioural inputs. STDSIM is designed to closely model the HIV epidemic in small communities and would not have been suitable for use at the international level, despite the fact that it does explicitly model changes in behaviour. A limitation of all sto-
chastic models is the need for repeated runs to ensure reasonably stable results. To run a stochastic model for the countries with sufficient data in all regions of the world would have taken a prohibitive amount of time.

## Structure of the EPP model

The mathematical model used is fully described elsewhere (The UNAIDS Reference Group on Estimates Modelling and Projections 2002; UNAIDS Epidemiology Reference Group 2001), but is summarized below using a slightly simplified notation. EPP models both epidemiology, with a feedback loop from prevalence to incidence, and demography, with competing mortality risks and population renewal. This is important because AIDS mortality is a significant factor in the course of the epidemic. The model was deliberately kept simple to allow projections to be based on real data. The model is not subdivided by either age or sex.

Figure 14.7 shows how the model divides a population into three groups (infected, susceptible and at-risk, and susceptible and not-at-risk), and how people can move between these groups over time.

People enter either the at-risk or not-at-risk group on their 15th birthday. Exit from the not-at-risk group is by death from a non-AIDS-related cause. Exit from the at-risk group is either through a non-AIDS-related death or by becoming infected with HIV and moving to the infected group.

Entry to the population at age 15 years occurs at a constant rate, based on birth rates and rates of survival to age 15 years observed in the population being modelled. Adjustment is made for the impaired fertility of women infected by HIV and for the vertical transmission of HIV. HIVinfected children are assumed not to survive to age 15 years. Death rates from causes unrelated to HIV infection are assumed to be constant. Deaths resulting from AIDS are governed by a mortality function based on a Weibull distribution, which gives survival times after HIV infection. The Weibull survival function is based on data from observational studies in Uganda and the median survival time is compatible with data from Haiti, Thailand and Uganda.

The EPP model is controlled by four main epidemiological parameters:

| $t_{0}$ | The start year for the epidemic |
| :--- | :--- |
| $s_{0}$ | The initial proportion susceptible |
| $r$ | Proportionality constant of the force of infection |
| $\phi$ | (phi) | | The relative recruitment rate into the susceptible category |
| :--- |

These parameters interact, but their main influence is exercised on the shape and location of different parts of the epidemic curve. These effects are shown in Figure 14.8.
Figure 14.7 Flow of people through the EPP model

Figure 14.8 The effects on HIV prevalence of changes in the main epidemiological parameters in the EPP model

The main demographic parameters governing the model are:

| $m$ |  | Modal survival age after HIV infection (Weibull level <br> parameter) |
| :--- | :--- | :--- |
| $k$ |  | Shape parameter for Weibull survival function |
| $\mu$ | (mu) | Adult mortality rate from non-HIV related causes |
| $\lambda$ | (lamda) | Proportion of non-infected children surviving to age |
|  |  | 15 years |
| $\nu$ | (nu) | Vertical transmission proportion |
| $\beta$ | (beta) | Birth rate for the adult population |
| $\delta$ | (delta) | Low fertility adjustment for HIV-positive adults |

In the mathematical exposition below, the following variables are also used, but as they are either derived from the formal parameters listed above, or treated as constants in the normal use of the model, they are not regarded as formal parameters. These are defined below.

Auxiliary constants:
$\begin{array}{lll}\Delta & \text { (Delta) } & \text { Time increment for differential equations } \\ \varepsilon & \text { (epsilon) } & \text { Initial exogenous force of infection }\end{array}$
Endogenous variables, dependent on formal parameters:
$\theta(t)$ (theta) Force of infection between susceptible and infected, at contact time $t$
$\sigma(x)$ (sigma) Proportion of infecteds surviving x years after infection

Finally, the numbers and proportions of not-at-risk, susceptible and infected persons at time $t$ are denoted as shown below:

| Number | Proportion |  |  |
| :--- | :--- | :--- | :--- |
| $N(t)$ | Not-at-risk population | $n_{t}$ | Not-at-risk proportion |
| $S(t)$ | Susceptible population | $s_{t}$ | Susceptible proportion |
| $I(t)$ | Infected population | $i_{t}$ | Infected proportion $=$ <br> prevalence |
| $P(t)$ | Total population |  |  |
| $F(t)$ | 15-year olds entering <br> population | $f_{t}$ | 15 -year-old proportion <br> susceptible |
|  | $1-f_{t}$ | 15 -year-old proportion <br> not-at-risk |  |

The dynamics of the system are given by the following equations. The number of people aged 15 years entering the adult population at time $t$ is the number of uninfected children born 15 years ago multiplied by the probability of surviving to age 15 .

$$
F(t)=\lambda \beta[N(t-15)+S(t-15)+(1-v) \delta I(t-15)]
$$

The proportion of susceptible people entering the population at time $t$ is a function of the overall current proportion of the adult population that is not at risk, governed by the formal parameters $f$ and $s_{0}$, the initial proportion of susceptible people.

$$
f_{t}=f\left(n_{t}\right)=\frac{\exp \left(\phi\left[n_{t}-1+s_{0}\right]\right)}{\exp \left(\phi\left[n_{t}-1+s_{0}\right]\right)-1+1 / s_{0}}
$$

Note that since at time zero there are no infected persons, $1-n_{0}=s_{0}$, so for any value of $\phi, f_{0}=s_{0}$. Similarly, if $\phi=0$, then the proportion of susceptible 15 -year olds is the same as the initial proportion of those who are susceptible at all times, $f_{t}=s_{0}$. If $\phi<0$, recruitment to the susceptible group declines over time; if $\phi>0$, recruitment increases.

The Weibull function gives the proportion of those infected surviving $x$ years after infection.

$$
\sigma(x)=\exp \left(-\mu x-[x / m]^{k}\right)
$$

The force of infection at the $t$ is given by:

$$
\begin{array}{ll}
\theta(t)=\varepsilon & \text { for } t=0 \\
\theta(t)=r \cdot i_{t} & \text { for } t>0
\end{array}
$$

Having defined these variable components, it is now possible to formulate the change-of-state equations governing transitions between the population classes.

$$
\begin{aligned}
& \frac{\Delta N(t)}{\Delta t}=\left(1-f_{t}\right) F(t)-\mu N(t) \\
& \frac{\Delta S(t)}{\Delta t}=f_{t} F(t)-[\theta(t)+\mu] S(t) \\
& I(t)=\int_{x=0}^{t} \theta(x) S(x) \sigma(t-x) d x
\end{aligned}
$$

The last of these equations is presented as an integral equation rather than a differential, because this is the easiest way to express the fact that the infected population consists of survivors who were infected at a range of times in the past.

## Fitting the EPP model to surveillance data

The four epidemiological parameters ( $t_{0}, s_{0}, r$ and $\phi$ ) were fitted to prevalence data from antenatal clinic surveillance using maximum likelihood fitting. The model was fitted twice for each country, once for the clinics in urban areas and once for those in rural areas.

## Alternative implementation of EPP model

The EPP package is designed for use by national AIDS programme managers, to help validate the UNAIDS estimates and projections. Not all the underlying calculations and parameter estimates that are needed for this chapter are the outputs of the standard EPP package, which makes the epidemic scenarios defined by the counterfactual assumptions difficult to create. Therefore, an alternative implementation of the same mathematical model was created as a spreadsheet using the Microsoft Excel program.

## Current levels and projections of HIV prevalence

## Subregions with a bigh prevalence of HIV

Estimates of the current levels of HIV infection and projections of future levels are necessary to be able to calculate the proportion of these infections that is attributable to unsafe sex and thus the proportion that is potentially avoidable.

The current estimates and projections of HIV prevalence in the African subregions (under the baseline scenario of no behaviour change) were based on fits of the EPP model to antenatal clinic surveillance data. These projections were prepared by UNAIDS/WHO. The parameter estimates from these model fits were used in the spreadsheet version of the model to calculate the future prevalence, incidence and number of infections for each of the countries concerned. Subregional estimates were created by combining these estimates, weighted by the total population of each country. Weighted estimates were used because the EPP model could not be fitted for those countries with insufficient data on prevalence (11
countries). It is important to note the time scales used in making the model-based estimates. The last available prevalence estimate generally exerts more leverage on the fitted curve than do other points, and a more robust fit is generally obtained when more data points are used. Therefore prevalence estimates for 2001 were included where available and 2001 was taken as the base year for all projections. The projections of avoidable infections extend until 2006 because the model is designed to give reasonably accurate short-term predictions over a five-year period.

## Other subregions

For the 146 countries in which the prevalence of HIV/AIDS is low, a different approach was used to model the epidemic. For countries with epidemics that are concentrated in groups with higher-risk behaviour (e.g. men who have sex with men; injecting drug users, sex workers and their clients), a three-step process was followed to produce the current estimates (for the end of 2001) of HIV/AIDS prevalence. First, for each country, groups at the highest risk of acquiring HIV/AIDS were identified and estimates of the size of these groups were made. Next, estimates of point prevalence were made by applying the most recent prevalence rates for these groups to the populations. Finally, prevalence in populations at a lower risk of infection was estimated by allowing for transmission from high to low groups via sexual mixing. This estimate was made in one of the following ways. For countries with data from pregnant women, an adjusted prevalence rate from this group was applied to the number of women of reproductive age (aged 15-49 years) to produce an estimate of the number of women infected via sex with a partner from a group at an increased risk of being infected with HIV. Alternatively, for some countries where the epidemic was more recent and there were no data for populations at a lower risk, assumptions were about the number of infected people at a higher risk who had sexual partners with no other risk of infection. A transmission probability was then applied to produce an estimate of the number of women infected via sex with a partner from a group at a higher risk of being infected with HIV.

Projections of the extent of these epidemics up until 2006 were based on assumptions about saturation levels for each of the groups at a higher risk of infection, the time to saturation, and the spread over time from populations with a high risk to populations with a low risk of being infected with HIV.

For these same 146 countries (excluding countries with a generalized epidemic where EPP was used), trends in prevalence of HIV among groups at a high risk of infection were compiled and compared. Saturation levels for each risk group and time to reach saturation were determined by reviewing available data from countries in the subregion. The particular level of, and time to, saturation were applied to the risk groups
in each country based on current level of prevalence and rate of increase in the groups, and by comparison with saturation levels and rates in neighbouring countries.

Using this approach, we projected low growth for countries with longrunning and relatively stable epidemics (e.g. Brazil, Myanmar, the United Kingdom). For countries with recent epidemics, but rapid rates of growth, the projections show much higher rates of increase (e.g. China, Estonia). For all of these countries, we assumed that there was no general heterosexual transmission except from individuals in groups at a higher risk of infection to their lower-risk sexual partners. These procedures, which have been previously described, gave us projections of adult HIV prevalence over time (Stover et al. 2002).

Estimates of incidence were made by using assumptions about survival (median adult survival for those without highly active antiretroviral therapy-HAART—was nine years), growth of populations and levels of accessibility to treatment with HAART. The specific assumptions and procedures used to translate prevalence into estimates of incidence and mortality have been described in detail elsewhere (Stover et al. 2002; The UNAIDS Reference Group on Estimates Modelling and Projections 2002; Walker et al. 2003).

## Attributable infections and disease burden

In most subregions, some data were available on the probable mode of transmission for at least a sample of prevalent infections. These data have been used to estimate how many infections were sexually acquired in each subregion. The estimated burden due to unsafe medical injections and blood transfusions was taken from chapter 22 and from a WHO/UNAIDS review of blood safety. To calculate the proportion of infections that results from unsafe sex, the numbers of all people who, according to the model, were infected via unsafe blood transfusions, unsafe medical injections (based on the subregional level estimates) or due to injected drug use (based on country-level estimates) were combined to form the group infected via non-sexual transmission. The number of infections remaining, i.e. those acquired via sexual contact (either heterosexual or homosexual), was divided by the total number of infections to give the percentage of infections due to unsafe sex.

However, to estimate how many of the HIV infections prevalent in 2001 were truly attributable to unsafe sex, it is not enough to simply calculate how many infections arose from unsafe sex at a particular point in time. The burden of infections which result from unsafe sex is determined by the total number of cases of sexually transmitted HIV infection that have arisen since the beginning of the epidemic. In countries with low-level epidemics, estimates of attributable infections based on the mode of transmission of prevalent cases and estimates which account for the effects of past sexual transmission will be broadly similar. In
countries where prevalence is high, there will be a greater discrepancy between the two estimates. We calculated additional estimates for countries with a high prevalence by re-running the EPP model using the fitted value of the $s_{0}$ parameter (the initial proportion at risk) reduced to $5 \%$ of its original value. This value was used because it is estimated that $5 \%$ of HIV transmission is due to unsafe injections and blood transfusion in these countries (all in the WHO African Region). This estimate is based on the probable mode of transmission for existing infections. Estimates of HIV prevalence based on this reduced value of $s_{0}$ demonstrate what might have happened had there never been any sexual transmission in these populations. The difference in the number of infected persons estimated in 2001 and the number predicted by the model for 2001, under the altered circumstances, was taken to be the number of infections which were attributable to sexual transmission (see Table 14.12). The results shown for the two African subregions correspond to attributable burden, as defined by the CRA methodology. The results presented in Table 14.12 for the other subregions are an approximation of attributable burden, based only on the exposure of prevalent cases. To obtain better estimates of attributable burden in these subregions, we would need information on the patterns of sexual mixing between the groups at a high risk of infection and the general population for the duration of the epidemic.

The fraction of infections attributable to unsafe sex was applied to the mortality and disease burden (Table 14.13). Prevalent HIV infections are the result of episodes of HIV transmission which occurred over the 15 or so years before measurement. Prevalent AIDS cases and recent deaths will be, on average, the product of transmission patterns from approximately 10 years before measurement (in populations where there is no treatment for AIDS). The estimates for the non-African subregions are based on the assumption that the ratio of sexual to non-sexual transmission has not changed significantly over that time. The model-based estimate for Africa accounts for this possibility. If the ratio of sexual to non-sexual transmission has changed significantly over time, the estimates of attributable disease burden based on the current ratio may be inaccurate.

## AVOIDABLE INFECTIONS

## The counterfactual exposure scenarios

As described earlier, it was not possible to measure relationships between specific behaviours and the risk of acquiring HIV infection in a way that could be generalized to all populations. It may be that consistent relationships of this sort do not exist. Therefore counterfactual exposure scenarios cannot be defined in terms relating to measurable changes in behaviour. Predicting changes based on hypothetical scenarios, which are
not linked to a particular group of behaviours but to corresponding model parameters, is the best possible method for estimating how many future infections are potentially avoidable.

The counterfactuals were defined in a way that could be applied in subregions with both low and high prevalence. The counterfactual scenarios selected relate to decreases in the number of people having unsafe sex as represented by model parameters. The scenarios were chosen to provide a range of estimates based on proportional changes in the size of the at-risk group. The counterfactuals were operationalized differently for countries with low and high prevalence because the methods used to project future HIV prevalence in the two situations require different inputs. Three levels of reduction in unsafe sex were used in the calculation of the avoidable proportion of future infections: $100 \%, 50 \%$ and $10 \%$. These levels were achieved by estimating what would happen if all, $50 \%$ or $10 \%$ of the people who were having unsafe sex immediately ceased doing so. In theory, the intermediate counterfactual scenarios ( $50 \%$ and $10 \%$ reductions) could have been engineered to describe a situation in which those who were having unsafe sex reduced the amount of unsafe sex that they were having. The net effect would be the same because the approach is based on person-time at risk, and assumes that length of exposure is proportional to risk of infection.

## Reversibility

Infection with any of these STIs need only occur once to produce disease. Therefore removing exposure to the STI will automatically reduce the risk of infection with immediate effect and this is demonstrated by the results of the HIV prevalence projections under the different counterfactual scenarios. However, in reality it is unlikely that all exposure could be removed and the spread of infection reversed at a particular point in time. Infectious people will remain in the population even if all risky behaviour ceases. Unless every person with an infection (married and unmarried alike) stopped having sex without a condom (i.e. if there was no unsafe sex) they would continue to infect new people. This is the reason for considering counterfactual scenarios that include partial reduction in unsafe sex, as described above.

## Countries with a bigh prevalence of HIV infection

It is possible to define counterfactuals in terms of changes in the size of the EPP model's at-risk group for the countries in the two African subregions. Reductions were made to the size of this group at the start of 2001, first by moving a specified fraction of the at-risk group to the not-at-risk group, and second, by slowing recruitment to the at-risk group by the same amount. Three reductions in the original size of the at-risk group were made: $10 \%, 50 \%$ and $95 \%$. The greatest reduction (resulting from total cessation of unsafe sex) thus resulted in only $5 \%$ of the
original at-risk group remaining at risk after 2001 and recruitment to this group was cut to $5 \%$ of its former level. The size of this group was not reduced to zero because a certain fraction of HIV-infected people will continue to contract their infection through a non-sexual mode of transmission in a non-generalized epidemic. This proportion is estimated to be $5 \%$ of infections in sub-Saharan Africa. While some people will contract their infection in one way, and transmit it in another, the degree to which this happens cannot be estimated for this work.

The ratio of sexual vs non-sexual transmission among those already infected is known, but the ratio of sexual vs non-sexual exposure among the uninfected is not. Implicit in the use of a $95 \%$ reduction in the atrisk group as the theoretical minimum level of unsafe sex is the assumption that these ratios are the same. This may be incorrect because if a mode of transmission is very efficient (e.g. infected blood transfusion) then the incidence of infection among susceptible people who are exposed in this way may be higher than that among people who are otherwise exposed to HIV infection. If different modes of transmission have different rates of infection, the modes most likely to produce an infection will be over-represented among cases of infected people in comparison with the distribution of the different exposures among uninfected people. If the non-sexual modes of transmission in Africa are significantly more efficient than sexual transmission, then the fraction of the at-risk group which is exposed to HIV infection via sexual transmission may be $>95 \%$. However, the opposite could also be true if unsafe medical injections were the most common form of non-sexual transmission; such injections may be associated with a lower infection rate because the reused syringe does not always come into contact with the body fluids that could potentially transmit the infection. There is no means to assess the relative exposure to the different modes of infection and we must instead rely on the data from HIV-infected people, therefore $95 \%$ is an uncertain assumption.

The changes to the model were made through the $s_{0}$ parameter, and not the $r$ parameter because the latter represents the transmission of infection, and the former describes the fraction of the population that is at risk of infection. Conceptually, transmission can be affected by changes in the level of unsafe sex (e.g. the proportion of sexual acts protected by condoms) but this could not be used satisfactorily to describe a counterfactual scenario. To model a total cessation of unsafe sex, we could not reduce $r$ to zero because this would correspond to a total cessation of all HIV transmission. It is not possible to calculate a value of $r$ which is related to the cessation of sexual transmission only. Two implicit assumptions in this approach are worthy of comment:

- a proportionate relationship between hazardous and unsafe sex: we have assumed that, when we reduce the size of the group of people
who have hazardous sex, the size of the group having unsafe sex will decrease by the same amount.
- random mixing in the at-risk population: the EPP model assumes random mixing, i.e. each person in the population has an equal chance of contacting another member. This assumption gives a good representation of the natural dynamics of a generalized epidemic of an STI. The question arises, in relation to the counterfactual scenarios, of whether random mixing is still a reasonable assumption in relation to the "hard core" of those remaining at risk after the sudden decrease in hazardous sexual behaviour. We would argue that in the case of sub-Saharan Africa, where the alternative modes of transmission are predominantly unsafe medical injections and unsafe blood transfusions, random mixing is still a close approximation. In the case of injecting drug users, one might want to model far more intensive contacts within the group of people at risk than outside of it, but use of injected drugs is not as important in these subregions as it is elsewhere in the world.

The spreadsheet (Excel) implementation of the EPP model was used, after the modifications described below were made in order to include the changes described by the different counterfactual scenarios. Recruitment of new members into the at-risk group was slowed by a specified amount, as defined in the counterfactual, starting in 2001 and continuing until the end of the projection in 2006. The slowing of the recruitment to the at-risk group was achieved by reducing the value of the $s_{0}$ parameter by the specified fraction, with effect from 2001. All the other model parameters remained unchanged. At the start of 2001, the size of the at-risk group was reduced to the fraction of its former size defined in the counterfactual, and the people removed from this group were added to the not-at-risk group. These modifications had the effect of reducing the pool of people who could potentially become infected with HIV, and therefore lowered the number of new cases occurring. Figure 14.9 shows how these modifications affected the projected infections. The dynamic relationship between the at-risk and infected groups remains the same, but the relative sizes of the two groups of susceptible people (at-risk and not-at-risk) are drastically altered and the rates of recruitment to both groups are changed.

Although the number of future infections would be small in the absence of unsafe sex, it was necessary to use a model to estimate the avoidable infections for the African subregions for two reasons. First, one of the counterfactual scenarios involves a reduction of only $10 \%$ in unsafe sex, which means that prevalence and the number of new infections remain high. Second, the relationship between current prevalence and the number of new infections in the future is not linear, even over a five-year period.
Figure 14.9 Effect of the modifications made to the EPP model which were used to calculate the number of new HIV infections occurring under different counterfactual scenarios

Countries with a low prevalence of HIV infection
The counterfactuals for other subregions were again engineered to correspond to situations in which unsafe sex was reduced by $10 \%$, $50 \%$ and $100 \%$ (no unsafe sex). Existing data on the distribution of prevalent HIV infections by mode of transmission was applied to the projections for the countries with a low prevalence of HIV infection. Reductions in unsafe sex were assumed to result in a decreased number of new STIs that were equal in proportion to the reduction in unsafe sex.

### 4.2 Other sexually transmitted infections

Estimation of the relationship between unsafe sex and other STIs (chlamydia, gonorrhoea, syphilis and HPV) is subject to the same constraints as that between unsafe sex and HIV infection. Relative risks of infection with chlamydia, gonorrhoea and syphilis following certain behaviours have been estimated. However, like HIV infection, these relative risks will change as the prevalence of infection changes. This problem is compounded by an even greater lack of information for any of these STIs than for HIV. As a result, we have not attempted to quantify this relationship, and assume that for all these STIs, by definition, all current prevalent infections are attributable to unsafe sex. Therefore, the total burden of disease attributed to these STIs can be considered to arise from unsafe sex. This includes cervical cancer attributable to infection with HPV; recent work suggests that all cases of cervical cancer are attributable to infection with sexually transmitted HPV (Walboomers et al. 1999).

In order to make a reasonable estimate of the future prevalence of these STIs, it is necessary to use a mathematical projection model. In common with that for HIV, such a model would need to be fitted to existing time-series prevalence data to create a projection of the future levels of infection. Since there is no appreciable mortality as a consequence of most of these other STIs, a suitable model would be much simpler than those used for HIV. Cervical cancer due to HPV infection would necessitate a model which accounts for mortality. However, the necessary time-series prevalence data are not available for a sufficient number of countries to make this a viable approach. The methods used to calculate the number of new HIV infections that are potentially avoidable cannot therefore be used for these STIs.

STIs have been virtually eliminated from some populations in the recent past. In the early 1950s, the Chinese government initiated a programme to eradicate sexually transmitted diseases that was successful in the short term. The campaign relied on mass screening to identify and treat people with an STI and also involved the abolition of commercial sex work. The methods used might not be transferable to other cultures, but demonstrate that the problem of STIs can be confronted. It has been
suggested that the incidence of STIs only began to increase after China resumed more open relations with the rest of the world in the early 1980s (Cohen et al. 1996).

With this in mind it seems reasonable to assume that all STIs are avoidable, given appropriate changes in sexual and treatment-seeking behaviour, if these changes are accompanied by the provision of suitable services.

## 5. Results

### 5.1 Prevalence of disease outcomes in 2001

Estimates of the current prevalence of HIV and other STIs were based on reported estimates from HIV surveillance and published studies. These were compiled and used to create subregional prevalence estimates (Tables 14.10 and 14.11). The estimates for the two African subregions were based on EPP model fits to antenatal clinic surveillance data. The prevalence in the other subregions was directly based on reported prevalence according to a variety of empirical sources (U.S. Census Bureau 2001).

### 5.2 Attributable infections and disease burden

The subregional estimates of the fractions of all HIV infections that are attributable to unsafe sex are given in Table 14.12. These comprise the percentage of infections prevalent in 2001 that were reportedly acquired through sexual contact. Therefore this fraction is directly attributable to unsafe sex. The feedback between prevalence and incidence has not been taken into account in the estimates for subregions outside Africa: in many of these subregions, the attributable fraction could be considerably higher if it included all infections for which sexual transmission had occurred at any point along the chain of transmission. As described above, the fractions were by definition $100 \%$ for other STIs.

### 5.3 Avoidable infections

The estimates of the fraction of infections which is potentially avoidable are given in the following tables and figures. Figure 14.10 shows the proportion of new infections that may be prevented by different reductions $(100 \%, 50 \%, 10 \%)$ in the level of unsafe sex relative to the number of infections which would be expected to occur if there were no change in sexual behaviour. The height of the bar shows the total proportion that could be avoided if there was no unsafe sex. The proportions within the bar show the reductions that would be seen if unsafe sex was reduced

by just $10 \%$ and if it was lowered by a half. These results are also given in Table 14.14.

Figure 14.11 shows how many new infections are predicted to occur in 2002-2006 in each subregion under the different counterfactual scenarios. These results are given in Table 14.15. The greatest changes would be seen in the African subregions, where sexual transmission dominates the epidemic. However in subregions such as WPR-B, which includes China, where a large number of new cases is predicted to occur, the proportion of infections that could be avoided is smaller, because use of injected drugs is a more important mode of transmission in this subregion.

It is important to consider the plausibility of the finding that almost all new HIV infections in Africa could be avoided if unsafe sex were to cease immediately despite the continuation of non-sexual transmissions. Intuitively, it seems unlikely that there would be almost no new HIV infections in the five years following the onset of behaviour change: transmission of the virus via other routes would continue, and it has been estimated that $5 \%$ of the newly-diagnosed infections in Africa in 2000 were acquired through a non-sexual mode of transmission. As discussed above, sexual and non-sexual transmission dynamics

cannot be considered in isolation. Even without considering the extent to which these transmission networks are interlinked, the sheer scale of the change to the susceptible population serves to illustrate why it is not implausible that HIV transmission would cease if unsafe sex stopped altogether in the African subregions. Consider, for example, the urban areas of an east African country with a population of eight million where the estimated prevalence of HIV infection among women attending antenatal clinics in 2001 is $11 \%$. This gives a total of 898000 prevalent cases, of which 45000 are thought to be non-sexually acquired. The EPP model fit to the observed prevalence data produces an estimate for the susceptible fraction of the total population of $20 \%$. Therefore, there are 1633000 people who could acquire HIV infection at the start of 2001.

Using the same example, to simulate the immediate and total cessation of unsafe sex, the at-risk group was reduced by $95 \%$, such that only $1 \%$ of the total population would be able to acquire HIV infections (5\% of the original $20 \%$ ), or 16000 people. The 898000 cases are still prevalent but not all prevalent cases are potential sources of a new infection. Some HIV-infected people will not exhibit risky behaviours and so will not have the opportunity to transmit infection. For a new case to arise, the HIV-infected people must have an effective contact (i.e. give a blood

transfusion or unsafe injection) with one of the 16000 members of the at-risk group. In a population of eight million people, the probability of this happening is now much reduced, thus the number of new infections resulting is very small. The non-linearity in the relationship between changes in unsafe sex and the number of infections avoided results in a large fraction of infections averted by a $10 \%$ reduction in unsafe sex in the African subregions.

## 6. Uncertainty

### 6.1 Exposure

## DATA QUALITY

Most of the behavioural surveys included in this analysis were large probability samples, which were weighted to be representative of the general population by age and sex. There may have been a selection or participation bias in these surveys. Reporting bias is probably inevitable in at least some surveys; people may have under-reported behaviours that are seen as undesirable, especially in the light of education and information campaigns aimed at promoting behavioural change. We have
limited means to assess the existence of such biases, and the assumption implicit in this work is that such biases can be ignored.

It is unclear how well quantitative household surveys measure sensitive information such as sexual behaviour and some surveys will have been designed and implemented better than others. There is little to indicate how good a survey is, apart from the quality of the data and an assessment of the questionnaire. One survey (Sri Lanka 1991 GPA survey) was excluded from the analysis because of poor quality data.

## Methodological issues

In creating the set of standard behavioural indicators, different questions were used as though they were synonymous. If these questions or their translations are not in fact equivalent, the calculated indicators will not measure the same thing in all places. This is quite likely, at least with respect to the questions and indicators which depend on a classification of partner type in different countries.

The aggregation of the country-level data to subregional level is perhaps a cause for concern. For some indicators, the values estimated for countries within a subregion varied by as wide a range as was observed between the countries in different subregions. Once combined at a subregional level, this variation was no longer apparent. In addition, countries for which no data were available did not contribute to the subregional estimate; it is unlikely that the subregional estimate would not change if we did have data for the missing countries. It is plausible that, within a subregion, the countries for which no data are available are systematically different from those countries in which sexual behaviour surveys have been carried out. These differences could be related to behaviour.

Extrapolation of the estimates of the prevalence of sexual risk behaviour to subregions where there were no data was based on comparison of the proportions of the population who were currently married in each subregion. Values from the most similar subregion were substituted for the missing data. In subregions where some data were available, the missing values were taken from the subregion which was most similar according to the available estimates. However, it was clear that the subregions did not vary in a predictable manner and this method of extrapolation introduced some unquantifiable error.

## ERROR

Confidence intervals can be calculated around the point estimates of behavioural indicators for individual countries. Almost all of these intervals are very narrow, mainly because most of the exposure data come from very large DHS. The error that was introduced by aggregating these estimates to the subregional level cannot readily be quantified: error is introduced because countries with no data are assumed to have average values for the subregion.

## Omissions

Having concentrated solely on heterosexual sex, the behavioural review has clearly underestimated the amount of risk in populations where the main mode of HIV transmission is sex between men. The data on the prevalence of sex between men are too scanty to be used in an analysis of this type, and to include only the available data would introduce more uncertainty into these estimates. Infections that result from sex between men are included in the burden estimates, and in the estimates of attributable and avoidable infection, for both low- and high-prevalence subregions.

### 6.2 Outcomes

## MODEL-BASED APPROACH

The accuracy of the estimates of the avoidable burden of HIV infection due to unsafe sex depends initially on the precision of the five-year projections of the HIV/AIDS epidemics. These projections represent only one possible future course of the epidemic. The projections for both countries with a high prevalence of HIV infection (using the EPP model) and countries with a low prevalence (using the saturation approach) must be considered as representing a likely course, not the certain future course, of the epidemic.

Beyond the accuracy of the projections of HIV prevalence under the business-as-usual scenario, there are other sources of potential inaccuracy in the estimates of avoidable infections. The estimated proportion of all infections that are not sexually acquired is central to the calculation of the proportion of avoidable infections in all subregions. The figure of $5 \%$ employed for Africa, though widely used, should be viewed as very uncertain. Information on mode of transmission is derived from reports on the way in which people who have been diagnosed with HIV infection are thought to have acquired the infection. There are limitations to this data. In many places, a diagnosis of HIV infection will not be made before the onset of symptoms. If diagnosis is delayed it may be more difficult to identify the source of infection, especially for those people who have had more than one type of exposure. Late diagnoses or failure to diagnose may introduce another bias because the people who receive a timely diagnosis may have acquired their infection in a different manner from those whose infections are not promptly diagnosed. Subregional data are based on national data that have been aggregated to the subregional level. The different national data may be subject to different biases. Countries for which no data are available have been assumed to have the average proportion of HIV infections for the subregion. This may have distorted the picture still further. The direction of this error may be influenced by the scale and stage of the epidemic, the health care system and the equity of access to health care.

## Africa

The EPP model is based on the assumption that sexual mixing patterns are homogeneous in a population. Therefore, the assumption implicit in the estimates of the numbers of avoidable HIV infections is that the reduction in prevalence of hazardous sexual behaviour is evenly distributed among the population. If declines in the prevalence of hazardous sexual behaviour are concentrated in certain groups, and the remaining risk behaviours (unsafe medical injections, unsafe blood transfusions and injected drug use) are also clustered, then the number of avoidable infections might be lower. If the remaining risk behaviours are evenly distributed throughout the population, the reductions in unsafe sex will have an effect on non-sexual modes of transmission. Infections acquired in one way are not necessarily transmitted in the same way (if they are passed on at all). Therefore sexually acquired cases of HIV infection may act as the source of infection for non-sexually-acquired cases. A reduction in unsafe sex that leads to fewer prevalent cases of HIV infection will therefore also lower the number of new non-sexually-acquired cases.

The assumption of random mixing must be tenable for the EPP model to perform well. This model is intended to give accurate projections of future HIV prevalence in a population with a generalized epidemic. If the modes of transmission that remain after unsafe sex is reduced were to be concentrated among certain groups, the subsequent number of new infections would be higher than that forecast using EPP. Therefore the estimate of the proportion of infections which is avoidable may be too high. However, given the current epidemic situation in the two African subregions, the assumption of random mixing, even in the absence of unsafe sex, may hold true because use of injected drugs is uncommon and unsafe medical injections and blood transfusions are less likely to be concentrated among specific groups.

### 6.3 Limitations

The departures from the standard relative risk methodology and the reasons for this have, for the most part, been fully discussed in the text. However, two further differences remain to be explained. The CRA framework requires that all estimates be presented separately for all age groups and for each sex. The estimates of avoidable infections under the different counterfactual scenarios should be made from 2000 until 2030. Neither has been done for unsafe sex because these extensions would greatly add to the uncertainty of the estimates.

The models used for the prevalence projections are only valid in the short term. To extend them beyond 2006 would require additional assumptions about changes in the availability of treatment and prevention efforts. The effects of treatment on transmission are particularly
hard to predict since treatment will tend to increase the prevalence of infection (by prolonging the survival of infected people), but may also reduce the contagiousness of infected persons. Some of the counterfactuals considered include that there will be a massive reduction in the amount of unprotected sex after 2001. This would inevitably have an impact on fertility, which should in turn lower recruitment to the sexually active population. The methods used to predict HIV prevalence do not account for such changes. In the EPP model, as described in section 4, the recruitment of sexually active adults into the two groups of susceptible people is based on the number of births 15 years earlier and on survival rates to the age of 15 years. Therefore changes in fertility initiated in 2001 would not affect the projections until 2016. The EPP model assumes a constant birth rate that does not change over time and that is the same in the two groups of susceptible people. Although it would be possible to alter the process for implementing the counterfactual scenarios to allow for large future changes in fertility, and the emergence of a dramatic fertility differential, there is no information on which to base these estimates.

Because there is no way to estimate the size of the decline in fertility under the counterfactual scenarios in any subregion, there is no way to accurately model these scenarios beyond the short term. Similar issues are encountered in estimating HIV prevalence by age group and sex. In all subregions, prevalence is different for men and women and varies by age group. The distribution of infections by age and sex varies by epidemic duration and is not necessarily the same in all countries in a subregion, which makes it complicated to establish a subregional breakdown. Estimates of the prevalence of HIV infection among men are not available in most countries but must be inferred from prevalence in pregnant women. Changes in the number of people who are at risk of infection can be expected to change the distribution of new infections by age and sex, but the direction of these changes cannot be anticipated. Therefore, to make estimates of avoidable infections by age group and sex would be to add more uncertainty to the existing estimates.

Finally, the most extreme counterfactual scenario presented above produces some dramatic results for the African subregions. Modelling the complete cessation of unsafe sex implies that, even within marriage, discordant couples would no longer have procreative sex. Such a scenario is artificial and unprecedented: there are no historical examples of a total and sudden cessation of exposure to an infectious disease at the macro level. The reason for including this scenario is that if STIs are eliminated from a population there would be no unsafe sex: in this chapter the counterfactual has been defined in terms of the level of unsafe sex. Under the counterfactual scenario of no unsafe sex, the extraordinarily rapid decline in new infections also produces a discontinuity in prevalence, as the average duration of infection rapidly rises among those

Figure 14.12 HIV prevalence projections for subregions in Africa under two scenarios: no change in current levels of unsafe sex and the total cessation of unsafe sex

Note: The line representing the HIV prevalence following the total cessation of unsafe sex has been interpolated between 2000 and 2001 for the prevalence under the counterfactual scenario.
who are already infected, which in turn implies a rapid increase in mortality, since mortality of the people who are HIV-positive increases with the time since infection. This mortality increase exacerbates the decline in prevalence, with the results shown in Figure 14.12.

In any single EPP counterfactual scenario for a subnational population, the apparent effect of the rapid transfer of a large fraction of the susceptible population from the at-risk group to the not-at-risk group would depend on the timing of the decline in risk relative to the "natural" epidemic peak and the level of saturation (the proportion of infected people among infected and susceptible persons). Three different situations are shown in Figure 14.13, which illustrates the model fits for a population in which HIV prevalence is still rising rapidly in 2001, a second population in which growth in prevalence has stabilized in 2001;

Figure I4.13 EPP projections of the size of the infected, at-risk and not-atrisk groups for three subnational populations under two scenarios: no change in current levels of unsafe sex and total cessation of unsafe sex

|  | No change (business-as-usual) | Total cessation of unsafe sex |
| :---: | :---: | :---: |
| Prevalence <br> still <br> increasing <br> in 2001 |  |  |
| Prevalence peaked around 2001 |  |  |
| Prevalence peaked before 2001 |  |  |
| Key: $\square$, not at risk; $\square$, at risk of infection; $\square$, newly infected; $\square$, already infected. |  |  |

and a third population in which HIV prevalence has begun to decline by 2001. The figure shows the relative contributions of the infected, at-risk and not-at-risk groups for two scenarios: no behaviour change (business-as-usual) and total cessation of unsafe sex.

When the data from populations at these three different epidemic stages are amalgamated at the subregional level, the business-as-usual scenario gives the impression of an epidemic with a much broader prevalence peak than that seen in any one national population. However, for the no-more-unsafe-sex scenario, because the decrease in unsafe sex is assumed to occur in the same calendar year in all places, it produces the artificial-looking declines in the number of new infections, shown in Figure 14.13.

## 7. Discussion and conclusions

Unsafe sex is a difficult exposure to address within the standard epidemiological framework of simple exposure measures and constant relative risks. The problem of relating behaviour patterns to risk of HIV infection is hardly a new one. Other researchers have tried to tackle this in many different ways. The Four Cities study (Buve et al. 2001b; Carael and Holmes 2001; Ferry et al. 2001) compared sexual behaviour in two African cities with a high prevalence of HIV infection and two cities with a relatively low prevalence in order to look for determinants of this heterogeneity. Individual and ecological analyses were carried out. Some behavioural factors were found to be more common in the cities with a high prevalence compared to the cities with a low prevalence of HIV infection. These were: young age at having sex for the first time (for women), young age at first marriage and the existence of a large age difference between spouses. Factors which affect transmission and which were more common in the cities with a high prevalence were herpes simplex virus (HSV-2, genital herpes) infection, trichomoniasis (for women) and lack of male circumcision. Factors that were not more common in the high-prevalence cities were: a high rate of partner change, sex with sex workers, concurrent partnerships, a large age difference between non-spousal partners, gonorrhoea, chlamydial infection, syphilis, dry sex and lack of condom use. The factors found more commonly in the cities with a high prevalence of HIV infection do not seem sufficient to explain the differences in prevalence (Buve et al. 2001a). A comparison of rural populations in Zimbabwe and the United Republic of Tanzania has also failed to find differences in sexual behaviour which could explain the higher HIV prevalence observed in the Zimbabwean population (Boerma et al. 2002). In this light, it is perhaps unsurprising that we have not been able to elucidate a relationship.

Using alternative methods for estimating the attributable disease burden, we found that most of the current burden of disease due to HIV infection is attributable to unsafe sex. If all sexual transmission were to cease, there would be just over 4 million new HIV infections between 2001 and 2006, compared to more than 26 million which are forecast to occur if there is no change in the pattern of transmission. Most of the avoidable infections are concentrated in the African subregions, which
is as expected given the current prevalence of HIV infection in these subregions. The other subregions where sexual transmission is expected to be important in the future are SEAR-D and WPR-B. These two subregions contain some countries which already report broad sexual spread of HIV infection, primarily through sex work (Cambodia, Myanmar) and even in countries where the current epidemic is now driven by injected drug use (Indonesia, China), HIV will spread more broadly from the injecting drug users to their sexual partners. In these countries, the fraction of future infections which would be averted by reductions in unsafe sex is higher than the fraction of current infections which is attributable to unsafe sex.
These findings do not come as a surprise. More important for intervention design and programme evaluation would be to identify which aspects of sexual behaviour contribute most to the spread of HIV in different settings. If this were known, the design and implementation of measures to prevent the spread of HIV infection could be improved. However, even in the absence of this information some measures are known to be effective in preventing HIV infection at the individual level. For example, increasing the levels of condom use can only help to slow the spread of infection.

## Acknowledgements

The following kindly provided data:
Measure DHS+, Macro International Inc. provided the DHS for 63 countries.

Australia: Pilot data were obtained from the Australian Study of Health and Relationships. The data were made available by Anthony Smith and provided by Richard de Visser.

India: Data were obtained from the International Institute for Population Studies (IIPS), Mumbai, courtesy of Ravi K. Verma.

Europe: Data for eight countries (England, France, Germany, Greece, Italy, Norway, Portugal and Switzerland) from the European New Encounter Module (NEM) project were provided by Michel Hubert, on behalf of the NEM group.

France: Data from the 2001 Knowledge, Attitudes, Beliefs and Practices (KABP) survey (Grémy et al. 2001) were made available by Ruth Ferry and provided by Julien Chauveau.

Honduras: Data from the Centers for Disease Control and Prevention Encuesta Nacional de Salud Masculina 1996 survey were provided by Leo Morris.

Rwanda and Madagascar: Data were provided by Population Services International (PSI), courtesy of Dominique Meekers.

## Models

We made use of the Epidemic Projection Package (EPP) and Spectrum. These are both available courtesy of the Futures Group.

We are greatly indebted to Tim Brown at the East West Center, not only for providing us with the source code for EPP but also for a modified version of the model, which made it possible to calculate the initial estimates of the avoidable infections in countries with generalized epidemics.

We are grateful to the UNAIDS/WHO Working Group on Global Surveillance of HIV/AIDS and STIs for making their country-specific models of HIV/AIDS available for use in this exercise.

## Notes

1 See preface for an explanation of this term.
2 The exception is the Indian study which was among people attending a clinic for sexually transmitted infections. The study was included to provide some information on Asia.

Surveys used to estimate exposure (continued)

## Chapter I 5

# Non-USE AND USE OF INEFFECTIVE METHODS OF CONTRACEPTION 

Martine Collumbien, Makeda Gerressu and
John Cleland

## Summary

This chapter estimates the burden of disease attributable to non-use of contraception and use of ineffective methods. The health outcomes include obstetric complications and abortion-related morbidity and mortality associated with unintended pregnancies (unwanted and mistimed). We have presented a model for linking data on contraceptive use and fertility preferences to unwanted births and unsafe abortions as intermediate outcomes, which were then related to the maternal disease burden.

The health outcomes considered were the conditions associated with unsafe abortion and unwanted births. The abortion-related conditions are a separate subcategory and the risk of abortion-related consequences is directly proportional to the risk of an unsafe abortion. The obstetric conditions linked to unwanted births are maternal haemorrhage, maternal sepsis, hypertensive disorders of pregnancy, obstructed labour and other maternal conditions. The burden of these obstetric complications attributable to non-use of contraception was assumed to be proportional to the percentage of unwanted births among all births.

Contraceptive use reduces the risk of unintended conception but does not altogether eliminate it, and failure rates are higher for traditional methods than for modern methods. The categorical variable "contraceptive use" has three levels of exposure: non-use, use of traditional methods and use of modern methods. Non-users experience the highest conception rates. The modern method category was used as the reference category for calculating the relative risk of having an abortion and an unwanted birth.

Not all conceptions lead to an avoidable burden, since many pregnancies are desired. We calculated how many unintended pregnancies are expected in one year by first estimating the proportion of women who would become pregnant and combining this with the probability that the
pregnancy would be unwanted or mistimed, based on current reproductive intentions. The proportion of women becoming pregnant was derived from contraceptive failure rates among modern and traditional method users and biological expectations of the number of conceptions among non-users. Within the non-users, conception rates were applied to the fecund women only, excluding those who would not be exposed to pregnancy for biological or behavioural reasons. Abortion probabilities were applied to determine how many of the mistimed and unwanted pregnancies would end as abortions and unwanted births. Unwanted pregnancies would contribute to both abortion-related burden and the obstetric burden of maternal complications. Mistimed pregnancies only contribute to the abortion-related burden since preventing mistimed births by use of more effective contraception does not avert-only delay-any potential associated obstetric burden.

As theoretical minimum exposure we have simulated the contraceptive distribution which would prevail if all women with a desire to either stop childbearing or postpone the next birth for at least another two years, adopt an effective modern method of contraception. All traditional method users and fecund non-users consist of women who want a birth in the next two years. At this theoretical minimum level, the relative risk of an unwanted birth and abortion becomes zero because only the reference category, modern method users, is at risk of unintended pregnancy. Counterfactual levels of relative risk were calculated to take account of the changing distributions of fertility desires within each exposure category.

Subregional ${ }^{1}$ levels of distribution of contraceptive use and the relative risk levels of abortions and unwanted births were derived by aggregating country estimates based on data from 58 Demographic and Health Surveys (DHS). This source includes data on childbearing intentions and contraceptive use at the time of survey. Average methodspecific and duration-specific failure rates were calculated from 18 countries with DHS calendar data on contraceptive use. In each country, the method-duration-specific failure rates were combined with the method mix and data on duration of use of current methods. Abortion probabilities were derived from the World Health Organization (WHO) estimates of incidence ratios (unsafe abortions per 100 live births).

It was estimated that globally $89 \%$ of the disease burden due to abortion complications is attributable to unprotected sex or use of less effective traditional methods. This amounted to 51000 deaths and 4.4 million disability-adjusted life years (DALYs), with $82 \%$ of the burden falling on women aged $<30$ years. The highest absolute burden is experienced in South Asia ( $35 \%$ of the total abortion burden) while in relative terms women in the two African subregions are the worst effected. The burden of disease attributable to maternal conditions arising from unwanted births was 98000 deaths and 4.5 million DALYs. In contrast to abortion, the largest part of the burden befalls women over $30(74 \%)$ since
a higher proportion of all births is unwanted among older women. For women aged $<30$ years, about $7 \%$ of all births could be averted if all women who wished to stop childbearing used a modern method. This proportion is as high as $40 \%$ for the older age group.

## 1. Introduction

Sexual intercourse contributes positively to health and general well-being in both men and women; it leads to increased intimacy in relationships. Sexual intercourse is also an important risk factor for disease and disability. The most important negative consequence of sex is the risk of contracting a sexually transmitted infection, including HIV, through unprotected intercourse. HIV and sexually transmitted infections (STIs) are discussed in chapter 14. In this chapter we have concentrated on the reproductive consequences of sexual intercourse. Notwithstanding recent developments in assisted reproduction, sexual intercourse is a requirement for reproduction for the overwhelming majority of couples. Motherhood is highly valued in most societies, but each pregnancy and childbirth carries a health risk for the woman, and where obstetric services are poor, maternal mortality is still very high. The most recent estimates show that, of the global 515000 maternal deaths in 1995, more than $99 \%$ occurred in Africa, Asia, Latin America and the Caribbean (Hill et al. 2001).

Reduction of maternal mortality and morbidity can be achieved by more effective treatment of pregnancy-related complications. The disease burden can also be reduced by avoiding pregnancies through adoption of effective contraception. Not all pregnancies and births are intended: many are either mistimed or unwanted at any time. Worldwide it is estimated that about 210 million recognizable pregnancies occur every year (The Alan Guttmacher Institute 1999)—of which about $15 \%$ end in spontaneous miscarriage or stillbirth. Another $22 \%$ are terminated by induced abortion and thus can be classified unambiguously as unintended. The remainder-some 133 million-result in the birth of a baby. Evidence from DHS and similar surveys has suggested that, globally, some $20 \%$ of all births are unintended (The Alan Guttmacher Institute 1999). Adding together unintended births and induced abortions, it may be concluded that about $40 \%$ of all pregnancies are unintended.

This chapter is concerned with estimating the burden of maternal complications and abortions that could be avoided if couples increased their use of effective contraception. We have presented a model for linking data on contraceptive use and fertility preferences to unwanted births and unsafe abortions. DHS data for 58 countries were used to calculate attributable fractions: what proportion of these unwanted births and unsafe abortions could be averted by perfect implementation of fertility preference through increased use of effective contraception. These
intermediate outcomes were then linked to estimates of the burden of maternal complications in pregnancy.

## 2. Risk factor definition and health outcomes

### 2.1 Health outcomes

The health outcomes considered for assessing disease burden due to lack of use of effective contraception are the conditions associated with unsafe abortion and unwanted births. The abortion-related conditions are a subcategory under the Global Burden of Disease (GBD) study's causes of maternal conditions. The main causes of mortality and morbidity associated with unsafe abortion are sepsis, following incomplete removal of the fetus, and perforation of the uterus. Based on the International Statistical Classification of Diseases and Related Health Problems (ICD10), the obstetric conditions other than the abortion-related include maternal haemorrhage, maternal sepsis and obstructed labour. Other complications include hypertensive disorders of pregnancy, and the category of "other maternal conditions". These maternal complications were the causes considered in attributing the burden of disease to unwanted births.

Some other conditions are exacerbated by pregnancy. Indirect obstetric complications result from existing disease (malaria, anaemia, hepatitis, cardiovascular disease, tuberculosis and hypertension) but are aggravated by the physiological effects of pregnancies (AbouZahr and Vaughan 2000). Suicide and violence may be pregnancy related, and other forms of psychological morbidity are associated with childbirth and unintended pregnancies. Since the magnitude and the strength of these relationships are largely unknown, none of these conditions have been included in the burden attributable to non-use of contraception.

The morbidity related to use of contraception has been excluded for this exercise. Those conditions include allergic reactions to barrier methods, intrauterine device (IUD)-associated bleeding, and wounds from surgical procedures. Morbidity associated with systemic contraceptive such as the oral contraceptive pill, includes the impact on cardiovascular and hormonal systems and carcinogenicity (AbouZahr and Vaughan 2000).

The burden of obstetric complications attributable to non-use of (or use of less effective) contraceptive methods is proportional to the percentage of all births that are unwanted. Intergenerational effects of contraceptive use on the health of offspring have not been considered, nor has the burden of perinatal outcomes associated with the delivery of unwanted births been taken into account. It is clear that by averting unwanted pregnancies, a proportion of perinatal deaths can be avoided. However, by averting unwanted births the disease burden throughout
infancy and beyond can be reduced. The potential contribution of contraception to infant survival through better birth spacing is also well known. Babies born within 24 months of an elder sibling are at elevated risk of dying in infancy (Trussell and Pebley 1984). Mistimed births may therefore be associated with higher disease burden in childhood. Because of the conceptual problems of considering health impact in the next generation, the outcomes have been restricted to maternal ones.

### 2.2 INTERMEDIATE OUTCOMES: UNWANTED BIRTHS AND UNSAFE ABORTIONS

In the "perfect contracepting society", all women, or couples, who do not wish to have a baby within the next year or so would use effective contraception. Under these circumstances, a small residue of unintended pregnancies would remain because of contraceptive failure but the overwhelming majority of births would be intended. In the real world, however, large discrepancies exist between reproductive wishes and contraception protection. These discrepancies arise for myriad reasons. In developing countries the main direct cause is lack of any contraceptive precautions despite the desire to delay the next child or have no more children. In the demographic literature, non-use of contraception among women desiring to space or limit childbearing is termed "unmet need" for contraception. Estimates of the prevalence of such unmet need in 55 developing countries in the 1990s ranged from $6 \%$ to $40 \%$ of all currently married women (Westoff 2000). The main underlying causes of unmet need in developing countries include a perception that risk of pregnancy is low, opposition to the use of contraception, stemming from the husband's attitude or religious considerations, and concerns about the safety or side-effects of methods. Lack of knowledge about contraceptive methods, or how to access them, are also important contributory causes in some countries.

In industrialized countries, contraceptive practice tends to be higher than in most developing countries. Nevertheless appreciable discrepancies between reproductive motivation and behaviour are also apparent. Contraceptive failure and irregular use of methods are more important direct causes of unintended pregnancies than in developing countries. For instance, in the United States of America about half of all unintended pregnancies are the result of failure or irregular use (Henshaw 1998). Unanticipated sexual intercourse no doubt represents a further risk factor, particularly for single women.

Attitudes towards becoming pregnant are complex and often ambivalent. Typically, two persons are involved, the woman and her husband or partner, whose views do not necessarily coincide. Attitudes may also change over time, particularly between the time before conception and the time following recognition of the pregnancy. For instance, a couple may have no fixed intention to have a baby but nevertheless be delighted when conception occurs. No unambiguous and generally agreed defini-
tion of unintended pregnancy exists. Rather researchers have used a variety of indirect and direct methods of measurement.

The most commonly available and used measure is that employed by the DHS. In this approach women are asked the following question about recent live births and the current pregnancy (if any): "At the time you became pregnant with (NAME OF CHILD) did you want to become pregnant then, did you want to wait until later, or did you want no more children at all?" This question leads to a three-way classification: births wanted at that time; birth not wanted then but later; birth not wanted at any future time. The latter two categories-mistimed and unwanted births-are often grouped together and defined as unintended births or pregnancies. Some authors use the terms unintended and unplanned interchangeably. However the concept of planning implies active preparation for pregnancy (e.g. cessation of contraceptive use, possible dietary changes, etc.) that makes it inappropriate for the large number of countries where contraception is still uncommon.

Unintended pregnancies may be subdivided into those that are unwanted at any time and those that are mistimed. Both categories may lead to induced abortion although in most settings it can be expected that unwanted pregnancies are more likely to be terminated than mistimed ones (Bankole et al. 1999). In 1995, it was estimated that approximately 26 million legal and 20 million illegal abortions occurred worldwide (Henshaw et al. 1999). The legality and safety of abortion are strongly correlated (Rahman et al. 1998). In the developed world where abortion is generally legal, abortion mortality is as low as 0.2 to 1.2 deaths per 100000 procedures. In non-legal settings, when an unskilled provider, using hazardous techniques, terminates the preg-nancy-often in unsanitary conditions-complications for the woman are likely. Of the 20 million illegal abortions globally, 19 million happen in developing countries (Henshaw et al. 1999). Where abortion is either illegal or highly restrictive, abortion mortality averages 390 deaths per 100000 procedures (but as high as 680 in Africa) (WHO 1998). WHO defines an "unsafe abortion" as a procedure for terminating an unintended pregnancy either by persons lacking the necessary skills or in an environment lacking the minimal medical standards or both (WHO 1998). About a third of unsafe abortions lead to serious complications, and about $13 \%$ of the pregnancy-related deaths worldwide are related to complications of unsafe abortion (The Alan Guttmacher Institute 1999).

When unintended pregnancies are not aborted, and no miscarriage or stillbirth occurs, the pregnancy results in a live birth. As mentioned before, in developing countries, the mortality and morbidity risk associated with complications during childbirth is substantial for any birth, whether intended or unintended.

Part of the total burden of obstetric complications during childbirth can, however, be avoided by preventing the unwanted pregnancies (i.e.
those not wanted at any time) through use of effective contraception (Fortney 1987; Winikoff and Sullivan 1987). Avoiding unwanted pregnancies will reduce maternal mortality in two ways: by reducing the number of pregnancies and by reducing obstetric risk (i.e. the risk per pregnancy). Unwanted births tend to occur when women are relatively old and already have several children. Risks to the mother's health of pregnancy and childbirth are higher at older ages. Hence, the obstetric risk as measured by the maternal mortality ratio (maternal deaths per 100000 live births), is reduced by averting high-risk births based on maternal age and parity but the effect is relatively small (Trussell and Pebley 1984; Winikoff and Sullivan 1987).

In many countries unwanted births are particularly likely to occur to women who have low education, poor nutrition and poor access to health services-all conditions associated with a higher maternal complication rate (Berkley 1998). However, this link between socioeconomic conditions and unwanted births is not universal. In countries with low levels of contraceptive practice, as in much of sub-Saharan Africa, educated women are as likely to report unwanted births as uneducated women (Adetunji 1998). However, these effects of obstetric risk (averting high-risk births), are dwarfed by the impact of reducing the overall incidence of pregnancies through the elimination of unwanted births (Fortney 1987). This elimination will have a huge impact on the maternal mortality rate (maternal deaths per 100000 women of reproductive age), and the lifetime risk of dying in childbirth or pregnancy.

So is it reasonable to assume that delivery complications associated with unwanted births are the same as those associated with wanted births? Apart from considerations of maternal age and socioeconomic status, another possibility is that mothers neglect unintended pregnancies in ways that put the mother herself at greater risk. The evidence is meagre but a recent analysis using five DHS concluded that unintended pregnancies are not selectively discriminated against in terms of obstetric care and thus probably did not represent excess risk to mother's health and survival (Marston and Cleland 2003a). As these five surveys include enquiries from Africa, Asia and Latin America, it is reasonable to generalize results, at least to developing regions. On balance, therefore, it is justifiable to assume that obstetric complications are the same for wanted and unwanted births.

How should mistimed (in distinction to unwanted) births be regarded in relation to delivery complications? Births may be classified as mistimed when the woman is too young and wants to delay the first birth, or when she feels births are too closely spaced or when other conditions are not yet conducive to childbearing. Births to very young women (aged $<18$ years) do carry a higher risk, and delaying some of those may therefore avert some obstetric risk, although the effect will be small (Trussell and Pebley 1984). However, reducing mistimed births by contraceptive practice will have little influence on the incidence of pregnancies as the
births will merely be delayed rather than averted. Such delay or postponement will thus not reduce the burden of delivery complications. As discussed earlier, the potential contribution of contraception to infant survival through better birth spacing is well known, with babies born within 24 months of an elder sibling being at elevated risk of dying in infancy (Trussell and Pebley 1984). In contrast to the strong evidence regarding childhood risks, it is uncertain whether shorter birth intervals are associated with an increased risk of maternal mortality or morbidity. The only two published studies give conflicting results (Conde et al. 2000; Ronsmans and Campbell 1998). It is therefore not justified to regard short intervals as a risk factor for obstetric complications. It may be concluded, therefore, that prevention of mistimed births through contraceptive use will make no contribution to the reduction of delivery complications.

### 2.3 The pathway from exposure to health outcomes

When assessing the 1990 disease burden attributable to unsafe sex, Berkley (1998) estimated the percentage of women with an unmet need for family planning and attributed an equivalent proportion of the obstetric and abortion burden to non-use or inappropriate use of contraception (Berkley 1998). In order to follow the comparative risk assessment (CRA) methodology, we have modelled the outcomes (intermediate outcome in terms of unwanted births and unsafe abortion and health outcome in terms of obstetric and abortion-related burden) from exposure (i.e. contraceptive behaviour).

The definition of exposure has to take into account the fact that contraceptive use reduces the risk of conception but does not altogether eliminate it. The probability of accidental pregnancy while using a method depends on the intrinsic or theoretical effectiveness of the method itself (method failure) and on whether it is used consistently and correctly (user failure). Some methods (e.g. condoms, oral contraceptives, withdrawal and periodic abstinence) are much more prone to user error than other methods (e.g. contraceptive sterilization, intrauterine devices). Withdrawal, or coitus interruptus, and periodic abstinence are distinguished from all other commonly used methods by their exceptionally high failure rates. In the family planning literature these two methods are often given the label "traditional" because they are not the product of advanced techniques of biochemistry or engineering. To capture this variability by method, exposure was divided into three levels: non-use, use of traditional methods and use of modern methods. The pathway from exposure to intermediate and health outcome is depicted in Figure 15.1. The diagram relates to sexually active women (non-virgins), and for clarity the categories of wanted pregnancies and births are omitted.

All three levels of exposure will lead to both unwanted and mistimed pregnancies, but the probability is lowest for the modern method users.

Figure I5.I Pathway from exposure to outcome

Failure rates for traditional methods are higher and no protection carries the highest risk. Modern methods have been used as the theoretical-minimum-risk reference category for calculating the relative risks of having an unintended pregnancy (subdivided into unwanted and mistimed) among traditional method users and non-users.

The next step in the model was to examine the reproductive outcomes of these unintended pregnancies: spontaneous fetal loss and stillbirths, abortions, mistimed and unwanted births. Both unwanted and mistimed pregnancies may end in miscarriage or stillbirth, and such events may cause obstetric complications. No evidence exists to suggest that the probability of miscarriage or stillbirth for unintended pregnancies differs from that of intended pregnancies (i.e. the ratio of unwanted over all stillbirths is the same as the ratio of unwanted births over all births). Therefore, these events have been excluded from the calculations of the attributable risk. Since the total burden of maternal complications is a separate input provided by WHO (independent from our model), and complications due to in utero loss are an integral part of this burden, the attributable burden of maternal complications associated with in utero loss has been accounted for. Both unwanted and mistimed pregnancies may be aborted. In terms of ultimate outcome or disease burden, the risk of abortion-related consequences is directly proportional to the risk of an unsafe abortion. Unwanted pregnancies may be carried to term and the burden of maternal complications will be proportional to the percentage of unwanted births among all births. As discussed earlier, mistimed pregnancies carried to term do not contribute to an attributable burden of disease, because this proportion of disease burden would only have been delayed if the pregnancy were not mistimed.

The model in Figure 15.1 was applied to data from 58 DHS to obtain subregional levels of exposure and the relative risk of having unwanted births and unsafe abortions.

## 3. DATA AND METHODS FOR EXPOSURE AND HAZARD

### 3.1 Data sources

In the analysis, we drew heavily on DHS data on childbearing intentions and contraceptive use at the time of survey. DHS were used for several reasons. First, they are the dominant source of information on fertility intentions and contraceptive use in developing countries, with good representation in all highly populated regions. Most of the most populous developing countries have conducted a recent Demographic and Health Survey: Bangladesh, India, Indonesia and Pakistan in Asia; Brazil and Mexico in Latin America; and Ethiopia and Nigeria in sub-Saharan Africa. Indeed China is the only conspicuous absentee but, as will be shown later, this omission is relatively unimportant because the attributable burden is small in this country.

A further reason for reliance on DHS is that all surveys are nationally representative and executed to a high standard, with abundant technical assistance where needed. Surveys are also highly standardized in content, with the important implication that measures of fertility intentions and contraceptive use are comparable across countries. A final pragmatic reason for using DHS is that well-documented, clean data files are available for public use. Other data, especially the reproductive health surveys by the Centers for Disease Control and Prevention (CDC) were considered, since they cover countries mainly in Latin America and eastern Europe. Because of restricted availability, different age ranges and inadequate detail to make analytically important distinctions, we chose to use DHS data only. Similarly, the use of the National Survey of Family Growth (United States) was briefly considered, but the very small overall burden of maternal complication and the different questions used did not warrant the considerable effort that would have been required.

The surveys used in these calculations were those available at the time of calculation in 2001. Table 15.1 lists the countries by subregion, giving the date of survey, whether the sample was restricted to ever-married women (those who are or have been married) or all women, and the legal status of abortion in each country. The table also indicates what proportion of the total female population aged 15-44 years in the subregion is represented by the country and the weights used for aggregating country-specific data into subregional estimates. Ten of the 58 surveys were done before 1990. Although fertility levels and preferences may have changed considerably in the last decade, these surveys were retained
Table 15.I DHS used in estimating exposure and relative risks

${ }^{\text {a }}$ Legal status of abortion: I, permitted only to save the woman's life or prohibited altogether; II, physical health (also to save the woman's life); III, mental health (also to save the woman's life and physical health); IV, socioeconomic grounds (also to save the woman's life, physical health and mental health); V, without restriction as to reason (Source: Center for Reproductive Rights [formerly Center for Reproductive Law and Policy] 1999).
b These weights represent the fraction of the total population (of women aged 15-44 years) of countries with data.
in the analysis since the differences in fertility levels within subregions are even wider.

DHS directly provide most of the information needed for the calculation of attributable risk ratios. This includes information on sexual activity (needed to define exposure), fertility intentions, type of contraceptive method used and probability of contraceptive failure. These are discussed below. However, DHS have one important defect: most do not collect information on induced abortion and those that do yield severe underestimates. The difficulty of obtaining reliable information on induced abortion is the most intractable problem in the study of human reproduction, perhaps not surprisingly in view of the fact that abortion is both illegal and stigmatized in many societies.

In this chapter, we have used unpublished 1995 national estimates of unsafe abortions compiled by WHO. These estimates were made indirectly from data on hospital admissions for abortion complications, weighted by the proportion of abortions that are thought to result in complications requiring admission. Information from community surveys and to a lesser extent from abortion providers' surveys and mortality studies have also been used to derive best possible estimates (WHO 1998). While this is the main base of data used to calculate abortion probabilities, DHS data have also been used for three central Asian republics (Kazakhstan, Kyrgyzstan and Uzbekistan) where abortion is legal and survey estimates are considered reliable (Westoff et al. 1998). In addition, data on legal rates of abortion were used to make adjustments in some countries (Henshaw et al. 1999).

The only other non-DHS data source used in the calculations were biological in nature. Monthly probabilities of conception among nonusers of contraception (i.e. fecundability) and intrauterine mortality were taken from the published literature (Bongaarts and Potter 1983; Leridon 1977).

### 3.2 Defining exposure and fertility preferences

Women who do not have sexual intercourse are obviously not at risk of complications of abortion or childbirth. Virgins and others need to be distinguished. Virgins are excluded from exposure and they do not affect the relative risk calculations. The proportions of virgins have been given as a separate input for each subregion. In 12 surveys (Table 15.1), mainly in Asia where premarital sex is relatively uncommon, only ever-married women were interviewed. For these countries never-married women have been categorized as virgins. All non-virgins were included in the appropriate category of exposure variable "contraceptive status". A large proportion of non-users is not exposed to risk of pregnancy for either biological or behavioural reasons. As the calculations involved estimating births over a 12 -month period, it was decided to classify women who reported no intercourse in the past 12 months as behaviourally unexposed.

Fertility surveys like the DHS include several questions on fertility intentions: total desired family size, whether more children are wanted, the number of additional children wanted and the intended status of recent births and current pregnancy. Retrospective data on recent births could not be used for our purposes of examining the relationship between unwanted births and contraceptive use, since the women were not asked whether they were using a method of contraception at the time of conception. Instead, we needed to use a forward-looking measure on desirability and timing of any future births. Women's response to the questions "Would you like to have a/another child or would you prefer not to have any (more) children?" and "How long would you like to wait from now before the birth of a/another child?" are considered to be relatively unbiased. Women have no reason to misreport their preference for more children (Bongaarts 1990). Moreover, these future childbearing wishes or intentions are predictive of subsequent childbearing (Westoff 1990).

The data used to link contraception with childbearing intentions are the same that provide the input for calculating the now ubiquitous measure of unmet need for family planning, routinely reported from fertility surveys (Dixon-Mueller et al. 1992; Robey et al. 1996). A woman has an unmet need for birth spacing when she wants to postpone the next birth for at least two years, she is not using contraception and is exposed to risk of conception (i.e. sexually active and menstruating). Similarly, women who want no more children and are not current users are defined to have an unmet need for limiting family size. Unmet need refers to the current status (at the time of interview), but we need to assume a steady state for one year in order to project the fertility implications over the next year for each combined level of exposure and fertility preference.

Since we wanted to estimate the yearly number of expected pregnancies, was this assumption that childbearing intentions stay constant for one year valid? Unless the women are re-interviewed the next year there is no way of knowing the exact fertility implications of the stated preferences and whether these preferences remain constant over a one-year span. Over long periods, childbearing intentions can change substantially, especially in countries progressing through a secular decline in fertility (Freedman et al. 1980). A woman's economic and social circumstances, health status and current marriage/partnership will influence her response about childbearing intentions. As these individual personal circumstances change so may her desire for more children. In the shorter term, however, stability of intentions is reasonably high. For instance, in a prospective study in Peru, aggregate levels of fertility preferences were shown to be consistent over a three-year period (Mensch et al. 1995). Even if circumstances and preferences change for individual women, at the aggregate level the changes are likely to be offset by other women whose life circumstances may change in the opposite direction.

### 3.3 Estimating the expected number of UNINTENDED PREGNANCIES

Referring back to Figure 15.1, the first stage was to estimate how many unintended pregnancies we expected in one year. This was done by first estimating the proportion of women who would become pregnant and combining this with the probability that the pregnancy was unwanted or mistimed. The proportion of women becoming pregnant was based on contraceptive failures among modern and traditional method users and on biological expectations of the number of conceptions among non-users.

## Contraceptive failure

Most enquiries of DHS do not collect information that permit the calculation of contraceptive failure rates. However in a subset of 18 developing countries where levels of contraceptive practice are high, the necessary data have been collected in the form of month-by-month calendars of contraceptive use spanning a 60 -month period prior to date of interview. The type of methods used, dates of starting and ending episodes of use together with main reason for stopping (including failure) are ascertained. Failure rates can be calculated by application of life table techniques to these data. Though this retrospective method of measurement makes heavy demands on the memory of respondents, recall is aided by prior entry into the calendar of live births, ascertained earlier in the interview, and the contraceptive data appear to be of high quality (Curtis and Blanc 1997).

We used an unpublished analysis of failure rates for all 18 countries where calendar data have been collected. Despite considerable intercountry variability, the ranking of methods according to failure rates is clear-cut and accords with other evidence (Trussell 1998). Failure rates are low for methods requiring no memory or skill from users (sterilization, IUD, implant, injectable), intermediate for theoretically effective methods that do require inputs from users (oral contraceptives, condoms) and high for periodic abstinence and withdrawal.

Failure rates not only vary by method and by type of user but also by duration of use. They tend to be higher during the initial period of use and subsequently decline. The reason for this trend concerns selectivity. Inefficient users of a method have a high probability of an early failure. With the passage of time, continuing users are increasingly selected for their proficiency of use and thus failure rates fall. This tendency is more marked for methods requiring skill or memory than for other methods. We have used the mean method-specific and duration-specific failure rates for these 18 countries to calculate country-specific aggregate failure rates for all 58 countries. In the left-hand panel of Table 15.2 we have presented the yearly probabilities of experiencing failure by duration of use for each method. These were calculated from the single-decrement

Table I5.2 Calculation of average method-specific failure rates from yearly probability of failure by duration of use for women aged 30-44 years, all countries combined

|  | Yearly probability of <br> experiencing contraceptive |  |  |  |  | Duration of use in <br> completed years <br> (proportional <br> distribution) | Average <br> failure <br> rate <br> (\%) |  |  |
| :--- | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: |
| Contraception method | Ist |  | 2nd | 3rd | $4+$ | 0 | Ist | 2nd | 3rd |

life table estimates of failure. The estimates should be interpreted as the cumulated percentage of couples who would experience failure by the end of the 12th month of use, in the absence of other reasons for stopping use. As can be seen, failure rates generally decline by duration of use, although the second-year failure rates are higher than the first year ones for pill, IUD, withdrawal and "other traditional" methods.

For each of the 58 countries, these method-duration-specific failure rates were then combined with data on duration of use of current methods. The resulting country-specific failure rates for each method were calculated separately for the two age groups. Table 15.2 shows the calculation of these method-specific failure rates for women aged 30-44 years (all countries combined).

The final step was to obtain aggregate failure rates for modern and traditional methods by taking into account the relative contribution of the different modern and traditional methods (method-mix) in each country. The country-method-specific failure rates (calculated as in Table 15.2) have been combined with the relative method mix, as shown in Table 15.3. For women aged 30-44 years, the average failure rate experienced by modern method users is $2.3 \%$, while $15.1 \%$ of the traditional method users will conceive in a year. For the younger age group these failure rates are higher at $4 \%$ and $17.3 \%$, respectively, due to their greater reliance on less effective reversible methods, and a shorter length of time for which current users have been using the methods (calculations not shown).

Table 15.3 Aggregate failure rates, calculated from method-specific failure rates and method mix for women aged 30-44 years, all countries combined

## Conception rates

The estimation of the expected conceptions among the non-users was based on fecundability, which is defined as the probability of conceiving in a month among fecundable women (Bongaarts and Potter 1983). Fecundable women are those capable of conceiving. Conception refers to recognizable conception signified by the delay of first menses after fertilization. Some non-users have obvious biological or behavioural characteristics that make them temporarily unexposed to the chance of conceiving: the currently pregnant, amenorrhoeic women, women who have not resumed sex since the most recent childbirth and women who reported no sex in the past year. Other non-users, such as those who have reached menopause or know themselves to be infecund, are permanently unexposed to the risk of conception. These women have thus been excluded and the conception rates applied to fecundable women who have been sexually active over the past year.

Fecundability is difficult to assess empirically and it is usually estimated from waiting times to conception. Most reliable estimates are available from measuring the length of interval between marriage to first birth among couples using no contraception. Coital frequency is the dominant behavioural determinant of fecundability and most of the variation of fecundability by age can be attributed to a decline in intercourse (James 1979). Fecundability has been tabulated either by age or by coital frequency, but not by both (Bongaarts and Potter 1983; Leridon 1977).

Without sex there can be no conception but there are other biological requirements: the woman needs to ovulate, and insemination must lead to a successful fertilization, which then has to result in a recognizable conception. Mathematical modelling of age-specific fecundability shows that the ability to conceive is quite constant between ages 25 and 40, while the ability to maintain a pregnancy starts to decline much earlier (Weinstein et al. 1990; Wood and Weinstein 1988). In our calculations intrauterine mortality was accounted for in the second step (Figure 15.1) when we estimated how many of the unintended pregnancies resulted in unwanted births and unsafe abortions.

While biological determinants of fecundability are fairly constant across populations, differences in frequency of sexual intercourse do have a substantial impact on fertility (Brown 2000; Weinstein et al. 1993). Increased frequencies of sexual intercourse raise fecundability, but the relationship is not linear. When coital frequency is low, the chance of conceiving is proportional to the frequency, but, at higher levels of monthly frequency, further increases are minimal (Potter and Millman 1986; Weinstein et al. 1990).

Should age-based or coitus-based estimates of fecundability be used? DHS data allow the calculation of both. Most surveys enquire about the most recent date of last sexual intercourse and frequency in the last month. We have used the data on the most recent date of the last intercourse to infer coital frequency, because it is less prone to recall error and normative responses than the question on coital frequency in the last month (Becker and Begum 1994). It is also available for more surveys included in our calculations. When the individual probability of coitus is constant throughout the month, the interval between two acts of intercourse is the reciprocal of the frequency. It has been shown-mathematically and empirically-that the distributions of the time since last sex and the interval between two acts have the same mean and variance (Leridon 1993). We could therefore estimate the coital frequency from the mean time since last sex. Our calculations were based on women who have been sexually active in the past year. Among these women, a large proportion did not have sex during the last month. Therefore, the average time since last sex was converted into monthly coital frequency for those who did have sex within the last month, while the others were given the value of 0 in order to derive the average monthly frequency among all women sexually active during the past year. Twelve countries lacked data on time since last sex, and for those we imputed frequencies taking the average values estimated from other countries for the three levels of fertility intention. The calculation of mean coital frequencies was done separately for samples of ever-married and samples that included all women. The frequencies for all women typically give lower values, especially among women who want to space their births (hereafter referred to as "spacers"), which include many women who may not have a regular partner, or not live with a partner.

Since the frequency of intercourse varies considerably according to childbearing intentions, with spacers and women who want to limit their births (hereafter referred to as "limiters") having less frequent sex than women who want a birth within the next two years, we have calculated expected pregnancies in two ways. The first uses model estimates of fecundability based on coital frequency (Bongaarts and Potter 1983), allowing different conception rates by fertility intention, while the second uses simple age-specific fecundability estimates, with monthly fecundability declining from 0.25 in the early 20s to 0 by age 45 years (Leridon 1977).

Table 15.4 shows the differentials in monthly coital frequencies by fertility desire and its impact on fecundability for the two age groups. Fecundability was expressed as the number of women expected to become pregnant at the end of one year, and this was contrasted with the age-specific fecundability as calculated from the monthly model estimates (Leridon 1977).

Overall, the mean coital frequencies derived from data on duration since last sexual intercourse seem very low, but reflect the fact that these are based on all women who had sex during the past year (rather than on those in stable cohabiting relationships). The effect of including unmarried, non-cohabiting women is especially evident among the spacers aged 15-29 years, a group which includes $25 \%$ of never-married women, compared with $13 \%$ among the limiters and $7 \%$ among those who desire a child soon. Single women have sex less frequently-and are likely to underreport sexual activity. For the 12 countries with evermarried samples, higher levels of coital frequency result in higher expected fecundability. But in most societies, sexual intercourse and therefore risk of pregnancy is not restricted to marriage. A study among nine African countries has shown that the time spent in marriage is not always a good proxy for sexual activity either, with high levels of inac-

Table 15.4 Mean monthly coital frequency by age and fertility preference for fecund non-users, and estimates of coitusbased and age-based fecundability

|  | 15-29 years | $30-44$ years |
| :--- | :---: | :---: |
| Mean coital frequency |  |  |
| Want children soon | 4.4 | 3.9 |
| Spacers | 2.1 | 3.0 |

| Coitus-based fecundability (proportion pregnant in a year) |  |  |
| Want children soon | 0.82 | 0.78 |
| Spacers | 0.54 | 0.71 |
| Limiters | 0.72 | 0.54 |
| Age-based fecundability (proportion pregnant in a year) | 0.97 | 0.75 |

tivity recorded by married women, especially in West Africa (Brown 2000). The differential in fecundability according to fertility preference persists when the analysis is restricted to married women only and remains important.

Guided by consistency checks on internal validity of the data (discussed below), the relative risk estimates presented in this chapter were calculated using age-based fecundability estimates. Because of the importance of the effect, however, we will return to this topic in the section on uncertainty of estimates at the end of the chapter.

### 3.4 Combining exposure and fertility intention

The expected number of unwanted pregnancies was calculated separately from mistimed pregnancies. In fact, pregnancies were estimated for all nine combinations of exposure (modern method use, traditional method use, no use) and fertility intention (want birth soon, later, never). As shown schematically in Figure 15.2, contraceptive failures can thus result in pregnancies that are classified as intended. They occur among women who want a birth within the next two years.

More detail is provided in Figure 15.3 showing the calculation of the expected proportion of women having an unwanted pregnancy in the next year for each level of exposure, using data for women aged 30-44 years (all surveys combined).

Among the non-users, $11 \%$ were currently pregnant, $19 \%$ were amenorrhoeic or had not resumed sex since last birth, $21 \%$ were infecund or menopausal and another $10 \%$ had not had sex in the past year, leaving

Figure 15.2 Combining data on exposure and fertility intention to estimate pregnancies

Figure 15.3 Expected proportion of women having an unwanted pregnancy in the next year, by exposure

only $40 \%$ of the non-users exposed to the risk of conception. Forty-five per cent of these fecundable women wanted to limit their families (i.e. have no more children) and, based on their coital frequency, they had a $75 \%$ probability of conceiving in a 12 -month period. The product of these three numbers $(40 \% \times 45 \% \times 75 \%)$ gave the proportion of all non-users who were expected to have an unwanted pregnancy in the next 12 months, namely $13.5 \%$.

Among traditional (and modern) method users there may also be women who are biologically or behaviourally unexposed, but they are implicit in the failure rates (in contrast to conception rates). In other words, the presence of unexposed women among users will depress failure rates and thus obviate the need to take further account of such women. The calculation of the expected number of unwanted births was simply the product of the 12 -month failure probability and the percentage of those who wanted no more children. For all surveys combined, the failure rates for modern and traditional methods were $2.3 \%$ and $15.1 \%$, respectively, and the percentage wanting no more children was $76 \%$ among modern method users and $64 \%$ among traditional method users. The calculations in Figure 15.3 show that a non-user is 7.9 times $(13.5 \% / 1.7 \%)$ more likely than a modern method user to have an unwanted pregnancy in the next year.

Table 15.5 illustrates the calculation of the distribution of expected pregnancies in the next year, according to fertility intention. The righthand panel shows that among the modern method users, $1.7 \%$ will experience an "unwanted" failure, while $0.1 \%$ will have an "intended" failure. Among 100 non-users, 13.5 will have an unwanted pregnancy and there will be 9.6 intended pregnancies. The last row gives the

Table 15.5 Distribution of expected pregnancies estimated from contraceptive use by fertility intention (women 30-44, all surveys combined)

|  | Level of exposure: Contraceptive use (\%) | Fertility intention: ${ }^{\text {a }}$ want birth |  |  | Percentage of women expected to have intended, mistimed and unwanted pregnancies (within level of exposure |  |  |

expected pregnancies, weighted by the contraceptive distribution. In total, $21 \%$ of women aged $30-44$ years are expected to get pregnant at current levels of contraceptive use. According to prevailing fertility intentions, $10 \%$ of women will have an unwanted pregnancy.

### 3.5 Estimating pregnancy outcomes

This section refers to the second step in Figure 15.1, estimating unwanted births and unsafe abortions from unwanted and mistimed pregnancies.

## SPONTANEOUS PREGNANCY LOSS

Before applying abortion probabilities to unwanted and mistimed pregnancies, we allowed for miscarriages and stillbirths. Recognizable intrauterine mortality is lowest in the early twenties (16\%), but reaches double this rate by age 45 years (Bongaarts and Potter 1983). From these tabulated data we calculated the average spontaneous pregnancy loss as $17 \%$ and $27 \%$ for the younger and older women, respectively. Pregnancy loss does not vary by fertility intention, and the expected pregnancies in Table 15.5 need to be reduced by $27 \%$, leaving $15.3 \%$ of women aged 30-44 years pregnant. Thus after accounting for pregnancy loss, 7.2\% of women have an unwanted pregnancy and $3.4 \%$ have a mistimed pregnancy. A proportion of these will be aborted while the rest will result in a live birth.

## Abortion probabilities

Abortion probabilities have been derived by converting the WHO country estimates of incidence ratios (unsafe abortions per 100 live births) to abortion probabilities (ratio of abortions to abortions plus births). For countries without estimates $(n=10)$ we took the WHO
regional abortion estimate (WHO 1998). The average abortion incidence ratio of 17.5 abortions per 100 live births translates into an overall abortion probability per pregnancy of $0.15(=17.5 /(100+17.5))$. Because intended pregnancies are most unlikely to be aborted, this probability needs to be converted to relate to unintended pregnancies only, while keeping the overall abortion ratios constant.

The main reason stated by women for having an abortion is to stop bearing children; following this is the wish to postpone pregnancy (Bankole et al. 1999). Other reasons included disruption of education and the belief that they were too young to have children, especially in Africa where single women are sexually active, all adding to the postponement component of abortion. An in-depth study in Maharashtra, showed that $54 \%$ of aborted pregnancies among married women were defined as unwanted and $42 \%$ as mistimed at the time of conception (Ganatra et al. 2000). In three central Asian republics, the proportion of unwanted pregnancies that were aborted ranged from $74 \%$ to $86 \%$, while two-thirds of all mistimed pregnancies were aborted (Westoff et al. 1998).

Consistent with the limited evidence available, our calculations assumed that the abortion probability of a mistimed pregnancy was half that of an unwanted pregnancy. Though this assumption is essentially arbitrary, it is consistent with the judgements of experts. It can be regarded as reasonable but nevertheless must be viewed with caution.

The relative distribution of mistimed, unwanted and planned pregnancies expected for 100 women (at the current contraceptive prevalence and childbearing intentions) was used to relate abortions to mistimed and unwanted births only. Of the 15.3 pregnancies among $30-44$-year olds (after spontaneous pregnancy loss), 3.4 are expected to be mistimed and 7.2 unwanted. So the abortion probability of unintended pregnancies is calculated as $0.15 \times 15.3 /(7.2+3.4 / 2)=0.25$. This probability implies that one in four unwanted pregnancies will be aborted compared with one in eight of mistimed pregnancies. Although we started from the same incidence ratio for both age groups, the fact that only unintended pregnancies are aborted leads to different abortion probabilities for the two age groups. In the countries with high rates of unsafe abortion and lack of systematic data, we know little about how abortions vary by age. Where official statistics are more complete, there are generally two age patterns of abortion ratios (Bankole et al. 1999). The first takes a Ushape, where abortion is high both among unmarried young women and older women who have reached their desired family size. The second pattern is a steady increase in the abortion ratio with age. As default we have chosen to use the same ratio for both age groups. Where consistency checks indicated negative levels of unwanted births in the younger age group (Guinea, Indonesia and Thailand) or where data on age patterns were available (Kazakhstan, Kyrgyzstan, Uzbekistan) the ratio was adjusted by age. For countries that needed correction, the abortion prob-
ability of (any) pregnancy to women aged 30-44 years was assumed to be three times the probability for pregnancies to younger women (estimate based on the data provided for the latter three countries in the article by Bankole et al. 1999).

We have implicitly assumed that abortion probabilities of unwanted (and mistimed) pregnancies are the same regardless of whether they resulted from method failure or non-use. Common sense suggests that women who act on their intention to prevent an unwanted pregnancy by adoption of contraception are more determined to regulate fertility than other women and thus more likely to seek a termination when pregnant. Very limited empirical evidence on differential abortion probabilities supports this expectation. In Turkey, for instance, $28.5 \%$ of unintended pregnancies in 1998 resulting from non-use were aborted, compared with $38.1 \%$ and $35.2 \%$ of pregnancies resulting from modern and traditional method failure, respectively (Senlet et al. 2000). In Kazakhstan, $51 \%$ of unintended pregnancies among non-users were aborted compared with $67 \%$ of (all) contraceptive failures (Westoff 2000). The inferred differences are relatively small and their generalizability is unknown. Hence, it was decided to apply the same abortion probabilities for all three contraceptive use categories. Nevertheless, since the desire to discontinue childbearing altogether is highest among modern method users, our simulations did result in higher abortion probability for all modern method failures relative to traditional method failures and conceptions among non-users.

## Probability and relative risk of having an abortion

Abortion probabilities have been combined with expected proportions of women who have unwanted and mistimed pregnancies in each exposure category. Table 15.6 provides the worked example of the expected proportion of women aged 30-44 years (all surveys averaged) having an abortion. The expected percentages of women having pregnancies are $27 \%$ lower than in Table 15.5, since they are adjusted for spontaneous pregnancy loss.

The abortion probability of 0.25 for unwanted births results in an expected proportion of $3.1 \%$ of non-users having an abortion in the next

Table 15.6 Probability of having an abortion in each exposure category and the resulting relative risk ratios

|  | Expected \% of women having pregnancies |  |  | Expected \% of women having an abortion | $R R$ of having an abortion |
| :---: | :---: | :---: | :---: | :---: | :---: |
|  | Intended | Mistimed | Unwanted |  |  |
| Modern users | 0.1 | 0.3 | 1.3 | 0.4 | 1.0 |
| Traditional users | 1.2 | 2.8 | 7.1 | 2.2 | 6.0 |
| Non-users | 7.1 | 4.9 | 9.9 | 3.1 | 8.7 |

year $(0.25 \times 9.9 \%$ [unwanted pregnancies] $+0.25 / 2 \times 4.9 \%$ [mistimed pregnancies]). Following the same logic, only $0.4 \%$ of modern method users are expected to have an abortion. Using the modern method users as the reference category the relative risk was derived as the ratio of expected proportion of women having an abortion among non-users compared with modern method users ( $R R=8.7$ ). Similarly, traditional method users were projected to be six times more likely to have an abortion than modern method users.

Probabilities of women in each exposure category of HAVING AN UNWANTED BIRTH

The proportions of modern and traditional method users and of nonusers who are expected to deliver an unwanted birth were calculated by applying the complement of the abortion probability to the unwanted pregnancies. Mistimed pregnancies that end as live births do not contribute to the burden of maternal outcomes. The worked example in Table 15.7 shows that with an abortion probability of 0.25 , threequarters of the $9.9 \%$ of non-users with an unwanted pregnancy are expected to carry it to term. With $7.4 \%$ of non-users having an unwanted birth in the next year, compared with $0.9 \%$ of modern method users, the relative risk is 7.8 .

Since the WHO abortion estimates relate to unsafe abortions only (which is required for the calculation of relative risk to have an unsafe abortion), we have potentially overestimated the expected number of unwanted births in countries where legal abortions are common. This does not affect the relative risk of unwanted birth, but it does affect the proportion unwanted among all births. As can be seen from Table 15.1, most surveys were done in countries with highly restrictive abortion laws, and therefore most abortions will be unsafe. For the countries with available data on legal abortions (Henshaw et al. 1999), the proportions of unwanted births among all births were calculated using legal abortion rates. The legal abortion ratio was used for Turkey. For Bangladesh and India, the official legal rates are very low and are underestimates of actual procedures performed (Henshaw et al. 1999). In India, abortion

Table I5.7 Probability of having an unwanted birth in each exposure category and the resulting relative risk ratios

|  | Expected \% of women having <br> pregnancies |  |  | Expected \% of women <br> having an | RR of having <br> an unwanted <br> birth |
| :--- | :---: | :---: | :---: | :---: | :---: |
|  | Planned | Mistimed | Unwanted | Uirth |  |
| Modern users | 0.1 | 0.3 | 1.3 | 0.9 | 1.0 |
| Traditional users | 1.2 | 2.8 | 7.1 | 5.3 | 5.6 |
| Non-users | 7.1 | 4.9 | 9.9 | 7.4 | 7.8 |

has been legal for 30 years, but abortion services by authorized facilities are inadequate, especially in rural areas. Many women are even not aware that abortion is legal and resort to abortions from both unskilled and skilled providers (Ganatra et al. 2000). In Bangladesh, with highly restrictive abortion laws, the legal rate refers to menstrual regulation services (manual aspiration evacuation of the uterus without prior confirmation of pregnancy). They are widely available, effectively providing abortion up to eight weeks of a woman's last menstrual period (Rahman et al. 1998). For India and Bangladesh we used the WHO estimates on unsafe abortions.

### 3.6 CONSISTENCY CHECKS

Two basic consistency checks guided the assessment of the plausibility of the data inputs and the method assumptions, and informed the adjustments done for a few individual countries. We compared both the total numbers of projected births and the proportion of unwanted births among all births with retrospective estimates based on the question "At the time you became pregnant with (NAME OF CHILD) did you want to become pregnant then, did you want to wait until later or did you want no more children at all?" Age-specific fertility rates published by DHS allowed the calculation of the yearly number of births in each age group. These rates were averaged for a period of three or five years prior to survey data in order to reduce sampling error. The number of recent births per year should agree with our expected number of births per 1000 women in each age group, after adjusting for the proportions of women who never had sex. Exact matches for each survey are not expected, but systematic patterns of excess or shortfall of births may imply regional biases.

Compared with the current births calculated from the age-specific fertility rates, the projection using age-based fecundability estimates (averaging the outcomes for all surveys) results in a $15 \%$ shortfall of expected births for the younger age group, and $2 \%$ excess for the older age group. What may contribute to the underestimation of expected births? A minor factor may be that we discount miscarriages and stillbirths before calculating abortions. Since some of the aborted pregnancies might have resulted in a spontaneous intrauterine death, we may have underestimated the pregnancies carried to term. A second factor may be abortion probabilities that are too high. While this is unlikely overall, the assumption of constant incidence ratios by age may contribute to the shortfall of expected births in the youngest age group. Continuing fertility decline would also contribute to the discrepancy between projected and retrospective fertility levels. Finally, underreporting of sexual exposure (both overstating virginity and time since last sex) may well be a major cause of the deficit of births to young women.

It should be pointed out that in terms of estimating the relative risk ratios of having an unwanted birth or an abortion, overall numbers of
births are less important than the relative distribution of births across fertility intention. As we indicated before, frequency of sexual intercourse is not the same for women who want a birth soon and those who either want to space or stop childbearing. Moreover, there is no reason to doubt the validity of these relative differences. This is an important factor contributing to the uncertainty around the estimates (discussed later).

This leads us into the second consistency check, the comparison of projected and retrospective estimates of the proportion of births that are unwanted. Compared with the proportion of the most recent births that were reported as unwanted, serious discrepancy was apparent with projected proportions of unwanted births: they were $63 \%$ and $143 \%$ higher for the $15-29$-year olds and the $30-44$-year olds, respectively. We discuss below potential biases that may account for the discrepancy.

The proportion unwanted among most recent births is available if this birth occurred within the last five, or in some surveys, three years. It is derived from the question "At the time you became pregnant with (NAME OF CHILD), did you want to have more children then, did you want to wait until later, or did you want no more children?" The question is meant to draw on the memory of the feelings that were held at the time of conception. Though little evidence exists to evaluate to what extent respondents later report as being wanted those children whose conception was initially unwanted, the most important reason why the "wantedness" of the most recent birth may not agree with our projected number of unwanted births is undoubtedly ex-post rationalization (Bongaarts 1990; Westoff 1981). Panel data in Morocco allowed the comparison of reports on the "wantedness" of 0-2-year-old children in 1992 with reports on the same births three years later (Westoff and Bankole 1998). Whereas $6 \%$ of children reported in 1992 as wanted at the time of conception were later described as unwanted, as many as $62 \%$ of the unwanted pregnancies in the first round were reported as wanted in 1995. The older the child, the more likely reports on the feelings or intentions had changed from unwanted to wanted. A comparison among five DHS confirms the result from Morocco. The percentage unwanted declines as the age of children increased, though the trend was less pronounced than in the Morocco data (Montgomery et al. 1997). Data on change in perception before and after a baby is born are not available. However, in a recent qualitative study in the United Kingdom of Great Britain and Northern Ireland among pregnant women and those who recently aborted, women generally agreed that conceptions which were initially "unplanned" or "unintended" could become "wanted", a term many women associated with the decision to carry the pregnancy to term (Barrett and Wellings 2002). Since we do not know how these concepts are translated and understood by different cultures, the magnitude of the rationalization bias cannot be quantified.

An additional explanation is that the most recent birth refers to a child of lower birth order than the projected next birth. Calculating orderspecific estimates on the "wantedness" of the last child and applying these to the birth order distribution shifted by one child allows assessment of the magnitude of this order effect on fertility preferences. The average effect is surprisingly low: $9 \%$ of women aged $<30$ years report their most recent birth as being unwanted, while this would be raised to only $11 \%$ by shifting the order by one child. For the older women the effect was equally small.

A last potential factor contributing to the discrepancy might be the underestimation of the proportion of unwanted pregnancies that are terminated. By considering unsafe abortions, rather than all abortions, we may have overestimated the expected unwanted pregnancies carried to term. When the relative abortion probability of unwanted over mistimed pregnancies is lower than two, then we could again overestimate the number of unwanted births.

Given the considerable differences between the various measures of preferred fertility and the known bias in underreporting of unwanted births (Bongaarts 1990; Westoff 1981), we have to tolerate a level of inconsistency between projected and retrospective estimates of "wantedness". Important biases other than our model assumptions are operating and this precludes the use of the extent of discrepancy as a guide to make adjustments. Nevertheless, for selected countries with available data on legal rates and age pattern of abortion, adjustments were done (as explained above). We have been guided more by disparity between the age groups, than any discrepancy in expected level of fertility. While the abortion adjustments do not affect relative risk ratios, they do lower the proportion of unwanted among all births, which is used in projecting how much of the obstetric burden can be avoided by reducing unwanted births.

### 3.7 Counterfactual scenario

## Counterfactual distribution of Contraceptive use

The burden of maternal outcomes, including abortion, attributable to lack of effective modern contraception was calculated as the reduction in current burden that would be observed if levels of exposure were reduced to a counterfactual distribution of contraceptive use. Theoreti-cal-minimum-risk distribution of contraception does not mean $100 \%$ modern use, but rather that all women with a desire to either stop or postpone childbearing for at least another two years, adopt an effective modern method of contraception. Perfect implementation of fertility preferences among limiters and spacers obviously results in a higher proportion of modern method users and fewer women using traditional contraception or no contraception at all. All traditional method users and fecund non-users now consist of women who want a birth in the next
two years. This theoretical minimum level of exposure was thus simply calculated by shifting all spacers and limiters into modern method use.

The potential impact fractions were used to estimate the proportional reduction in the total number of unwanted births and unsafe abortions by a change in contraceptive prevalence. Potential impact fractions generally assume that only exposure changes, while the relative risk of the outcome for each level of exposure stays the same. However, as we demonstrated in the previous section, the relative risk of an abortion (or unwanted birth) among the traditional method users not only depends on the failure rates, but also on the fertility preference among these users. The factors determining the relative risk among non-users are conception rates, fertility preferences and the proportion fecund among the nonusers. While both the failure and conception rates remain constant, the relative fertility preferences in each exposure category and the proportion of women who are fecund among non-users will change with a change in contraceptive distribution.

## Counterfactual relative risk ratios

How do we expect the relative risk to vary with a change in exposure? Under the scenario of theoretical-minimum-risk, all women with a desire to stop or space childbearing will adopt modern methods and all expected conceptions in traditional method users and non-users will now be intended pregnancies. Because only the reference group (modern users) is at risk of an unintended pregnancy, the relative risk of unwanted births and abortions will be 0 in other groups. For intermediate levels of shifting the counterfactual relative risk will be between 0 and the current level of relative risk.

In deriving these counterfactual levels of relative risk, the degree of shifting was assumed to be the same for spacers and limiters. The calculation involved computing counterfactual proportions of fecundable women among the non-users, and counterfactual fertility preferences in all three categories of exposure.

For each level of shifting, the counterfactual distribution of contraceptive use was determined by subtracting the number of women using traditional methods and no contraception at all and adding that to those using modern methods. The distribution of non-users was recalculated by keeping the number of infecund/menopausal women and those that were not sexually active in the past year constant; the number of fecundable women changed by subtracting the number of limiters and spacers who shifted to using modern methods; the number of pregnant and amenorrhoeic women changed since more effective contraception implies a reduction in the number of births, with at any one time a smaller proportion of women pregnant or in the amenorrhoeic state. Through a process of iteration we imputed the ratio of births in the counterfactual over current population and assumed that the number of pregnant and amenorrhoeic change to the same extent. These numbers were combined
in the counterfactual proportion of fecund women among non-users. The counterfactual distribution of fertility desires among the three categories of exposure was calculated taking account of the level of shifting and counterfactual proportion of fecundity among the non-users. Table 15.8 compares current with counterfactual exposure and fertility intentions, calculated for women aged 30-44 years, all countries combined, assuming $50 \%$ shifting.

These counterfactual contraceptive distributions, fertility desires and proportion fecund among non-users were then combined to obtain relative risks in the same way as explained in the previous section for the "current" relative risk levels. Table 15.9 contrasts the counterfactual relative risk for the same scenario of $50 \%$ shifting, among women aged $15-29$ years and 30-44 years, with the relative risk levels under current exposure.

The relative risks among non-users initially decline faster with the degree of shifting, compared with levels among traditional method users. When half of all non-users and traditional users who currently have an unmet need for spacing or limiting have adopted a modern method, the relative risk for a non-user to have an unwanted birth has decreased from 7.8 to 5.0. The relative risk for traditional users drops to a lesser extent (from 5.6 to 5.2 ). The steeper decline among the non-users can be explained mainly by the fact that the infecund, the menopausal and the sexually inactive women gradually become a larger proportion of all non-users. The pattern of the counterfactual relative risk levels by degree of shifting varies across countries. The average pattern (for all surveys combined, women aged 30-44 years) shows the most common pattern as depicted in Figures 15.4 and 15.5 of a near-linear decline for

Table 15.8 Current and counterfactual contraceptive distribution and fertility preferences among women aged 30-44 years, all surveys combined

|  | Current exposure and intention |  |  |  |
| :---: | :---: | :---: | :---: | :---: |
|  | Contraceptive use | Want birth soon | Want to space | Want to limit |
| Modern | 28.2 | 0.05 | 0.18 | 0.76 |
| Traditional | 8.1 | 0.11 | 0.25 | 0.64 |
| Non-use ${ }^{\text {a }}$ | 63.8 | 0.32 | 0.22 | 0.46 |
| Counterfactual exposure and intention (50\% shifting) |  |  |  |  |
| Modern | 37.4 | 0.04 | 0.22 | 0.74 |
| Traditional | 4.6 | 0.20 | 0.22 | 0.58 |
| Non-use ${ }^{\text {a }}$ | 58.1 | 0.49 | 0.17 | 0.34 |

[^58]Table I5.9 Relative risk ratios for unsafe abortions and unwanted births under current and counterfactual exposure, both age groups, all surveys combined

|  | RR under current exposure | $R R$ under counterfactual exposure <br> assuming $50 \%$ |  |  |
| :--- | :---: | :---: | :---: | :---: |
| Abortions | $15-29$ years | $30-44$ years | $15-29$ years | $30-44$ years |
| Modern | 1.0 | 1.0 | 1.0 | 1.0 |
| Traditional | 3.8 | 6.0 | 3.2 | 5.4 |
| Non-use | 6.2 | 8.7 | 3.8 | 5.4 |
| Unwanted birth |  |  |  |  |
| Modern | 1.0 | 1.0 | 1.0 | 1.0 |
| Traditional | 2.9 | 7.6 | 2.7 | 5.2 |
| Non-use | 4.5 |  | 3.1 | 5.0 |

Figure 15.4 Pattern of change in relative risk of an unwanted birth by level of switching for traditional method users, women aged 30-44 years

non-users, while the relative risks for traditional method users tend to stay relatively constant up to $50-60 \%$ shifting, declining rapidly to 0 thereafter.

For traditional use the relative risk of unwanted births and abortions sometimes increases initially at lower levels of shifting. This seems to happen when more spacers than limiters move into the modern method users, which has little effect on the distribution of fertility preferences among the traditional users, but affects the expected proportion of modern users who will be having relatively more "mistimed failures"

Figure I5.5 Pattern of change in relative risk of an unwanted birth by level of switching for non-users, women aged 30-44 years

rather than "unwanted failures". Thus the expected proportion of modern method users having unwanted births actually decreases slightly. Since the expected proportion of unwanted births among the non-users changes much faster, this pattern of an initial relative risk rise is not detected so much among the non-users.

### 3.8 Aggregating country-specific estimates into subregions

The country level results in terms of contraceptive exposure, relative risks of unsafe abortions and unwanted births were aggregated into subregional averages, weighting each country according to the size of the population (see Table 15.1 for weighting factors). The derived estimate was then taken as subregional average, assuming that the countries were reasonably representative of the whole subregion. Table 15.10 presents the coverage of subregional population by countries with data.

As can be seen from the subregional coverage presented in Table 15.10, the African, Latin American and some of the Asian subregions are well represented. The three subregions where relevant data are totally lacking are AMR-A, EUR-A and WPR-A, which mainly consist of industrialized low-fertility countries with small burdens of maternal mortality or unsafe abortion. The exposure distributions for these subregions were imputed from data provided in the United Nations (UN) report on levels and trends in contraceptive use (UN 1999). As the UN data were for married women aged 15-49 years, we assumed $90 \%$ of total estimate for the age group 15-29 years and $110 \%$ of estimate for 30-44year olds. Since safe abortion is widely available in most of these countries, the relative risk levels were arbitrarily set at 1.5 for unwanted births (both for traditional users and non-users). For abortion we took relative

Table 15.10 Coverage of subregional population by countries with data from DHS

| Subregion | Number of DHS per <br> subregion | Percentage of the subregional population <br> covered by countries with DHS data |
| :--- | :---: | :---: |
| AFR-D | 9 | 80 |
| AFR-E | 14 | 69 |
| AMR-A | 0 | 0 |
| AMR-B | 6 | 79 |
| AMR-D | 6 | 100 |
| EMR-B | 1 | 8 |
| EMR-D | 5 | 85 |
| EUR-A | 0 | 0 |
| EUR-B | 3 | 46 |
| EUR-C | 1 | 7 |
| SEAR-B | 3 | 100 |
| SEAR-D | 3 | 93 |
| WPR-A | 0 | 0 |
| WPR-B | 1 | 5 |

risks of 2 and 3, respectively, for traditional method users and non-users. It matters little what the real risks are since the burden of obstetric and abortion complications is negligible. Subregions that are cause for greater concern are EMR-B, EUR-C and WPR-B. Tunisia is the only country representing EMR-B and Kazakhstan the only one in EUR-C. Most worrying is that WPR-B, a subregion in which $83.5 \%$ of the population live in China, is represented solely by the Philippines. In China, because of the strict anti-natal policies, there will be very few unwanted births and most abortions are legal and safe. Therefore an adjustment was needed for WPR-B, which is discussed in the next section on deriving attributable burden.

### 3.9 Subregional estimates of input parameters

The inputs provided for calculating the attributable burden are the contraceptive distributions and relative risks under the current situation and counterfactual (theoretical minimum) scenario, and the proportion of all births that are unwanted.

We first estimated the proportions of women who were excluded from the analysis because they never had sex and were therefore not exposed to the possibility of pregnancies (i.e. virgins). Table 15.11 gives the proportion of the female population that is presumed to be virgins. Our method overestimates virginity in two ways. In the countries with evermarried samples, single women do not enter the analysis and are assumed to be virgins. Clearly, this assumption is not entirely valid. In the other

Table I5.II Average proportion of women who are virgins, by subregion

| Subregion | $15-29$ years | $30-44$ years |
| :--- | :---: | :---: |
| AFR-D | 23.6 | 0.5 |
| AFR-E | 26.1 | 0.5 |
| AMR-A | 15.0 | 1.5 |
| AMR-B | 39.4 | 4.1 |
| AMR-D | 43.0 | 3.7 |
| EMR-B | 65.1 | 7.4 |
| EMR-D | 48.8 | 4.2 |
| EUR-A | 15.0 | 1.5 |
| EUR-B | 46.5 | 3.1 |
| EUR-C | 42.1 | 2.1 |
| SEAR-B | 45.8 | 5.6 |
| SEAR-D | 27.6 | 1.2 |
| WPR-A | 15.0 | 1.5 |
| WPR-B | 59.8 | 8.7 |

countries virginity may be overstated to the extent that single women underreport sexual activity. The estimates for the three subregions where we lacked data, AMR-A, EUR-A and WPR-A, were informed by data from the British Sex Survey in 1990/91 (Johnson et al. 1994).

Current contraceptive use, averaged for each subregion, is shown in Table 15.12 and the counterfactual scenario in Table 15.13. The second table thus provides the contraceptive status that would have been observed if all women with a current need for spacing and limiting were to adopt a modern method. Note that a small residue of traditional method users remains; these are women who want a child within the next two years. The subregional variation in current contraceptive use is thus explained by variations in desired family size and extent of implementation of these desires through contraception (and abortion). Subregional variations in counterfactual contraceptive use reflect differences in desired family sizes and use of abortion as alternative means to implement fertility intentions.

Tables 15.14 and 15.15 show the relative risk estimates for having an unwanted birth and an unsafe abortion, respectively, under the current regime of contraceptive practice and fertility preferences. The levels for the counterfactual minimum risk have not been provided since they are all 0 , as explained earlier. As can be seen, there is wide subregional variation in relative risks, both for traditional method users and nonusers. The subregion that stands out is SEAR-D, where India represents a large part of the population. Modern contraception in India (and

Nepal) is dominated by sterilization, which has a very low failure rate. As very few modern method users become pregnant, the relative risks for the other two categories are raised. This observation has complicated the interpretation of the counterfactual relative risks for abortions, as one of our model assumptions has obviously been violated. Keeping failure rates and contraceptive method mix constant with an increase in contraceptive prevalence has become internally inconsistent with the fertility preferences. Where sterilization is the dominant modern contraceptive method, it is impossible to accommodate the needs of spacers at the current method mix. Increased contraceptive use among spacers in such settings would have to involve uptake of reversible methods but this trend would reduce the average effectiveness of modern method use, because reversible methods have higher failure rates than sterilization. And this, in turn, would reduce the relative risk of an abortion for traditional method users and non-users. The attributable fractions derived from these relative risks of unsafe abortions for these countries with high use of sterilization will thus be a slight overestimate. However, since spacers do not contribute to unwanted births, the relative risks for unwanted births remain unaffected. Only when limiters adopt methods other than sterilization, as method choice widens, would the relative risks for unwanted births be affected.

## 4. Attributable burden

By combining the relative risk values for an unsafe abortion (Table 15.15) with the data on current and counterfactual distributions of contraceptive use (Table 15.12 and Table 15.13), we have derived the attributable fractions for unsafe abortions (Table 15.16). These estimates show that a very large proportion of the disease burden due to abortion complications is attributable to unprotected sex or use of less effective traditional methods. The residual is the "unavoidable" burden associated with modern method failure.

Table 15.17 gives the estimated burden of disease attributable to unsafe abortions by subregion. Both deaths and total DALYs have been presented as well as the relative burden in each subregion, expressed as DALYs per 1000 women, to allow better comparison between the subregions. The estimated burden of abortion attributable to non-use and use of ineffective methods of contraception is 4.4 million DALYs, with $82 \%$ of the burden falling on women aged $<30$ years. South Asia with its large population (SEAR-D) has the highest abortion burden at about $35 \%$ of the total abortion burden in both age groups. Although AFR-D and AFR-E include smaller populations than SEAR-D, women in these subregions have the highest relative burden.

The calculation of attributable burden for unwanted births is slightly more complicated. The attributable fraction for unwanted births could not be applied to the total burden of obstetric complications in

childbirth, since the many wanted births also contribute to maternal deaths and morbidity. We thus had to restrict the burden to that proportion of all births that was unwanted as simulated from contraceptive failure, conception rates and fertility preferences. These proportions are presented in Table 15.18, together with the unadjusted attributable fractions. These fractions express what proportion of unwanted births can be avoided by perfect implementation of fertility preferences. The proportion of unwanted among all births is much higher for the older age group, as the desire to limit family size is much more prevalent than among younger women. The negative values for women aged 15-29 years in EUR-C and SEAR-B reflect the fact that the abortion probabilities assumed for these women were probably still too high. In calculations the proportion was set to 0 , and in the subregions concerned we may have slightly underestimated the burden of maternal complications in childbirth for the younger age group while overestimating it for older women. Finally, these proportions have been combined with the unadjusted attributable fractions (unwanted births only), to give the attributable fractions of all births that could be averted if all women who wish to stop childbearing used a modern method.

As mentioned earlier, the estimate for WPR-B needed adjusting since China, with very low rates of unwanted births, dominates the subregion. The easiest adjustment procedure was to keep the relative risk and contraceptive prevalence estimates for the Philippines, and adjust the

proportion of all births that are unwanted. The whole subregion has an average total fertility rate (TFR) of 2, and we can therefore calculate that $75 \%$ of the subregional births occur in China (with a TFR of 1.8), all of them assumed as wanted. Of course, this assumption cannot be totally correct nor can it be verified, but it is likely to be a close approximation to the truth because of the strict birth control policies that have been applied in China since 1979.

The burden of disease attributable to unwanted births totals 4.6 million DALYs (see Table 15.19). In contrast to abortion, the largest part of the burden befalls women aged $>30$ years ( $75 \%$ ). It is again the same subregions that are most affected, with those in Africa having the highest relative burden.

## 5. Sources of uncertainty

The calculation of aggregate level attributable fractions inevitably involves numerous uncertainties. One of the most serious concerns is the limited availability of data and the need to extrapolate results for a few countries to an entire subregion. Others relate to the quality of the input data, and to the method for simulating the expected numbers of
Table I5.19 Estimated burden of disease attributable to unwanted births (due to non-use of contraception), by subregion and age

unwanted births and unsafe abortions. Finally, the counterfactual estimates involved further assumptions.

While it was not possible, with one exception, to quantify the magnitude of the effect caused by the nature of the empirical data and assumptions, we can predict the direction in which they operate: whether they lead to an overestimation or an underestimation of the burden of maternal ill-health attributable to lack of effective contraceptive use. We have briefly reviewed the most important uncertainties and their likely effect on our estimates of relative risk and attributable fractions.

### 5.1 Robustness of data

## CURRENT CONTRACEPTIVE USE

Survey data on current contraceptive use have been routinely collected by means of national surveys for 30 years. Their quality is considered high. Trends over time are plausible and the relationship between contraceptive prevalence and fertility rates is strong. Measurement error, where it exists, is likely to take the form of underreporting. In some societies, clandestine use by women occurs (Biddlecom and Fapohunda 1998; Castle et al. 1999) and this is likely to be concealed in conventional surveys. Moreover, some evidence exists to suggest that women underreport male methods, such as condoms, because of shyness and embarrassment (Koenig et al. 1984). Thus some users may be misclassified as non-users, and exposure may be slightly overestimated. The effect on relative risk estimates of such errors will be in the direction of underestimation but is likely to be small compared with other errors.

## Contraceptive failure rates

Contraceptive failure rates were derived from enquiries of 18 DHS where detailed month-by-month information on contraceptive use episodes had been collected. Although this data source is undoubtedly the most appropriate, two types of uncertainty apply: the accuracy of the information and their representativeness. With regard to accuracy, the estimates (Table 15.2) are in general consistent with evidence from more carefully controlled prospective studies, with the exception of the condom where rates were lower than expected (Trussell 1998). However condoms are not a common method of contraception in most developing countries and any error is of minor significance. There are also doubts about representativeness. Calendar data are collected only in countries with high prevalence of use but the average results have been applied to all 58 countries. The validity of the underlying assumption-that failure rates are unrelated to overall levels of use-is unknown, but, again, the error is unlikely to be serious.

## Induced abortion

In countries where abortion is illegal, or highly restricted and heavily stigmatized, it is impossible to obtain reliable information on incidence by means of conventional direct questioning. Hence, in this chapter, we have had to rely on WHO's indirect estimates of unsafe abortion (WHO 1998). While these estimates are widely accepted and cited at global level, a very considerable band of uncertainty surrounds them. However, no means exist of assessing the possible magnitude, or even direction, of error. In a few countries, the number of legal terminations could be taken into account when estimating the projected number of unwanted births. In yet other countries, legal terminations are carried out but no information was available on their number and therefore no allowance could be made. This gap in data leads to an overestimate of relative risks of unwanted births.

## FERTILITY PREFERENCES

The method used to derive attributable and avoidable burden of disease depends heavily on women's statements about their future fertility desires or intentions. While experts agree that this way of measuring preferences is the least problematic of the several alternatives, interpretation is far from straightforward. For instance, attitudes toward future childbearing may be weakly held and ambivalent. Moreover, the attitude of the spouse, or male partner, is not taken into account. These considerations may partly explain why projected estimates of unwanted and mistimed pregnancies based on the pair of questions "Would you like to have a/another child or would you prefer not to have (more) children?" and "How long would you like to wait from now before the birth of a/another child?" are much larger than retrospective estimates of the "wantedness" of recent births and current pregnancies. While there is good reason-and some empirical evidence-to believe that the retrospective estimates are biased downwards by post facto rationalization, the size of the discrepancy between the prospective and retrospective estimates ( $63 \%$ and $143 \%$ for younger and older age groups, respectively) is a matter of concern. The direction of potential bias is clear. To the extent that preferences for future childbearing do not translate into unwanted and mistimed pregnancies, we will have overestimated relative risks as well as exposure.

## SEXUAL EXPOSURE

The method of estimating attributable burden involved the exclusion of virgins from the calculations and the classification of women who report no sexual intercourse in the past 12 months as behaviourally not at risk of pregnancy. In countries with a strong traditional emphasis on pre-marital chastity for women, it is to be expected that single women will underreport sexual activity, which would lead to an underestimate
of expected birth among non-users, thereby underestimating relative risks.

In countries where DHS field staff interviewed ever-married women only, the single women were implicitly categorized as virgins. Countries with no data on single women are typically those where it would be socially unacceptable to ask young unmarried women about sex and reproduction. Although levels of sexual activity will no doubt be low in these countries, the resulting pregnancies are very likely to be unwanted. Most of them will be terminated, often clandestinely and thus most probably "unsafe". Insofar that the WHO estimates on unsafe abortion include procedures to unmarried girls (as estimates are based to a large extent on hospital admissions for abortion complications), these abortions have been attributed to the married women. However, since the exposure for single women is more skewed towards non-users we will have underestimated the attributable burden.

## FECUNDABILITY

A major dilemma arose in the estimation of projected pregnancies among non-users of contraception. We had to choose biological estimates of the monthly probability of conceiving based on woman's age or on reported coital frequency. The reason for preferring age-based estimates was that they gave a closer fit between expected overall births and observed births in the recent past. The deficit in births was much bigger when estimates of fecundability were based on coital frequency, with expected births $39 \%$ and $11 \%$ lower than recent observed births for the 15-29 and 30-44 group, respectively. At low levels of intercourse, the impact of frequency of intercourse on fecundability is substantial with coitus-based conception rates well below the age-based rates, as shown in Table 15.4. The large shortfall in expected births compared with recent age-specific fertility does cast doubt on the reliability of sexual activity data, which appear to be too low to explain current fertility. Brown (2000) in his comparative study in Africa used the same Bongaarts and Potter model estimates of coitus-dependent fecundability with reported coital frequencies in the last month, and came to the same conclusion. However, in defence of the data he has shown good internal consistency between reported monthly frequency and time since last sex. Of course, at low frequencies, sex could be targeted to coincide with ovulation, increasing the probability of a pregnancy, although this would only affect women who desire a pregnancy soon and who are knowledgeable about the timing of ovulation.

The use of fecundability based on reported coital frequency would make a substantial difference to relative risks, reducing them by about a quarter. The relative risk of having an abortion for non-users would decrease from 8.7 to 6.7 , while the relative risk of an unwanted birth would decrease from 7.8 to 5.7 . This is explained by the fact women aged $30-44$ years who say they want to have no more children have less
sex (two times a month) than those who want to space (three times) or those who desire a child within the next two years (3.9 times).

Whereas coital frequency among contraceptive users also varies with fertility intention, failure rates were kept constant regardless of preference. For modern methods, the most important determinant of failure is imperfect use. However, among perfect users, frequency of intercourse is the most important characteristic determining method failure (Trussell 1995). Traditional method failure is likely to be more dependent on coital frequency. This assumption, though far less important than the choice of age-based rather than coitally-based estimates of fecundability for non-users, will act to bias relative risks upwardly.

### 5.2 Assumptions in the basic model

In addition to concerns about the robustness of the empirical data, we had to make several assumptions in the basic model that links exposure to outcomes. The most important of these were:

- The burden is limited to direct obstetric events.
- Obstetric morbidity and mortality are the same for wanted and unwanted births.
- Abortion probabilities are zero for those who want another child in the next two years and are twice as high for limiters than spacers; probabilities are not affected by the proximate cause (failure vs nonuse) and are the same for the two age groups.

## Choice of outcomes

The crucial dilemma in defining the burden was whether or not to include perinatal mortality, much of which stems from unwanted pregnancies. Expert opinion was divided. The final decision to exclude perinatal mortality was based on the judgement that its inclusion would open up a Pandora's box of other intergenerational effects, going well beyond the perinatal period into infancy and childhood. Beyond the mortality of the unwanted children, short interbirth intervals are known to be a major risk factor for infant mortality and can be prevented by contraceptive use to cause better child spacing.

## Obstetric burden is the same for wanted and unwanted births

The evidence base for judging whether the obstetric burden is the same for wanted and unwanted birth was meagre. To the extent that unwanted births are concentrated among older women of low socioeconomic status, it would have been justifiable to assume a higher risk. However, because births at late maternal ages constitute a small fraction of all births and because the link between socioeconomic status and unwanted childbearing varies between subregions, it was decided, by default, to
assume no difference. The effect of errors in this assumption would be to raise relative risks and the attributable burden.

## Abortion probabilities

Several potential biases stem from assumptions that had to be made about the distribution of abortions by age group and exposure status. We made the simplifying assumption that no pregnancies occurring to women who report the desire for a child in the next two years are aborted. Because life circumstances change, this is no more than a close approximation to the truth and a small upward bias on relative risks is possible. A more important possible form of bias operating in the same direction is the assumption that abortion probabilities for unintended pregnancies are the same for non-users and for users who experience contraceptive failure. The available empirical evidence on this matter was insufficient to propose differing probabilities but it is nevertheless likely that modern method users do have a greater propensity to seek terminations than traditional method users and non-users, in which case relative risks would be overestimated. This bias may be offset to the extent that modern method users are more likely than others to seek safe abortions rather than unsafe, illicit abortions.

A bias operating in the opposite direction arises from the assumption that women who experience an unintended pregnancy when they want no more children are twice as likely to seek an abortion than those who wish to postpone the next pregnancy. Such a differential accords with common sense, at least for married women, and is consistent with the available shreds of evidence, but the size of the assumed difference is essentially arbitrary and may be too high. Because modern method users contain a disproportionately large number of limiters, relative risks may be underestimated.

The age pattern of abortion is known to vary between countries as a reflection of large differences in the proportion of young single women who are exposed to the risk of unintended pregnancy and differences in age at marriage. The simplifying assumption that abortion probabilities were constant by age may have led to an overestimation of abortion in the younger age group and an underestimation among older women. This will not affect the relative risks of unsafe abortion or unwanted birth by contraceptive use status but for the younger age group we may have underestimated the proportion of all births that are unwanted and thus the burden of obstetric complications.

### 5.3 Summary of uncertainty

Table 15.20 attempts to summarize in a necessarily crude manner the possible magnitude and direction of data defects and model assumptions on relative risks. A positive symbol (+) indicates that the effect may be to bias risks upwardly and a negative symbol (-) the opposite. A zero

Table I5.20 Possible effects of data limitations and assumptions on relative risks

|  | RRs <br> Abortion | RRs <br> Unwanted births |
| :--- | :---: | :---: |
| Robustness of empirical data |  |  |
| - Contraceptive use | - | - |
| - Failure rates | - | - |
| - Induced abortion | 0 | + |
| - Fertility preferences | +++ | +++ |
| - Sexual exposure | -- | -- |
| - Fecundability | ++ | +++ |
| Assumptions in the model | 0 |  |
| - Definition of burden | -- | 0 |
| - Obstetric burden is same for unwanted and wanted births | -- |  |
| - Abortion probabilities | - |  |
| - No abortions among those who want birth soon | ++ | 0 |
| - Same for failure and non-use | -- | 0 |
| - Twice as high for limiters than spacers | 0 | 0 |
| - No age pattern | 0 |  |

(0) denotes that the direction of the uncertainty, or possible bias, cannot be established. The number of symbols represents our judgement on the magnitude of the possible bias. As may be seen, positive biases are broadly balanced by negative biases.

Quantifying a range around our estimates is not an easy task, and beyond the scope of this exercise. Varying fecundability by fertility desire alone could lead to a $25 \%$ reduction in relative risk levels. Allowing for other biases that work in the same direction we may set $25 \%$ as a minimum range of uncertainty around the estimates at country level. The extrapolation to subregional level may well introduce the biggest cause of uncertainty. Given these inherent limitations in the data and in the complexity of the various assumptions adopted to apply the methodology, the subregional estimates presented are approximate and reflect actual disease burden in general terms.

## 6. Discussion of attributable burden

The calculation of the burden of disease attributable to non-use of modern contraception methods has required a long and complicated series of steps, mainly arising from the fact that exposure has two dimensions: a behavioural one (use or non-use of contraception) and an attitudinal one (the desire to avoid or delay childbearing). Despite the inevitable degree of uncertainty surrounding estimates, some stemming
from inadequacies of empirical evidence and others from necessary assumptions, the key results make good intuitive sense and certainly provide a reliable basis for setting priorities at global and regional levels.

It is estimated that about 57000 women die each year and that 4.9 million healthy life years (measured in DALYs) are lost because of abortions. Globally, about $90 \%$ of this burden is attributable to non-use of modern contraception. Regional differences in the attributable burden are strikingly large. In east and southern Africa (AFR-E), the estimated annual attributable burden exceeds 18500 DALYs per 1000 women aged 15-29 years, and is also high in West Africa, South Asia and some Middle Eastern countries (AFR-D, SEAR-D and EMR-D). By comparison, it is under 40 per 1000 women aged 15-29 years in the industrialized low-fertility subregions AMR-A, EUR-A and WPR-A. Of course, one reason stems from differences in exposure: variations in the propensity of women who want to delay or avoid pregnancy to use modern contraception. But the more important reason concerns differences in access to legal and safe abortion services. Regions with high attributable burden of abortion-related mortality and morbidity are characterized by restrictive abortion laws, and vice versa. From a public health perspective, both issues (low contraception access and use and restrictive abortions) have important policy implications.

The magnitude of abortion-related mortality and morbidity is dwarfed by the obstetric burden stemming from complications of pregnancy and childbirth. It is estimated that about 415000 women die each year from obstetric causes and that about 25 million healthy life years (measured in DALYs) are lost to these conditions. However, only a minority of these pregnancies are unwanted and hence the proportion of this overall disease burden attributable to non-use of modern methods is much lower than for the abortion-related burden: 7\% among younger women rising to $40 \%$ in older women, among whom the desire to avoid all further childbearing is much more common. For both age groups combined, the estimates suggest that 98000 obstetric deaths, representing nearly $20 \%$ of all such deaths, could be prevented each year if all women who desire no more children were to use modern contraceptives. The attributable burden is thus appreciably larger than the attributable abortion-related burden. Huge subregional differences are again apparent. In five subregions (AFR-D, AFR-E, AMR-D, EMR-D and SEAR-D) over 10000 healthy life years are lost per year per 1000 women aged $30-44$ years. The equivalent figure for the industrialized subregions (AMR-A, EUR-A and WPR-A) is below 20. In addition to access to and the use of modern contraception, these stark contrasts stem largely from variations in the coverage and quality of obstetric services.

## 7. Avoidable burden

There is little time lag between a change in contraception and the effect on burden of maternal complications. Current abortions and unwanted births are due primarily to non-use of contraception in the previous year. Thus, determining avoidable risk is very much like calculating attributable risk, but for "exposure in the future". Since fertility in today's medium- and high-fertility subregions is expected to drop in the future, the risk for each woman of death from an obstetric complication is also expected to decrease. However, the total burden of abortion-related complications and maternal outcomes may continue to increase in the next three decades, because the absolute number of women of reproductive age and the total number of births will continue to increase in the highfertility subregions with the highest burden of maternal mortality.

In calculating counterfactual scenarios and attributable burden, the level of obstetric care and the quality of abortion services available were assumed to remain constant at current levels. Only the numbers of unwanted births and abortions determine the potential decrease in burden by uptake of contraception. However a reduction in unintended pregnancies is not the only pathway to lower levels of disease burden. In industrialized countries, there are still high levels of unintended pregnancies and abortions, but the disease burden associated with these is minimal because of the high quality of obstetric and abortion services. Indeed, the avoidable burden in absolute numbers may change more through a decline in the risk attributed to each pregnancy-by improvements in quality and provision of safe obstetric and abortion servicesthan through a decline in unintended pregnancies resulting from the use of effective contraception. It should be emphasized that improvement in risks related to abortions in many low-income countries requires above all a political will to change restrictive laws. Whatever the future may hold in terms of the risk attached to a single pregnancy or birth, it remains relevant and valid to estimate the proportion of the burden avoidable by increased effective use of contraception to avert unwanted births and abortions.

How should future attributable fractions be calculated and what are the necessary assumptions about fertility decline and levels of exposure? Fertility is expected to vary over the next three decades according to the UN medium-variant projections. Specifically all developing countries are now projected to reach replacement level fertility of 2.1 births per woman in the course of this century. Indeed the next UN projection will assume declines to 1.85 births per woman (UN 2002). These projections are rooted in evidence from the past 100 years that suggests that, once fertility has started to decline, it continues to fall until the achievement of low levels. This process of fertility transition appears to be relatively impervious to socioeconomic development. For instance, fertility has declined under conditions of rapidly improving standards of living, as in
many east Asian countries. It has also declined under conditions of economic stagnation or decline, as in Europe in the 1930s and much of east Africa in the past 20 years. Whatever the underlying forces of change, these fertility declines will be achieved primarily through increased levels of contraceptive use (and perhaps abortion), accompanied in some countries by rising age at marriage.

We thus need to project a future contraceptive distribution based on expected declines in fertility in the next three decades. Cross-country comparisons show that a fall in TFR of one child roughly corresponds to an increase in contraceptive prevalence of 15 percentage points (Ross and Frankenberg 1993). However, inferring contraceptive use from future fertility is complicated by the fact that abortion is an alternative means to regulate fertility. In countries experiencing simultaneous fertility decline and rapid changes in desired family sizes, unwanted births, abortion and contraception levels may all rise in parallel. This counterintuitive trend reflects the fact that in societies where couples want large families of, say, five or six children, exposure to the risk of an unwanted pregnancy is bound to be low. As fertility desires fall, the risk increases. For instance, in a society where couples want two children and women marry at 20 years of age, the desired family size will typically be achieved when the wife is in her mid-20s, leaving her exposed to the potential risk of unwanted pregnancy for the next 20 years. Thus it is not surprising that rapid declines in desired fertility can give rise to situations where increased contraceptive practice is unable to meet the growing need for fertility regulation.

One of the clearest examples is the Republic of Korea. As documented from longitudinal data in this country (Bongaarts and Westoff 2000), early on in the fertility transition, both levels of contraceptive use and the incidence of abortion rose in parallel, which in itself provides evidence for a growing unmet need for contraception. While abortion levels reached a peak and declined, contraceptive prevalence continued to rise, as the Republic of Korea progressed through the fertility transition.

The sequence of events in the Republic of Korea is not inevitable. In countries where effective contraception has not been promoted, and is thus relatively inaccessible, heavy reliance on abortion may persist. This is true in Japan and much of eastern Europe and central Asia (Henshaw et al. 1999). But in countries where abortion is very common, evidence suggests that improved availability of family planning services and wider choice of effective contraception can cause a rapid decline in abortion (Henshaw et al. 1999). This is the trend observed in central Asia, where abortion is being replaced by contraceptive use (Westoff et al. 1998). Thus widely varying patterns of change in population levels of contraception and abortion levels are evident in different populations (Marston and Cleland 2003b).

We therefore needed to make assumptions about the level of unmet need at future expected levels of TFR and contraceptive use. What
change in unmet need is to be expected from recent trends? There has been a steady increasing potential need for limiting births (adding the met need and unmet need), in the 1980s and the 1990s in developing countries (Westoff and Bankole 2000). Whereas the average proportion of women using contraception for limiting births increased faster than the potential need in Latin America, Asia and north Africa, this was not true for sub-Saharan Africa, where the proportion of women with an unmet need for limiting increased during the past two decades (Westoff and Bankole 2000).

As explained before, with rapid rates of social change, the need for contraception can grow faster than contraceptive use itself, resulting in rising incidence of unintended pregnancies, unwanted births and unsafe abortions. This implies that at the same levels of future fertility (TFR), populations could have different levels of unmet need, and that women will make trade-offs between abortion and contraception, depending on the legality, availability and perceived quality of services. However, the prediction of changes in unmet need (reductions in Asia and Latin America vs increases in Africa) made the calculation of avoidable risk too complex to operationalize.

The most effective and practical means of obtaining estimates of future exposure levels was to start from the relationship between fertility desires and TFR, and then to infer future contraceptive levels from the projected fertility desires. Fertility changes because of a decline in fertility desires and/or a better implementation of fertility preferences by couples. Future exposure to the risk factor considered here will depend on both. Therefore, the decrease in the maternal burden of disease (linked to a decline in pregnancies) can be split in two components: a reduction due to a lower desired family size and one due to a better implementation of fertility desires. Subregions with a high burden of maternal complications are going through a fertility transition and the desire for smaller families will continue to increase.

We have thus inferred the change in family size desires from the expected decline in TFR. Whereas the fertility preferences within each category of exposure will shift to higher proportions of women with an intention to stop or postpone childbearing, we can keep the propensity to translate desire into effective contraceptive protection constant. We have assumed that within each level of fertility intention (want children now, spacers, limiters), the relative distribution of non-users, traditional and modern method users stays the same, providing us with an estimate of future exposure. The future levels of contraceptive use implicit in the lower family size desires can be taken as the "business-as-usual" exposure. This reflects a rise in use expected from declines in desired family sizes, but is obviously dependent to a large extent on continued or increased investment in subsidized contraceptive services.

Based on this business-as-usual scenario, the avoidable burden then refers to the burden associated with unwanted births and unsafe abor-
tions that could be avoided through perfect implementation of future fertility preferences, over and above the burden that is avoided by the general trend towards lower fertility and the desire to have smaller family sizes. Simulating business-as-usual exposure levels for different time points in the future also requires associated business-as-usual relative risk levels and proportions unwanted among all births.

The step-by-step derivation of all the input data needed for the calculation of avoidable risk is given, followed by a discussion of the trends in input data. Avoidable risk was calculated for 2001, 2005, 2010, 2020 and 2030. For 2001, the 2000 input levels have been used.

### 7.1 BUSINESS-AS-USUAL EXPOSURE AND OTHER INPUTS TO CALCULATE AVOIDABLE BURDEN

## Establishing the association between fertility desire AND TFR

We have related the levels of fertility intention (want more children soon, spacing and limiting) aggregated across the three levels of exposure (modern methods, traditional methods, fecund non-users) to the TFR in the following way. Using the data from the 58 DHS , the cross-sectional linear associations between each of the current aggregate levels of fertility preference and the TFR were assumed to represent rates of change in the fertility desire for a one-unit change of TFR. Among the nonusers, the proportions of women that are not currently exposed to the risk of pregnancy, either behaviourally or biologically, were also correlated to the TFR. With a fall in fertility there will also be a decline in aggregate levels of women who are pregnant and amenorrhoeic at any point in time; these were regressed as one category against the TFR. Amenorrhoeic women include those who abstain sexually after childbirth. Since both the numbers of women who did not have sex in the past 12 months (other than those who are also amenorrhoeic) and menopausal or infecund women are expected to change little with levels of TFR they were combined and then regressed together against the TFR. The regression coefficients were calculated separately for the 15-29- and 30-44year age groups. Table 15.21 shows the results in terms of the slopes (rate of change along the regression line) and also the R -squared values.

## Projected fertility dechine

The expected decline in fertility was calculated from current TFRs and projected TFR levels using the UN projections (medium-variant) for each time point in future. Table 15.22 shows the subregional average TFRcurrent and projected-and the resulting projected decline at each time point. For 2001, the current levels were kept at calculated 2000 levels.

The sudden drop in fertility from current levels of 4.2 to 2.1 in 2005 in the EMR-B subregion is spurious and explained by the fact that

Tunisia is the only country represented. Fertility has changed dramatically since the last Demographic and Health Survey in 1988.

## Projected levels of fertility preferences

The calculation involved different steps, explained here in detail for women who want to limit family size, using Ghana for illustrative purposes.

1. The current overall percentage of women who want to limit childbearing: This was calculated from the distribution of fertility preferences within each level of exposure. For example, in Ghana, 11.4\% of women aged 15-29 years are modern method users, $10.1 \%$ use tra-
ditional methods and $78.5 \%$ are not using any contraception at all. Among the modern method users, $11 \%$ want to limit their family size. So $1.2 \% ~(=11.4 \% \times 11 \%)$ of all women aged $15-29$ years are modern method users with a desire to limit family size. Since $7 \%$ of traditional method users want no more children, $0.7 \%$ of all women are traditional method users with desire to limit family size. Among the nonusers $47 \%$ are currently fecund and, among these, $6 \%$ want to stop childbearing. This gives $2.2 \%(=78.5 \% \times 47 \% \times 6 \%)$ fecund nonusers with a desire to limit family size. Adding all limiters together gives an aggregate percentage of $4.1 \% ~(=1.2 \%+0.7 \%+2.2 \%)$ of all 15-29-year olds who want no more children.
2. Projected decline in fertility: Fertility in Ghana is projected by the UN to fall by 0.4 children from a current TFR of 4.4 to 4.0 in 2005.
3. Future overall percentage of women who want to limit childbearing in 2005: The projected fertility decline (0.4) was multiplied by the coefficient representing the change in the percentage of limiters (see Table 15.21: -6.56 ) and added to the current percentage $(4.2 \%)$. So in $2005,4.2+6.56 \times 0.4=6.6 \%$ of $15-29$-year olds are projected to want to limit their family size.
4. Steps 1 to 3 were repeated for the four other variables, using the appropriate coefficients in Table 15.21. By 2005, the percentage of women who want more children is projected to decline from $12.9 \%$ to $12.4 \%$ and women who want to space to increase from $41 \%$ to $42.1 \%$. The percentage pregnant and amenorrhoeic would decline from $29 \%$ to $26.3 \%$, while the percentage of infecund and not sexually active women would change from $13 \%$ to $12.7 \%$.

## Projected business-as-usual levels of contraceptive use

Having calculated the new overall distribution of fertility preferences in the population, we used the relative distribution of modern method users, traditional method users and fecund non-users within each level of fertility desire (current scenario), to estimate our business-as-usual exposure variable. For example, $29 \%$ of the limiters were modern method users, $17 \%$ used traditional methods and $54 \%$ were fecund nonusers. Keeping the propensity to translate fertility intention into contraceptive practice constant, we have $29 \%$ of the $6.6 \%$ limiters aged 15-29 years, i.e. $1.9 \%$ using modern methods in 2005 . Adding this to the $12 \%$ of the $12.4 \%$ women who want a child soon and the $21 \%$ of the aggregate $42.1 \%$ spacers who are using a modern method, we have derived an aggregate percentage of $12.3 \%$ modern method users in 2005 $(=1.9 \%+1.4 \%+8.9 \%)$. In total, $10.7 \%$ are traditional method users and $77.1 \%$ are non-users (this last category includes the $26.3 \%$ pregnant and amenorrhoeic and $12.7 \%$ infecund and not sexually active).

## OTHER INPUT FOR BUSINESS-AS-USUAL SCENARIO

The relative distribution of fertility preference within each exposure level was calculated (e.g. 1.9 of the $12.3 \%$ or $16 \%$ of modern method users want no more children). The relative composition of the non-users in five categories of fecund, pregnant, amenorrhoeic, infecund/menopausal and no sex in the past year was also recalculated, and together with the projected contraceptive use levels used as input into the simulations. From this we derived the business-as-usual levels of the relative risk of having an abortion, the relative risk of having an unwanted birth as well as the proportions of unwanted among all births.

These calculations were done for each of the 58 countries at different time points (2005, 2010, 2020, 2030). For 2001, we used the current (2000) levels of contraceptive use and fertility desire. For each time point in the future we estimated five contraceptive prevalence distributions: business-as-usual exposure, theoretical minimum, and three other counterfactuals, shifting $10 \%, 20 \%$ and $30 \%$ of fecund non-users and traditional method users into the modern use category. For each of these we used the corresponding relative risks for abortions, unwanted births and proportion of unwanted births among all births.

### 7.2 Trends in business-AS-USUAL EXPOSURE AND relative risk levels

We have presented the trend in modern method use as derived through aggregating the country data into subregional estimates from 2001 (which was kept as the same as the 2000 level) to 2030. Table 15.23 shows these trends separately for the two age groups. For the three subregions with missing data, we kept the contraceptive distribution constant at the estimated 2000 level.

As expected from the fertility decline (Table 15.22), the contraceptive levels, reflecting the associated decline in fertility desire, are increasing steadily. As suggested by the regression coefficients (Table 15.21), the increase is more marked for the older age group. Since the expected fall in fertility by 2030 is largest for the two African subregions, the business-as-usual contraceptive levels are predicted to increase most steeply here.

In the business-as-usual scenario, the relative risk levels also varied from the current one, as shown in Tables 15.24 and 15.25 for unwanted births and abortions, respectively. The increase is more marked for nonusers than it is for traditional method users. The increase is explained by the fact that the proportion of limiters increases among all three levels of exposure, but relatively more among the non-users.

Logically, as fertility desires are projected to go down with time, and keeping the propensity to translate desire into contraceptive behaviour at 2000 levels, the proportion of unwanted births among all births increases steadily, as can be seen from Table 15.26.

Table I5.23 Projected trends in the proportion of women using a modern method, business-as-usual scenario

### 7.3 BUSINESS-AS-USUAL AND COUNTERFACTUAL SCENARIOS

The main assumptions underlying the projected exposure and risk are as follows:

- Fertility in developing countries will fall in line with the UN medianvariant projections.
- The cross-sectional relationship between fertility desires and fertility itself can be used to project future changes in fertility desires.
- In the business-as-usual scenario, the propensity to translate fertility desires into contraceptive use will remain unchanged.
- The relative popularity of different contraceptive methods and failure rates will remain unchanged.
- The proportion of infecund and sexually inactive non-users will remain constant.

## Fertility trends

The UN medium-variant fertility projections are widely accepted as a reasonably dependable guide to the future. The UN's past record of successful projection over the short term of 20-30 years is impressive and no specific reason exists to doubt recent projections (Bongaarts and

Table I5.24 Projected trends in relative risk of having an unwanted birth, business-as-usual scenario

Butatao 2000). In our view, fertility projections are therefore not a major source of uncertainty, nor is it possible to conjecture about possible departures from projections and their effect on our estimates.

## LINK BETWEEN FERTILITY AND FERTILITY DESIRES

The relationship between achieved and desired fertility is not straightforward. Nevertheless, over the longer term, they tend to move in parallel. To represent this link we calculated cross-sectional correlations in the 58 study countries between fertility rates and fertility intentions and then assumed that these relationships would remain constant over the next 30 years. While we accept that a degree of uncertainty surrounds this procedure, we doubt whether it represents a serious bias.

## PROPENSITY TO TRANSLATE FERTILITY DESIRES INTO CONTRACEPTIVE PRACTICE

In the business-as-usual scenario it was assumed that the proportion of limiters and spacers who use contraception to achieve their intentions remains constant. This assumption was made in adherence to the busi-ness-as-usual concept that exposure changes with changing fertility desires, while the propensity to translate these into effective contraceptive use remains the same. Yet the empirical record of the past 40 years suggests that it is an artificial and unrealistic assumption. Fertility has declined in the past both because desired fertility has fallen and because
desires have been better implemented (Feyisetan and Casterline 2000). A more realistic representation of business-as-usual, of course, would act to reduce the avoidable burden.

## Method mix and failure rates

Estimation of future scenarios used the assumption that choice of methods-or the method mix-within each country would remain the same, as with failure rates. Several forms of uncertainty may be identified: the development and uptake of newly developed forms of contraception; the possibility of a drift towards more effective existing methods; and greater resort to barrier methods in response to the HIV pandemic. The development and widespread use of radically new methods of contraception seems increasingly unlikely in view of lack of major investment by the pharmaceutical industry (Hagenfeldt 1994). The development of a contraceptive vaccine, for instance, seems an increasingly remote possibility. More plausibly, general shifts from less to more effective methods might occur-and indeed are underway in the countries of the former Soviet Union. With the exception of these latter countries, where in the past, access to modern contraception was severely restricted, little evidence exists to support the view that the contraceptive method mix will change over the next 30 years. Contraception in developing countries, unlike Europe or North America, has always been dominated by effective methods: sterilization, intrauterine devices and hormonal methods. In our view, an increased dominance of these methods is possible but not particularly likely. Any such trend would increase relative risks. Offsetting this might be increased uptake of condoms, the only existing contraceptive method that offers protection against HIV and other STIs. So far, no tendency towards greater use of condoms for family planning (and dual protection) within marriage has been recorded (UN 1999). With regard to contraceptive failure for users of specific methods, the assumption of no change is reasonably robust. We are unaware of any evidence of secular trends in the probability of failure.

## InFECUNDITY AND SEXUAL INACTIVITY AMONG NON-USERS

A final assumption in the estimation of future scenarios was that the projection of infecund and sexually inactive non-users would remain constant. As the general health of adults improves, physiological infecundity is more likely to decline than increase, and prolonged sexual abstinence may become less common for the same reason and because of the erosion of customs of postpartum abstinence in sub-Saharan Africa. Any such trend would probably serve to increase relative risks and increase exposure and the avoidable burden.

Table 15.27 summarizes effects of assumptions on estimates of avoidable risk. A positive symbol (+) indicates that the effect may be to bias risks upwardly and a negative symbol (-) the opposite. A zero (0)

# Table I5.27 Possible effects of assumptions on estimates of avoidable risk 

| Future fertility trends | 0 |
| :--- | :---: |
| Future fertility desires | 0 |
| Translation of desires into contraceptive use | ++ |
| Method mix and failure rates | 0 |
| Infecundity and sexual inactivity | - |

denotes that the direction of the uncertainty, or possible bias, cannot be established.

## Acknowledgements

We are obliged to Iqbal Shah and Elisabeth Aahman for access to the unpublished WHO estimates of unsafe abortion at country level. We are grateful to Mohammed Ali for giving access to the unpublished contraceptive failure rates. We have greatly benefited from the helpful comments by the five anonymous reviewers and the regular encouraging feedback from Majid Ezzati.

## Note

1 See preface for an explanation of this term.

## Chapter 16

# UNSAFE WATER, SANITATION AND HYGIENE 

Annette Prüss-Üstün, David Kay, Lorna Fewtrell and Jamie Bartram

## Summary

The disease burden from unsafe water, sanitation and hygiene (WSH) is estimated at the global level taking into account various disease outcomes, principally diarrhoeal diseases. The risk factor is defined as including multiple factors, namely the ingestion of unsafe water, lack of water linked to inadequate hygiene, poor personal and domestic hygiene and agricultural practices, contact with unsafe water, and inadequate development and management of water resources or water systems.

For estimating disease burden of infectious diarrhoea, exposure scenarios are established according to water supply and sanitation infrastructure, the level of faecal-oral pathogens in the environment and populations assigned to these scenarios. The total burdens from schistosomiasis, trachoma, ascariasis, trichuriasis and hookworm disease are all wholly attributable to unsafe WSH and have been quantified at global level as an additional exercise.

Unsafe WSH is an important determinant in a number of additional diseases, such as malaria, yellow fever, filariasis, dengue, hepatitis A and hepatitis E, typhoid fever, arsenicosis, fluorosis and legionellosis, some of which present a high disease burden at global level.

For infectious diarrhoea, six exposure levels were defined, with the lowest risk level corresponding to an ideal situation where WSH plays no role in disease transmission. Exposure prevalence, in terms of infrastructure, was determined from the Global Water Supply and Sanitation Assessment 2000. This assessment is a synthesis of major international surveys and national census reports covering $89 \%$ of the global population. The parameters considered included access to improved water sources and improved sanitation facilities.

Relative risk estimates were based on reviews and large multi-country studies for areas with high faecal-oral pathogen loads in the environment (i.e. principally in developing countries). The proportion of disease
due to unsafe WSH in regions with low faecal-oral pathogen loads was based on a study analysing the relative importance of etiological agents causing diarrhoeal diseases, supported by evidence from selected studies considered to be of high quality. A low faecal-oral pathogen load in the environment was assumed if sanitation coverage exceeded $98 \%$ (which corresponds to the situation in most developed regions).

For the high faecal-oral pathogen exposure group, Esrey's multicountry study (1996) suggests that a mean reduction in diarrhoea of $37.5 \%$ is possible following the introduction of improved water supply and sanitation in developing country environments. For the low faecal-oral pathogen exposure group, data from the study by Mead et al. (1999) suggested that the proportion of diarrhoeal illness attributable to food in the United States of America was approximately $35 \%$ (excluding those illnesses wholly transmitted by food). We have therefore estimated that approximately $60 \%$ was attributable to unsafe WSH. A review by Huttly et al. (1997) of epidemiological studies on hygiene practices in seven nations identified a median reduction of diarrhoea incidence of $35 \%$.

Selected additional studies have suggested ranges of reductions in diarrhoea incidence that could be achieved by reducing the transmission of faecal-oral pathogens through the implementation of interventions, such as point of use treatment and disinfection of stored water (Quick et al. 1999; Semenza et al. 1998). However, this transition has been poorly documented by exposure-risk information, and we considered it appropriate to examine both optimistic and pessimistic estimates in defining the uncertainty around these values.

The disease burden from unsafe WSH was estimated to have been 1.73 million deaths in the year 2000, and $88 \%$ of the global burden of diarrhoeal disease due to infectious diarrhoeal diseases. In addition, schistosomiasis, trachoma, ascariasis, trichuriasis and hookworm disease are fully attributable to WSH-related factors. Typically, the fraction of diarrhoeal disease attributed to unsafe WSH in developed countries is approximately $60 \%$, whereas in developing countries as much as $85-90 \%$ of diarrhoeal illness can be attributed to unsafe WSH. The major part is borne by children in developing countries.

This estimation of the global disease burden caused by unsafe WSH suggests a significant burden of preventable disease attributable to this cause in developing nations, and a non-negligible burden in developed countries.

## 1. Introduction

The disease burden caused by the risk factor unsafe WSH was estimated at the global level in 1990 (Murray and Lopez 1996a). This original estimate examined WSH in terms of diarrhoeal and selected parasitic diseases, based on the partial attribution of their disease burden to the
risk factor. It was found that worldwide the risk factor accounted for $5.3 \%$ of all deaths and $6.8 \%$ of all disability-adjusted life years (DALYs). Other communicable (e.g. hepatitis A and E, malaria) and noncommunicable diseases (arsenicosis, fluorosis, methaemoglobinaemia) were not considered in that assessment.

### 1.1 Rationale for a composite risk factor

Faecal-oral diseases account for the dominant health outcome of the unsafe WSH risk factor and are the main focus of this chapter. However, not all of them could be included in this estimate (e.g. hepatitis A and E). For infectious diarrhoea, the unsafe WSH risk factor comprises a number of transmission routes mediated by a complex interaction of infrastructure issues, which might affect, for example, microbiological hazards from poor quality drinking water, water availability, microbial risks from inappropriate disposal of faecal wastes and behavioural aspects. The transmission routes interact with the efficiency of interventions such as hygiene within the home, hand-washing and rigorous application of point-of-use treatment within domestic properties. Clearly, in any global assessment, the contribution of each element, together with the plethora of interactions, cannot be precisely quantified in every setting. However, as hazard estimates come from large surveys performed in several countries (Esrey 1996), variations in behaviour and their effects on the transmission of faecal-oral pathogens have, to some extent, been internalized in our estimates.

It is likely that the relationship between faecal-oral pathogen dose and the probability of infection is log-linear for many of the infectious diarrhoeal diseases, reaching a plateau for higher exposures (Briscoe 1984; VanDerslice and Briscoe 1995). Sometimes several component causes (see Figure 16.1) may produce similar infection outcomes. This can mean that the introduction of a single intervention in isolation (e.g. the provision of cleaner water supplies) designed to break an infection pathway may result in a negligible reduction in overall disease burden. This is particularly true in communities where the environmental load of faecal-oral pathogens is high (e.g. a community with low sanitation coverage, faecally contaminated drinking-water supplies, irregular refuse collection and poor hygiene practices). This renders the attribution of a disease fraction to a specific factor particularly difficult and, indeed, potentially misleading to the policy-making community. For this reason, it is necessary to consider WSH as interrelated parts of a single causal web in which cutting one major pathway of transmission may well show no (or minimal) effect on the total disease burden, but may, in other circumstances, provoke a dramatic response. Importantly, however, removing a basic pathway (e.g. by providing safe drinking water or improved sanitation) is likely to be a precondition for the success of subsequent interventions to reduce disease burden.

Figure 16.1 Transmission pathways of faecal-oral disease

Management actions concerning water supply and sanitation often involve water resource management, including the control of insect vectors of disease (such as malaria) and soil-borne helminths (such as ascaris). Similarly, environmental management to control disease vectors impacts directly upon water supply and sanitation. Furthermore, access to improved water sources has a significant impact on exposure to agents of some water-based diseases (such as schistosomiasis) and diseases with water-related insect vectors, and improved sanitation reduces certain vector-borne diseases such as trachoma. These intimate interconnections of exposure pathways and control mechanisms suggest that treating water, including supply and resource management, as an integral part of the risk factor unsafe WSH is rational.

### 1.2 Defintition of risk factors

Unsafe WSH adversely affects health through multiple routes.

1. Transmission through contact with water that contains organisms such as Schistosoma spp.
2. Transmission through vectors proliferating in water ecologies related to dams, irrigation schemes and other water resources projects (e.g. malaria, schistosomiasis, lymphatic filariasis). This should be included although it is currently unclear how or whether it can be quantified.
3. Transmission through the ingestion of water as it occurs during drinking and, to some extent, bathing. This category includes diseases from faecal-oral pathogens, dracunculiasis, arsenicosis, fluorosis, from other toxic chemicals and due to excess proliferation of toxic algae.
4. Transmission caused by poor personal, domestic or agricultural practices, including when personal hygiene is affected by lack of water. This includes person-to-person transmission of faecal-oral pathogens, foodborne transmission of faecal-oral pathogens as a result of poor hygiene or use of contaminated water for irrigation or cleaning. Lack of water is in particular linked to diseases such as trachoma and scabies.
5. Transmission through contaminated aerosols from poorly managed water systems (e.g. legionellosis).

Water-related injuries that could be prevented by appropriate water management were not considered in the current estimate because of the different management approaches to their remediation. They were, however, covered by the World Health Organization (WHO 1998), although their disease burden was not quantified. Many social, geographic and behavioural factors, such as hygiene, the domestic storage and potential contamination of potable water, the use of sanitation facilities, etc. are important determinants of health outcome. This set of factors has complex social and behavioural drivers that are highly heterogeneous both within and between nations. In reality, they would modify the effects of the pathways defined in (i) to (v) above. It is beyond the scope of the current assessment to attempt to quantify the unique impacts of this set of factors in each setting.

Diseases relating to unsafe WSH, and their inclusion in the current estimate, are listed in Table 16.1. This first assessment of disease burden should be considered an initial estimate, which will benefit from refinement as additional information becomes available. Table 16.1 is not exhaustive, as the linkages between water and health are extensive and complex. For example, it is likely that the role of inadequate water for food production, and therefore nutrition, will be particularly important, in addition to the direct impact of infectious diarrhoea on nutrition.

### 1.3 Evidence of causality on infectious diarrhoea

As illustrated in Table 16.1, numerous separate faecal-oral illnesses fall under the "umbrella" of infectious diarrhoea. Their commonality derives from their mode of transmission, in that the source of the pathogen is human (or less commonly, animal) faeces which can cause infection in a new host upon ingestion. The shortest route of transmission is from person-to-person (a hygiene issue), while longer routes include transfer of pathogens to a food crop, as well as to drinking water or recreational

| Disease outcome | Included in current estimate |
| :---: | :---: |
| Infectious diarrhoea, including: cholera, salmonellosis, shigellosis, amoebiasis, other bacterial, protozoal and viral intestinal diseases ${ }^{\text {a }}$ | Yes (acute effects only) |
| Typhoid and paratyphoid fevers | Partly included in estimate for infectious diarrhoea, but would benefit from separate, more precise consideration |
| Hepatitis A | No |
| Hepatitis E | No |
| Fluorosis | No |
| Arsenicosis | No |
| Legionellosis | No |
| Methaemoglobinaemia | No |
| Schistosomiasis ${ }^{\text {a,b }}$ | Yes |
| Trachoma ${ }^{\text {a,b }}$ | Yes |
| Ascariasis ${ }^{\text {a,b }}$ | Yes |
| Trichuriasis ${ }^{\text {a,b }}$ | Yes |
| Hookworm ${ }^{\text {a,b }}$ | Yes |
| Dracunculiasis ${ }^{\text {b }}$ | No (disease close to eradication) |
| Scabies | No |
| Dengue ${ }^{\text {a }}$ | No |
| Filariasis ${ }^{\text {a }}$ | No |
| Malaria ${ }^{\text {a }}$ | No |
| Japanese encephalitis ${ }^{\text {a }}$ | No |
| Onchocerciasis ${ }^{\text {a }}$ | No |
| Yellow fever | No |
| Impetigo | No |
| Drowning ${ }^{\text {a }}$ | No |

[^59]water, as summarized in Figure 16.1. The predominant route will depend upon the survival characteristics of the pathogen as well as local infrastructure and human behaviour. While some of the diseases contained in the group diarrhoeal disease, as defined for the purpose of this project, are relatively mild and self-limited, others may be more severe and cause long-lasting sequelae (Hunter 1997). The disease burden based on these studies has not been taken into account in this estimate.

The fact that faecal-oral pathogens can be spread via the water route is well established (Andersson and Bohan 2001; Esrey et al. 1991; Hunter 1997; Snow 1855). The following sections briefly outline the evidence
for infectious diarrhoea causality in relation to water, sanitation and hygiene. For the most part, studies examining the issue have been intervention studies, which have looked at changes in water supply, excreta disposal or hygiene practices, and assessed the effects on diarrhoea morbidity or mortality rates (generally in young children). Another significant group of investigations comprise case-control studies, particularly following outbreaks suspected to be caused by potable water contamination in developed nations.

## SANitation

Ideally, sanitation (i.e. human excreta management) should result in the isolation or destruction of pathogenic material and, hence, a break in the transmission pathway. In a comprehensive literature review, Esrey et al. (1991) identified 30 studies, from a variety of different countries (including Bangladesh, Brazil, Chile, Guatemala, Kenya, Malaysia and Panama), that examined the impact of sanitation on disease transmission. Twenty-one of those studies reported health improvements (median $22 \%$ reduction in diarrhoea morbidity), with a greater median reduction being seen in the rigorous studies ( $36 \%$ reduction). Several studies have isolated various faecal-oral pathogens from the faeces of sick people and the transmission of such pathogens isolated from infected faeces to human hosts has been shown in numerous studies (e.g. for Shigella [Dupont et al. 1989]). Clearly, the relationship is both plausible and coherent.

## Water

The number of outbreaks of infectious diarrhoea caused by faecal-oral pathogens in developed countries attests to the efficiency of this mode of transmission. In the United States, for example, 14 outbreaks of infectious etiology associated with drinking water were reported for the twoyear period 1997-1998 (Barwick et al. 2000).

In developing countries, it is not only water contaminated at source or during distribution that is an issue, but water stored within the home which may also become contaminated (arguably a hygiene issue). For example, in a literature review, VanDerslice and Briscoe (1993) found 11 observational studies showing that mean coliform levels (an indicator of contamination) were considerably higher in household water containers than in the original source waters.

Numerous epidemiological studies and outbreak investigations have found an association between poor water quality and infectious diarrhoea. In France, water that did not meet microbiological standards was associated with an increased risk of gastroenteritis (RR 1.36, CI 1.24-1.49) (Ferley et al. 1986). In the Philippines, Moe et al. (1991) reported an odds ratio (OR) of 1.92 (CI 1.27-2.91) for diarrhoea following consumption of water contaminated with high levels of Escherichia coli (a faecal indicator bacteria). Mahalanabis et al. (1991)
reported that children with prolonged diarrhoeal illness (more than 14 days) were more likely to drink water from an unprotected water source (OR 1.56, CI 1.18-2.06). Birmingham et al. (1997) conducted an epidemiological investigation to identify sources of infection and risk factors for cholera in Burundi during an epidemic in 1992. Water from Lake Tanganyika was implicated, as a case-control study found that both bathing in the lake (OR 1.6, CI 1.1-2.1) and drinking its water (OR 2.78 , CI $1.0-7.5$ ) were independently related to illness; additionally Vibrio cholerae O1 was isolated from the lake water.

As seen above, the causal relationship between ingesting water of poor sanitary quality and diarrhoeal illness has been observed worldwide, using a variety of techniques and assessing quality in a number of different ways. The biological gradient can be illustrated by increases in infectious diarrhoea morbidity as contamination levels increase, and also as consumption of water from a single contaminated source increases. For example, Njemanze et al. (1999) examined the annual diarrhoeal incidence rate (per 1000 population) in 39 communities in Imo State, Nigeria, in relation to the characteristics (including pollution) of their drinking water source. Sources were classified from A to C with A representing the most desirable sources (with favourable geology, sparse population and clean and unpolluted water). Diarrhoeal incidence rate was found to show a statistically significant increase with a mean of 1.61 for category A, a mean of 6.25 for category B, and a mean of 15.6 for category C.

The relationship between infectious diarrhoea and transmission of pathogens through water is both plausible and coherent. Isolation and enumeration of specific pathogens in water are often not feasible or very imprecise; thus a more common measure of faecal contamination is derived from the use of indicator bacteria. There have been many studies using such indicator species that have demonstrated the faecal contamination of drinking water sources in both developed and developing countries (e.g. Ampofo 1997).

## Hygiene

A number of studies have attempted to examine the role of personal and domestic hygiene, although in many cases some of the "hygiene" measures or interventions could also impact on sanitation, and hygiene interventions may also interact with water quality.

Six studies examined by Esrey et al. (1991) identified reductions in diarrhoea morbidity associated with the uptake of hygiene interventions. These ranged from $14 \%$ to $48 \%$, with a median reduction of $33 \%$. In a more recent review, Huttly et al. (1997) identified a further four studies addressing the impact of improved hygiene. All four studies showed a decrease in diarrhoea, as did a subsequent study of Curtis et al. (2000). These studies were conducted in diverse locations including Bangladesh, Burma, Guatemala and the United States.

The temporal adoption of hygiene measures can be illustrated by the study by Ahmed et al. (1993). This group compared cleanliness and diarrhoea levels in villages with and without hygiene education interventions. Higher adoption rates of the intervention were associated with a better cleanliness state, which was paralleled by a decrease in diarrhoea and malnutrition rates. These differences were found to increase over time as more villagers adopted the intervention.

Alam et al. (1989) studied the effect of four different hygiene measures (source of washing water; presence of faeces in the yard; handwashing before serving food; and hand-washing after defecation). They showed decreasing diarrhoea incidence as the number of adopted hygienic practices increased (4.9 cases per child-year for one practice to 2.6 cases for all four; $P<0.01$ ).

A review by Feachem (1984) documented the presence of pathogens on the hands following toilet activities. In the same review, Feachem also noted a number of studies on hand-washing which demonstrated the almost complete removal (98-100\%) of seeded bacteria.

### 1.4 EVIDENCE OF CAUSALITY ON OTHER OUTCOMES

## Schistosomiasis

Schistosomiasis is caused by infection with trematodes of the Schistosoma species. Transmission of the disease occurs when people come into contact with water containing cercariae (the mobile larval stage of the life cycle), which penetrate the skin. Water is contaminated by infected humans who excrete the schistosome eggs in their faeces or urine (depending upon the Schistosoma species). The final link in the chain of infection is provided by an intermediate snail host, which the parasite needs in order to complete its life cycle. Current knowledge on disease transmission indicates that the disease is fully attributable to unsafe WSH.

Esrey et al. (1991) identified 12 studies that related water and sanitation facilities to the rates of schistosomiasis. Reported decreases in infection rates varied between $59 \%$ and $87 \%$, with the median value of the rigorous studies being a $77 \%$ reduction. Numerous studies, in addition to those identified above, have noted the relationship between contact with contaminated water and high levels of infection with schistosomiasis (Hunter 1997). These have been conducted in various countries and have examined different Schistosoma species. Lima e Costa et al. (1991) found that individuals reporting water contact less than once a week had a smaller excess risk of schistosomiasis than those reporting water contact at least weekly (OR 3.0, CI 1.3-6.6 in comparison to OR 4.3, CI 2.6-7.0).

A number of studies have examined reinfection with schistosomiasis following an intervention programme (such as treatment of infected individuals). In China, Zhaowu et al. (1993) found that reinfection was
associated with the frequency of water contact, the type of water contact and the proximity of residence to snail-infected water. In Brazil, discontinuation of a control programme led to an increased prevalence of schistosomiasis (Coura-Filho et al. 1994). Risk factors for the disease included any form of water contact (OR 2.79, CI 1.19-6.85).

The relationship is plausible and the results of numerous studies are coherent and do not conflict with what is known about the disease. Interventions centring on water and sanitation provision designed to either decrease water contamination or decrease contact with contaminated water have proved to be effective in reducing the rates of schistosomiasis (e.g. Barbosa et al. 1971; Jordan 1972).

## TRACHOMA

Trachoma is a chronic contagious eye disease, which can result in blindness, caused by Chlamydia trachomatis. Transmission occurs by several routes (Dolin et al. 1997), all of which are hygiene related (e.g. direct infection by flies, person-to-person from clothing used to wipe children's faces and by hand-to-face contact). Risk factors for the disease include lack of facial cleanliness, poor access to water supplies, lack of latrines and a high number of flies.

A total of 16 studies were identified by Esrey et al. (1991) which examined the role of WSH on the level of trachoma. The median reduction in trachoma was $50 \%(0-91)$ from all the studies and $27 \%(0-9)$ when considering the rigorous studies. More recently Prüss and Mariotti (2000) identified 39 studies which examined the level of trachoma in relation to environmental causation; they report that relative risks ranged between 1 and 4 . Thirteen of the 16 studies identified by Esrey et al. (1991) reported positive effects, i.e. a water, sanitation or hygiene intervention resulted in lower levels of trachoma. The studies were conducted in a variety of locations including Australia, China, India, Mexico, Mozambique, the Sudan and Tunisia.

Prüss and Mariotti (2000) reported that the biological gradient was verified in most of the studies in which it was investigated, although they also noted that few studies examined this issue. Preventative measures through hygiene education and interventions aimed at reducing fly numbers have both resulted in decreases in trachoma (Emerson et al. 1999; Sutter and Ballard 1983).

## ASCARIASIS

Ascariasis is caused by the large roundworm Ascaris lumbricoides. Eggs are passed in the faeces of an infected person and in poor sanitation conditions may contaminate the soil. Ingestion of infective eggs, from contaminated soil or from uncooked products contaminated with soil or wastewater containing infective eggs, cause the disease. Transmission does not occur from person to person. The knowledge on transmission pathway indicates that the disease is fully attributable to unsafe WSH.

The eggs can survive for months or years in favourable conditions and can, thus, pose an infective hazard for a considerable period of time.

A total of 14 studies examining the level of ascariasis and water and sanitation provision were identified by Esrey et al. (1991). These studies reported reductions between $0-83 \%$, with a median reduction from all the studies of $28 \%$. More recently, Cifuentes (1998) reported big differences in infection between children exposed to untreated wastewater and those exposed to either partially treated wastewater or rainwater irrigation (OR 5.71-13.18, depending upon the age group under consideration). Similar results were reported by Habbari et al. (2000), who showed that Ascaris infection was five times higher in children in the wastewater impacted regions compared to control regions. In Indonesia, Toma et al. (1999) reported a $64 \%$ reduction in Ascaris infection in people who used a latrine compared with those who did not.

A biological gradient is suggested from the results of the four rigorous studies identified by Esrey et al. (1991) where the rate of morbidity reduction was dependent upon the level of sanitation facility. The work of Cifuentes (1998) also indicates a dose-response relationship with children exposed to increasingly contaminated water having increased rates of infection.

The relationship is plausible and the study results are coherent. Eggs have been isolated from faecal samples, soil samples, water samples and hand-washing samples (Jonnalagadda and Bhat 1995). Additional experimental evidence is provided by the studies that have examined the increased use of latrines and noted the parallel decrease in both egg counts in soil and levels of infection (e.g. Arfaa et al. 1977).

## TRICHURIASIS

Trichuriasis is caused by ingestion of the human infectious eggs of the whipworm Trichuris trichiura. The infection is not directly transmissible from person to person. As with other faecal-oral transmitted diseases, the mode of transmission indicates that the disease is fully attributable to unsafe WSH, although the risk factors for trichuriasis in relation to WSH do not seem to have been as well researched as the other illnesses covered here. Studies of prevalence often show an association between Ascaris and Trichuris infection (Anderson et al. 1993; Saldiva et al. 1999; Smith et al. 2001), suggesting similar modes of transmission.

Of the studies that were identified, Henry (1981) found that Trichuris infections decreased by $50 \%$ after water supplies and latrines were installed in a rural area of Saint Lucia. Rajeswari et al. (1994) noted that the prevalence of infection was associated with a number of factors, including socioeconomic status, water supply, sanitary disposal of faeces and family size. Similarly, Narain et al. (2000) found that open field defecation and large family size were independently associated with Trichuris infection.

## HOOKWORM DISEASE

Hookworm infection is caused by Ancylostoma duodenale or Necator americanus, and results from the ingestion or skin penetration of the hookworm larvae that live in the soil. Larvae develop in the soil through the deposit of faeces containing eggs from infected persons. The disease is therefore caused by poor sanitation and hygiene practices. The disease is not transmitted from person to person.

Eleven studies were identified by Esrey et al. (1991) which examined water, sanitation and hookworm infection. From the nine that could be used to calculate a reduction in morbidity, the range was $0-100 \%$, although only one of these was considered to be rigorous. Sorensen et al. (1994) found that the severity of hookworm infection was lower in children coming from communities with good sanitary facilities.

Norhayati et al. (1995) studied the reinfection of children in a hookworm endemic area. In the absence of any interventions the reinfection rate at 4 -months post-treatment was $30 \%$. The authors suggested that long-term strategies incorporating education on personal hygiene, provision of toilets and safe water supply were required to control the rapid reinfection. Humphries et al. (1997) reported that hookworm egg counts were significantly higher in Vietnamese women who used fresh human faeces as a fertilizer in comparison to those who used either treated human faeces or did not use human faeces as a fertilizer.

## 2. Methods

The approach builds on methods presented in Prüss et al. (2002), which are further developed in this estimate.

There is strong evidence that, even in developed nations, there is a considerable burden of disease associated with poor-quality potable water or inappropriate sewage disposal and sanitary control. This was demonstrated by disease outbreaks such as the cryptosporidiosis and Escherichia coli O157 epidemics, which affected Canada, the United States and the United Kingdom of Great Britain and Northern Ireland (Andersson and Bohan 2001; Bouchier 1998; Bruce-Grey-Owen Sound Health Unit 2000). In addition, there is a background of sporadic cases in which unsafe WSH has been implicated (Fewtrell and Delahunty 1995). Hence significant health gain is achievable through further improvement in developed nation WSH conditions. This improved condition represents the theoretical minimum exposure in which no disease transmission would occur through unsafe WSH.

As the five transmission pathways of the various outcomes caused by unsafe WSH are quite different (see section 1.2 of this chapter), two approaches for estimating the disease burden were chosen according to the outcome. The estimates of the burden of infectious diarrhoeal disease caused by unsafe WSH are based on exposure information. The burden of other diseases is entirely due to unsafe WSH.

### 2.1 Estimating exposure for diarrhoeal diseases

For estimating the burden of diarrhoeal disease caused by unsafe WSH, we used a scenario-based approach to define exposure categories. In this approach the risk of diarrhoeal disease is conditioned by a typical exposure or a representative combination of risk factors at commonly encountered levels. Six scenarios ${ }^{1}$ (Table 16.2) were defined on the basis of the following:

## Table 16.2 Exposure scenarios

| Level | Description | Environmental faecal-oral pathogen load |
| :---: | :---: | :---: |
| VI | Population not served with improved water supply and no improved sanitation in countries which are not extensively covered by those services (less than 98\% coverage), and where water supply is not likely to be routinely controlled | Very high |
| $\mathrm{Vb}^{\text {a }}$ | Population having access to improved water supply but not served with improved sanitation in countries which are not extensively covered by those services, and where water supply is not likely to be routinely controlled (less than 98\% coverage) | Very high |
| $\mathrm{Va}^{\text {a }}$ | Population having access to improved sanitation but no improved water supply in countries where less than 98\% of the population is served by water supply and sanitation services, and where water supply is likely not to be routinely controlled | High |
| IV | Population having access to improved water supply and improved sanitation in countries where less than $98 \%$ of the population is served by water supply and sanitation services, and where water supply is likely not to be routinely controlled | High |
| $111{ }^{\text {b }}$ | IV and improved access/quality to drinking water; or IV and improved personal hygiene; or IV and drinking water disinfected at point of use, etc. | High |
| II | Population having access to improved water supply and sanitation services in countries where more than $98 \%$ of the population is served by those services; generally corresponds to regulated water supply and full sanitation coverage, with partial treatment for sewage, and is typical in developed countries | Medium to low |
| 1 | Ideal situation, corresponding to the absence of transmission of diarrhoeal disease through WSH | Very low |
| a Transitions between exposure levels Va and Vb do not generally occur. |  |  |
| Cluster of possible improvements over scenario IV, but not reaching scenario II. |  |  |

- the type of water and sanitation infrastructure; and
- the load of faecal-oral pathogens in the environment based on qualitative assessment of sources and disease circulation in the community.

This choice was based on the absence of comprehensive exposure information at individual level and also the lack of relative risk information relating to individual exposure. Risk information was gathered from the literature to match each of the scenarios.

Scenario I represents the minimum theoretical risk and II the situation typically encountered in developed countries. These two scenarios have very low to medium loads of faecal-oral pathogens, characterized by more than $98 \%$ coverage in improved water supply and sanitation and a regional incidence of diarrhoea of less than 0.3 per person per year (Anonymus 2000; Murray and Lopez 1996b). Scenarios IV-VI are in a high faecal-oral pathogen environment, typical for developing countries. Scenario III represents any intervention that improves on scenario IV, and does not currently occur widely. As such, various transitions can be proposed for scenario III and so it is represented as a cluster of possibilities rather than a specific scenario (see Figure 16.2).

Figure 16.2 Scenarios determining risk of diarrhoeal disease from unsafe WSH

## Data sources and quantification of exposure

The exposure scenarios were selected according to available information on exposure-risk relationships and exposure information from the Global water supply and sanitation assessment 2000 (WHO/UNICEF/ WSSCC 2000). The data on water supply and sanitation coverage provided in this assessment are a compilation of two main sources: household surveys, and to a lesser degree assessment questionaires. Relevant information from available household surveys performed on a large scale was accessed, including:

- Demographic Health Surveys (DHS) performed by Macro International and funded by the United States Agency for International Development;
- United Nations Children's Fund's (UNICEF) Multiple Indicator Cluster Surveys (MICS);
- national census reports; and
- other national sample household surveys.

DHS and MICS are national cluster sample surveys, covering several thousand households in each country. The samples are stratified to ensure they are representative of urban and rural areas of each country. In household surveys, consumers are asked to identify the type of water facility they use from a list of technologies. In estimating coverage for the Global Water Supply and Sanitation Assessment 2000, the types of access to services were categorized into "improved" (e.g. borehole, protected dug well, simple pit latrine) and "not improved" (e.g. unprotected well, vendor-provided water, bucket latrines). In addition, national assessment questionnaires were completed by the relevant national agencies in cooperation with WHO and UNICEF country staff. The resulting country estimate for coverage was then based on linear regressions prepared according to available survey data. In the rare cases where household survey data were not available, the coverage figures adopted were those estimated by a local expert committee, based on national assessments and information provided by the country's water authorities.

The Assessment 2000 provides data for water supply and sanitation for almost every country, with information typically available for more than $90 \%$ of the population in every region. It is the only comprehensive assessment of this kind and is, therefore, the single source used for assessing exposure in this analysis. Overall, the Assessment 2000 represents more than $89 \%$ of the global population. Only the European and Western Pacific Regions contain large data gaps, with information on water supply and sanitation coverage lacking for some large countries. Subregions ${ }^{2}$ with low information coverage include EUR-A ( $25 \%$ information coverage), EUR-B ( $65 \%$ ), EUR-C $(11 \%)$ and WPR-A ( $15 \%$ ). In
each case (based on those countries responding), we considered that the available figures on coverage were likely to be representative of the whole subregion. Countries without information were ascribed subregional coverage rates.

Using data from the Assessment 2000, it is not possible to assess whether those served with improved water corresponded to those with improved sanitation, as only coverage was reported. Reports suggest a strong societal and individual preference for improved water supply over improved sanitation, and this is further supported by the higher levels achieved worldwide for improved water supply when compared to improved sanitation. In apportioning populations among exposure scenarios IV and Vb , we therefore assumed that people with improved water supplies were likely to have access to improved sanitation.
The population of each country was thus assigned to the various scenarios based on the Assessment 2000 as described above, and popula-tion-weighted regional means were calculated. The resulting exposure distribution is represented in Table 16.3. In 2000, the percentage of people served with some form of improved water supply worldwide reached $82 \%$ ( 4.9 billion), and $60 \%$ ( 3.6 billion) had access to improved sanitation facilities. In 2000, one sixth ( 1.1 billion people) of the world's population was still without access to improved water supply and two fifths ( 2.4 billion people) lacked access to improved sanitation.

[^60]Scenario I does not occur on a large scale and, in global terms, is probably negligible, hence its omission from Table 16.3. Scenario III is a poorly characterized series of transition states between IV and II and is not separately accounted for. Such scenarios are nevertheless important concepts in policy development and are therefore retained in the model described in Figure 16.2.

### 2.2 RISK FACTOR-DISEASE RELATIONSHIPS FOR DIARRHOEAL DISEASES

## APPROACH

We selected major reviews, multi-country studies or studies of superior design to quantify the transition between two or more chosen exposure scenarios. This included the review and multi-country study by Esrey (Esrey 1996; Esrey et al. 1991), the reviews by Huttly et al. (1997) and Mead et al. (1999), in conjunction with key literature and high quality studies published since the review papers (Payment et al. 1991, 1997; Quick et al. 1999; Semenza et al. 1998). The majority of this literature was based on intervention studies and surveillance information. The final selection of used studies depended largely on the degree to which the study exposure data could be matched with the chosen exposure scenarios and also the sample size and quality of studies. Brief details on the chosen studies are outlined in Table 16.4.

## Relative risk for exposure scenario II

The ideal situation (scenario I) is the theoretical minimum ( $\mathrm{RR}=1$ ). In scenario II, the pathogen load is mostly transferred from land to water (e.g. in discharge of normally treated sewage, such as biological secondary treatment, to surface water). Such pathogens can potentially pass through potable water treatment systems, which can not guarantee $100 \%$ pathogen elimination in even the most advanced plants used in developed nations. Water contaminated with such pathogens is also used for other purposes such as recreation and irrigation. Hygiene behaviour is still imperfect in scenario II, and small population groups may still be served with poorly regulated community supplied water. In scenario I, the ideal scenario, all this would not occur.

Relative risk for scenario II was based on the review by Mead et al. (1999). Mead et al. assessed the level of all infectious foodborne illness in the United States, using data from a large number of surveys and other sources (including FoodNet, the National Notifiable Disease Surveillance System, the Public Laboratory Information System, the Foodborne Disease Outbreak Surveillance System, the National Hospital Discharge Survey, the National Vital Statistics System and a number of published studies). Based on the literature, they also estimated the percentage of each disease caused by foodborne transmission. This is a very comprehensive study based on more than 400000 diagnosed cases, bringing
Table I6.4 Key studies and reviews

| Reference | Study population | Sample size | Outcome measured/ reported | Reductions | Comments |
| :---: | :---: | :---: | :---: | :---: | :---: |
| Esrey (1996) | Representative populations from Bolivia, Burundi, Ghana, Guatemala, Morocco, Sri Lanka, Togo, Uganda | 16880 | Diarrhoea morbidity nutritional status, child development | $20.8-37.5 \%$ <br> according to type of infrastructure | Detailed examination of effects of incremental improvements in water and sanitation based on survey data |
| Huttly et al. (1997) | Bangladesh, Burma, India, Indonesia, USA for hand-washing; Bangladesh, Guatemala, Thailand, Zaire for various other forms of behaviour | NA | Diarrhoea morbidity | Median reduction 35\% for hand-washing; median 26\% for other hygiene behaviours | Review paper/5 intervention studies on hand-washing and 5 on other hygiene behaviours |
| Mead et al. (1999) | Gastrointestinal illness in the USA population | More than 400000 diagnosed patients | Foodborne illness | Approx. 60\% of gastrointestinal illness due to unsafe WSH ${ }^{\text {a }}$ | Surveillance data |
| Payment et al. (1991) | 606 households in Montreal, Canada | 2408 | Diarrhoea morbidity | 35\% | Water quality intervention |
| Payment et al. (1997) | 1400 families in Montreal, Canada | 5253 | Diarrhoea morbidity | 14-40\% | Water quality intervention |
| Quick et al. (1999) | Two Bolivian communities | 791 | Diarrhoea morbidity | 45\% for all age groups | Water quality intervention |
| Semenza et al. (1998) | Householders in Nukus, Uzbekistan | 1583 | Diarrhoea morbidity | 62-85\% | Water quality intervention |
| NA Not applicable. a Extrapolated from | ly results for the purpose of this analysis. |  |  |  |  |

together numerous different data sources and some assumptions relating to likely levels of underreporting. According to this study, about $35 \%$ of intestinal illness in the United States is foodborne. The level of faecal-oral illness due to unsafe WSH was estimated as $100 \%$ of the cases of infectious diarrhoea, less the percentage due to foodborne transmission. This is probably an underestimate as it is likely that unsafe WSH play a role in some foodborne transmission (e.g. through irrigation of food products with pathogen-contaminated water or via an infected food handler). After deduction of the portion of foodborne transmission and accounting for likely ratios of person-to-person transmission through aerosols of certain viruses (estimated as up to $25 \%$ for rotavirus and astrovirus), the remaining fraction attributable to unsafe WSH is about $60 \%$. This order of magnitude is supported by intervention studies acting on point-of-use treatment of drinking water in Canada (Payment et al. 1991, 1997) and hand-washing in the United States (Black et al. 1981), reporting reductions of $40 \%, 35 \%$ and $48 \%$, respectively. A $60 \%$ reduction in disease corresponds to a relative risk of $2.5(\mathrm{RR}=1 /(1-0.6))$ for exposure scenario II.

## Risk transition between scenarios II and IV

Scenarios II and IV represent high and low environmental pathogen loads. Intervention studies were not available, as it is not possible to transform environments high in pathogen load into environments low in pathogen load; doing so would imply completing the coverage in improved water supply and sanitation in a reasonable time frame and without simultaneous change in other major determinants of health. Therefore, relative risks for scenarios between II and IV were estimated using selected studies.

- Scenario IV and improved drinking-water quality: Quick et al. (1999) examined the level of diarrhoea prevention that could be achieved through point-of-use water treatment along with safe water storage. This study was selected as the intervention strongly reduces the pathway of transmission through drinking water, and "simulates" the reduction that could be achieved by improved drinking water quality and its handling inside the house. The study randomized 791 participants into two groups. The intervention group received a special storage container (preventing hand contact with the stored water) and a supply of disinfectant. The control group not receiving the intervention was similar in terms of demographic characteristics, sanitary conditions and baseline water quality. During the baseline investigations only $5 \%$ of household samples were free of E. coli. During the study period this varied between $0 \%$ and $13 \%$ of the control group (with the median level being between 5000 and 85000 of E. Coli $/ 100 \mathrm{ml}$ ), while the intervention group exceeded $50 \%$ of households at all times, rising to almost $80 \%$ on one occasion (median $E$.
coli counts were zero, throughout). Overall diarrhoea reductions of $44.7 \%$ in the total population and $54.5 \%$ in children have been reported by Quick et al. ( $\mathrm{RR}=1.81$ and 2.20 ). The reduction of $44.7 \%$ was selected as a component in the transition between II and IV in this analysis.

In a randomized intervention study in 240 households (120 with and 120 without access to municipal piped water) with a total population of 1583 in Uzbekistan (Semenza et al. 1998), approximately half of the households without piped water were trained to chlorinate their drinking water within the home and store it in a safe manner. Diarrhoea morbidity was markedly lower in the home-chlorination group (28.8/1000 subjects per month), compared to $75.5 / 1000$ in the piped water group and $179.2 / 1000$ in the no piped water group (i.e. a $62 \%$ reduction in diarrhoea rates for an intervention with home chlorination of drinking water, as compared to those living in areas with access to piped water $[\mathrm{RR}=2.6]$; in individuals without a piped supply, the same intervention achieved a $85 \%$ reduction in disease $[R R=6.7])$. The authors considered that home chlorination of water was unlikely to affect disease transmission via other routes, and suggested that a large fraction of the diarrhoeal pathogens in this area were spread through water.

- Scenario IV and improved personal bygiene: reductions in diarrhoea morbidity have been reviewed by Huttly et al. (1997), and handwashing resulted in a median $35 \%$ reduction in diarrhoea incidence $(\mathrm{RR}=1.5)$. The results of this review outlined possible achievements due to a reduction in the transmission pathway of hygiene, which in itself is conditioned by the pathogen load in the environment.

Risk transition between scenarios IV and VI
The multi-country study conducted by Esrey (1996) provided data to allow calculation of relative risks between scenarios IV, Va, Vb and VI. This study examined whether incremental health effects relating to diarrhoea and nutritional status resulted from incremental improvements in water and sanitation conditions and was based on DHS from eight countries from five different regions (Bolivia, Burundi, Ghana, Guatemala, Morocco, Sri Lanka, Togo, Uganda). DHS included information on diarrhoea prevalence, child weight, child height, child age, source of drinking water and type of sanitation facility. In addition, the survey data were supplemented by field studies that determined current levels of diarrhoea prevalence in children aged 3-36 months. According to this study, a reduction of $20.8 \%$ in diarrhoeal disease rates $(R R=1.26)$ could be observed when progressing from scenario VI to Vb (i.e. when providing an improved water supply), and $37.5 \%(R R=1.6)$ when progressing from VI to Va (i.e. when providing improved sanitation facilities). When progressing from VI to IV (i.e. when providing both an improved water

Table 16.5 Relative risks

|  | Exposure categories or transition between scenarios |  |  |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | 1 | 11 | III | IV | Va (to IV) | Vb (to IV) ${ }^{\text {a }}$ | $\begin{gathered} \text { VI (to } \\ \text { Vb) } \\ \hline \end{gathered}$ | VI (to Va and IV) |

abtained by calculating the remaining risk differences between VI to Vb as compared to VI and IV .
b Relative to the scenario below.
c See text
supply and improved sanitation facilities), a reduction of $37.5 \%$ was also achieved. This implies that no further reduction in diarrhoeal disease is achieved when implementing an improved water supply, when improved sanitation is already available. These data are supported by the review of Esrey et al. (1991), which provides similar results for the same types of interventions.

The resulting relative risks are obtained by multiplying the relative risks between each scenario, summarized in Table 16.5.

According to our model, the risks of diarrhoea incidence in developing countries are 2.8 to 4.4 times higher (Table 16.5) than current risks in developed countries. The same order of magnitude of difference in diarrhoea rates was reported by various compilations of health statistics or studies (Esrey 1996; Murray and Lopez 1996b).

### 2.3 Estimating risk factor-Disease relationships for diseases other than diarrhoeal diseases

The World bealth report 2001 (WHO 2001) provided estimates of the burden of additional diseases that are exclusively (or virtually exclusively) caused by unsafe WSH (Table 16.6).

### 2.4 Sources of uncertainty

## METHOD

The method is based on typical scenarios, characterized by a combination of sub-risk factors, which should represent most of the world's situations. Certain population groups may not be captured by any one of these scenarios, but the number of groups is probably small, which may

Table 16.6 Global disease burden caused by selected water-related diseases other than infectious diarrhoea in 2000

| Disease | Deaths (000s) | DALYs (000s) |
| :--- | :---: | :---: |
| Schistosomiasis | 11 | 1713 |
| Trachoma | 0 | 1161 |
| Ascariasis | 6 | 1252 |
| Trichuriasis | 2 | 1640 |
| Hookworm disease | 6 | 1829 |
| Total | 25 | 7595 |
| Source: WHO (200I). |  |  |

be partly internalized in the risk estimates. For example, differences are likely to exist in the specific WSH practices in the various households in the same exposure scenario. The effect of these differences should, however, largely be captured in the large samples on which this study is based. The current study is therefore based on average risks for large population groups within which a variety of individual practices and situations are represented.

## Exposure estimates

The Water Supply and Sanitation Assessment 2000, which reports individual country data, exhibited variable precision between respondents, particularly in relation to rural and tribal populations. A more precise exposure estimate would require actual assessments, such as the water quality of the supply. Such measures are impractical on a large level. The Assessment 2000, however, captures exposure information for a majority of the world's countries and represents a solid source of information. Uncertainty in water supply and sanitation coverage has therefore not introduced major uncertainty into our analysis.

## RISK ESTIMATES

This analysis used large surveys and multi-country studies where available. It is therefore based on risk averages, i.e. the average of risk related to the described scenarios across the world and across an array of situations. While this method may not be suitable for specific local settings, it should provide a reasonable estimate for large regions.

Where no large surveys, reviews or multi-country studies were available (i.e. in part the transition between scenarios IV and II), the use of sentinel studies for "global" application may constitute a significant source of error. Therefore, this analysis has been selective on the basis of study quality and coverage, to ensure maximum transferability.

As much of the described imprecision will remain largely unquantifiable, upper and lower uncertainty boundaries are based on varying the

Table 16.7 Low and high relative risk estimates

|  | Exposure scenario |  |  |  |  |  |  |
| :--- | ---: | ---: | ---: | ---: | ---: | ---: | ---: |
|  | I | $I I$ | $I I I$ | $I V$ | $V a$ | $V b$ | VII |
| Lower estimate | I | 2.5 | Variable | 3.8 | 3.8 | 4.9 | 6.1 |
| Best estimate | I | 2.5 | Variable | 6.9 | 6.9 | 8.7 | 11.0 |
| Upper estimate | I | 2.5 | Variable | 10.0 | 10.0 | 12.6 | 16.0 |

estimates of the potentially greatest source of uncertainty-the transition between scenarios IV and II (i.e. from an environment with a high faecal-oral pathogen load to one with a low faecal-oral pathogen load). The lower estimate was based solely on the improvement that can be achieved by implementing personal hygiene measures ( $35 \%$ risk reduction or a RR of 1.54). This is comparable with the best estimate, which is based on a combination of improved water quality and improved hygiene (see Table 16.5). For the upper estimate, the additional risk reduction relating to the provision of continuous piped water supply (i.e. improved access to water) was considered in addition to hygiene improvements. This is represented by a relative risk of 2.6 (from a $62 \%$ risk reduction from the study by Semenza et al. 1998) in addition to that resulting from hygiene improvements. The resulting relative risks for each of the estimates are summarized in Table 16.7.

The same relative risk is assumed for all age groups. As most of these rates have been assessed for children and the largest disease burden also occurs in that age group, the error of applying the same relative risks to adults is probably small. Also, several studies that have assessed both relative risks for children and adults have shown that figures do not generally differ dramatically, although the impact on young children tends to be higher (e.g. Quick et al. 1999).

It should be noted that faecal-oral disease transmission is partly conditioned by the prevalence of the risk factor at community level. For example, protection of drinking water depends on the effective implementation of an intervention by all members of the community, whereas studies have often been performed at individual level, generally resulting in underestimation of the benefits of community-wide interventions.

## SEQUELAE AND DELAYED EFFECTS

Estimation of the burden of disease due to infectious diarrhoea is based upon the acute diarrhoeal episode and associated mortality. Several of the agents of infectious diarrhoea are associated with other health effects, often delayed. These may add significantly to the burden of disease, as is the case of campylobacteriosis, for example. Inadequate evidence was available to reliably estimate the additional burden of disease.

## 3. Results

The attributable fractions, deaths and number of DALYs are listed in the annex tables (see CD-ROM accompanying this book), for the 14 subregions, males, females and eight age groups.

Globally, in the year 2000, almost 1.73 million deaths due to diarrhoeal diseases were attributable to unsafe WSH as defined in the exposure variable used in this work; $68 \%$ of them are children. Most of these deaths, $>99 \%$, occur in developing countries. The attributable fractions of diarrhoeal disease vary between $60 \%$ in developed countries to $85-90 \%$ in developing countries. The difference in disease burden between developed and developing subregions, despite the relative similarities in attributable fractions, is largely due to the lower incidence and case fatality rates of diarrhoeal disease in developed nations. The African subregions alone, together with SEAR-D and EMR-D, bear $88 \%$ of the death burden. The disease burden in males and females is similar. The disease burden from the five other diseases that have been quantified separately is 25000 deaths and 7.6 million DALYs, also concentrated in developing countries. This chapter highlights and confirms the concentration of the burden of disease due to the risk factor unsafe WSH in poor countries and on children- $99.7 \%$ of DALYs and $99.8 \%$ of deaths occur in developing countries, with $80 \%$ of DALYs among children. Globally, $3.1 \%$ of all deaths and $3.7 \%$ of DALYs were attributable to water, sanitation and hygiene, caused by the diseases we could include in this analysis. In the age group 0 to 4 years, these percentages amounted to $11 \%$ of all deaths and $9 \%$ of all DALYs, which shows the importance of this risk factor.

## 4. Projections of future exposure

As the methods for estimating disease burden rely heavily on water supply and sanitation coverage, these are the main parameters that need to be projected for estimating future burden. Progress with water supply and sanitation coverage is affected by factors such as demographic change, income, policies and investments, education, technology, types and management of infrastructure, and involvement of the community and the public and private sectors. In practice, these vary widely within and between countries, making future projections difficult and complex.

To some extent these factors respond to major national and international policy initiatives. The International Drinking-water Supply and Sanitation Decade (1981-1990) established momentum that certainly produced an acceleration of investments from 1981 to 1990 and beyond this period. The Millennium Declaration established the targets of halving the proportion of the population not served with safe water supply by 2015 and improving sanitation for the urban poor. The impact of these historic and future activities on either overall progress with service levels or upon the factors outlined above is difficult to assess. The
proposed coverage forecast method and respective coverage figures generated are presented below.

While efforts are ongoing to develop a model for forecasting improved water supply and sanitation coverage based upon understanding of the factors outlined above, the lack of sufficient data has limited the value of this in preparing future projections. Water supply and sanitation coverage may be predicted by certain distal causes such as income and education; however, in the given time frame a prediction based on past evolution and future demographic changes was preferred. Prediction on the basis of the Human Development Index provided similar results at global level. Global data sets on service coverage generated by WHO in the 1980s were primarily based on country reporting and provided results with limited comparability. More recently, WHO and UNICEF have assessed water supply and sanitation coverage in 1990 and 2000 (WHO/UNICEF/WSSCC 2000), based on household survey data and data by service providers (water agencies, ministries) in the absence of survey data. This shift in methodology provided more reliable and comparable data. The prediction was thus based on the following points.

- It was assumed that the same number of people that acquired coverage between 1990 and 2000 would acquire coverage per decade during the next three decades.
- Population projections from the United Nations Statistics Division (UN 2001) were used.
- For EUR-B and EUR-C, progress in the decade 1990-2000 shows declining trends and does not provide a reasonable basis for projection. Zero change in absolute numbers served was assumed.

It is important to note that this projection assumes that local, national and international efforts as undertaken in the last decades, will continue. The method further assumes no development of approaches or technologies that will enable a shift for part of the population into exposure scenario I, the ideal scenario.

Coverage was projected separately for each subregion. A summary of projected water supply and sanitation coverage is provided in Table 16.8, and a detailed projection per subregion, according to the exposure scenarios used in this analysis, is presented in Table 16.9.

The data presented suggest that the water supply goal and target ${ }^{3}$ adopted in the Millennium Declaration are likely to be achieved globally if a similar effort as compared to that undertaken in the last decade is continued until the year 2015. For certain subregions, however, the target may not be achieved, namely those in the African continent, as well as EMR-B (where coverage is already high and where half of the population are likely to experience an important risk reduction), EURB and EUR-C, under the assumption that past trends will continue.

Table 16.8 Global projection of water supply and sanitation coverage

| Year | Total population (millions) | Access to improved water sources |  |  | Access to improved sanitation |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  |  | Population served (millions) | $\begin{gathered} \% \\ \text { served } \end{gathered}$ | Population not served (millions) | Population with access (millions) | \% having access | Population without access (millions) |
| 1990 | 5255 | 4072 | 77 | 1183 | 2582 | 49 | 2673 |
| 2000 | 6057 | 4976 | 82 | 1081 | 3646 | 60 | 2411 |
| 2010 | 6826 | 5894 | 86 | 932 | 4739 | 69 | 2087 |
| 2015 | 7207 | 6353 | 88 | 854 | 5285 | 73 | 1922 |
| 2020 | 7579 | 6802 | 90 | 777 | 5831 | 77 | 1748 |
| 2030 | 8270 | 7681 | 93 | 589 | 6902 | 83 | 1368 |

It is not always possible to see clear trends within scenarios. This is likely to be due to highly variable rates of population growth and movement of populations between scenarios. Greatest health gains are likely to be associated with movement of populations from scenario VI to better circumstances. AFR-D and AFR-E contain the highest proportion of population in scenario VI. The forecasts indicate that the situation is not likely to change dramatically over the next 30 years if the trends of the last decade continue.

SEAR-D and WPR-B present large proportions of their population with fairly good levels of coverage but relatively low proportions of people served with sanitation facilities (scenario Vb ). AMR-A, EUR-A, and WPR-A have reached or will soon reach $100 \%$ coverage (scenario II). SEAR-B and AMR-B are projected to make good progress, tending from exposure scenarios Vb and VI to IV and II. AMR-D, in addition to developing a trend similar to the trend above is likely to make considerable progress towards scenario II. EUR-C should experience a large shift into scenario II (two large countries that were close to full coverage in 1990 will reach such status by 2010).

## Sources of error/SENSITIVITY analysis

Factors such as water scarcity, competition for water resources and the cumulative effects of pollution of water resources are likely to both increase the cost of interventions and reduce their sustainability. This is due to pressures on both the quality and availability of water resources and would suggest that the projections might be optimistic estimates.

## Notes

1 The scenarios are equivalent to exposure categories used in other chapters in this book, in the sense that there is increasing risk across scenarios defined based on faecal-oral load. The term scenario is used here, as the shift from one level of faecal-oral load to another may occur due to changes in any of the multiple dimensions of exposure (water, sanitation and hygiene).
2 See the preface for an explanation of this term.
3 To halve the proportion of people not having access to water supply services by 2015 compared to 1990 .

## Chapter I7

# URBAN AIR POLLUTION 

Aaron J. Cohen, H. Ross Anderson, Bart Ostro, Kiran Dev Pandey, Michal Krzyzanowski, Nino Künzli, Kersten Gutschmidt, C. Arden Pope III, Isabelle Romieu, Jonathan M. Samet and Kirk R. Smith

## Summary

Current scientific evidence, derived largely from studies in North America and Western Europe (NAWE), indicates that urban air pollution, ${ }^{1}$ which is derived largely from combustion sources, causes a spectrum of health effects ranging from eye irritation to death. Recent assessments suggest that the impacts on public health may be considerable. This evidence has increasingly been used by national and international agencies to inform environmental policies, and quantification of the impact of air pollution on public health has gradually become a critical component in policy discussions as governments weigh options for the control of pollution.

Quantifying the magnitude of these health impacts in cities worldwide, however, presents considerable challenges owing to the limited availability of information on both effects on health and on exposures to air pollution in many parts of the world. Man-made urban air pollution is a complex mixture with many toxic components. We have chosen to index this mixture in terms of particulate matter (PM), a component that has been linked consistently with serious health effects, and, importantly, levels of which can be estimated worldwide. Exposure to PM has been associated with a wide range of effects on health, but effects on mortality are arguably the most important, and are also most amenable to global assessment. Our estimates, therefore, consider only mortality. Currently, most epidemiological evidence and data on air quality that could be used for such estimates comes from developed countries. We have had, therefore, to make assumptions concerning factors such as the transferability of risk functions, exposure of the population and their underlying vulnerability to air pollution, while trying to ensure that these assumptions are transparent and that the uncertainty associated with them is assessed through appropriate sensitivity analyses.

In order to provide estimates for all 14 subregions, ${ }^{2}$ models developed by the World Bank were used to estimate ambient concentrations of inhalable particles (particulate matter with an aerodynamic diameter of $<10 \mu \mathrm{~m}, \mathrm{PM}_{10}$ ) for PM in 3211 national capitals and cities with populations of $>100000$ using economic, meteorological and demographic data and the available measurements. To allow the most appropriate epidemiological studies to be used for the estimation of the burden of disease, the estimates for $\mathrm{PM}_{10}$ were converted to estimates of fine particles (particulate matter with an aerodynamic diameter of $<2.5 \mu \mathrm{~m}$, $\mathrm{PM}_{2.5}$ ) using available information on geographic variation in the ratio of $\mathrm{PM}_{2.5}$ to $\mathrm{PM}_{10}$. Population-weighted subregional annual average concentrations of $\mathrm{PM}_{2.5}$ and $\mathrm{PM}_{10}$ were obtained using the population of the cities in the year 2000 .

Our estimates of the burden of disease were based on the contributions of three health outcomes: mortality from cardiopulmonary disease in adults, mortality from lung cancer, and mortality from acute respiratory infections (ARI) in children aged $0-4$ years. Numbers of attributable deaths and years of life lost (YLL) for adults and children (aged 0-4 years) were estimated using risk coefficients from a large cohort study of adults in the United States of America (Pope et al. 2002) and a metaanalytical summary of five time-series studies of mortality in children, respectively. Base-case estimates were calculated assuming that the risk of death increases linearly over a range of annual average concentrations of $\mathrm{PM}_{2.5}$, between a counterfactual (or referent) concentration of $7.5 \mu \mathrm{~g} / \mathrm{m}^{3}$ and a maximum of $50 \mu \mathrm{~g} / \mathrm{m}^{3}$.

The results indicate that the impact of urban air pollution on the burden of disease in the cities of the world is large, but this is likely to be an underestimate of the actual burden, on the basis of an assessment of sources of uncertainty. There is also considerable variation in our estimates among the 14 subregions, with the greatest burden occurring in the more polluted and rapidly growing cities of developing countries. We estimated that air pollution in urban areas worldwide, in terms of concentrations of PM, causes about $3 \%$ of mortality attributable to cardiopulmonary disease in adults, about $5 \%$ of mortality attributable to cancers of the trachea, bronchus and lung, and about $1 \%$ of mortality attributable to ARI in children. This amounts to about 0.80 million premature deaths ( $1.4 \%$ of the global total) and 6.4 million YLL $(0.7 \%$ of the global total). This burden occurs predominantly in developing countries, with $39 \%$ of attributable YLL occurring in WPR-B and $20 \%$ in SEAR-D. The highest proportions of the total burden occurred in WPRB and EUR-B, where urban air pollution caused $0.7-1.0 \%$ of the burden of disease.

We quantified the statistical uncertainty of our base-case estimates by estimating the joint uncertainty in the estimates of annual average concentration of PM and the estimates of the relative risks. Estimates worldwide and for most subregions vary by less than two-fold (50\%
uncertainty interval). Model uncertainty due to assumptions about the shape of the concentration-response function, the choice of counterfactual level for PM, and other factors were assessed in sensitivity analyses. For the most part, the worldwide estimates in each sensitivity case are within the $50 \%$ uncertainty intervals for the base-case estimates. The sensitivity analyses indicate that our base-case estimates were most sensitive to our choice of concentration-response function and theoretical level of minimum exposure.

## 1. Introduction

The potential for serious consequences of exposure to high levels of ambient air pollution was made clear in the mid-20th century, when cities in Europe and the United States experienced episodes of air pollution, such as the infamous London Fog of 1952 and Donora Smog of 1948, that resulted in large numbers of excess deaths and hospital admissions. Subsequent clean air legislation and other regulatory actions led to the reduction of ambient air pollution in many regions of the world, and particularly in the wealthy developed countries of North America and Europe. New epidemiological studies, however, conducted over the last decade, using sensitive designs and methods of analysis, have identified adverse health effects caused by combustion-derived air pollution even at the low ambient concentrations that now generally prevail in cities in North America and western Europe (Health Effects Institute 2001). At the same time, the populations of the rapidly expanding mega-cities of Asia, Africa and Latin America are increasingly exposed to levels of ambient combustion-related pollution that rival and often exceed the levels experienced in developed countries in the first half of the 20th century. Current scientific evidence, derived largely from studies in North America and western Europe, indicates that urban air pollution causes a spectrum of effects on health, ranging from eye irritation to death (Anonymous 1996a, 1996b). Recent assessments suggest that the impacts on public health may be considerable (Brunekreef 1997; Cifuentes et al. 2001; COMEAP 2001; Künzli et al. 2000; Ostro and Chestnut 1998). This evidence has increasingly been used by national and international agencies to inform environmental policies, and quantification of the impact of air pollution on public health has gradually become a critical component in policy discussions as governments weigh options for the control of pollution.

Quantifying the magnitude of the impact of air pollution in cities worldwide, however, presents considerable challenges owing to the limited availability of information on both effects on health and on exposures to air pollution in many parts of the world. Measurements of urban air pollution, when available, are available largely for a nonrepresentative sample of urban areas. Many areas of the world lack measurements of any kind, and these must then be estimated using
statistical models (see below). On the basis of these considerations, we defined the target population for this risk assessment exercise as the residents in the year 2000 of national capital cities and of cities worldwide with populations of $>100000$.

Man-made urban air pollution, which is derived largely from combustion processes, is a complex mixture containing many toxic components. We indexed this mixture in terms of PM, a component that has been consistently linked with serious effects on health, and, importantly, the levels of which can be estimated worldwide. Exposure to PM has been associated with a wide range of effects on health, but its effects on mortality are arguably the most important, and are also most amenable to global assessment. Our estimates, therefore, consider only mortality. Currently, most epidemiological evidence and data on air quality that could be used for such estimates come from developed countries. We have had, therefore, to make assumptions concerning factors such as the transferability of risk functions, exposure of the population and their underlying vulnerability to air pollution, while trying to ensure that these assumptions are transparent and that the uncertainty associated with them is assessed through appropriate sensitivity analyses.

The general framework for estimating the global burden of disease attributable to specific risk factors is described in chapters 1 and 25. Briefly, the approach involves estimating an attributable fraction(s) for each risk factor in each of the 14 subregions of the world. Estimating the attributable fraction for urban air pollution requires several steps. First, the exposure to urban air pollution of the population of each subregion must be estimated. Second, a theoretical minimum level of exposure must be specified. The attributable fraction quantifies the impact of exposure above this theoretical minimum level. Finally, deriving the attributable fraction requires the estimation of the gradient of risk between the theoretical minimum level and the estimated subregional exposure. These risk functions are derived from epidemiological studies for the purposes of estimating the global burden of disease. As discussed below, epidemiological studies generally estimate exposure to air pollution in terms of ambient concentrations, thus, we use the term "concentration-response" (rather than "exposure-response") to describe the risk function.

This chapter describes our approach to estimating the attributable fraction and presents our estimates of the attributable burden of disease caused by urban air pollution. First, we briefly review background information on exposure to air pollution and then describe our choice of the theoretical minimum level and the approach to estimating the exposure to PM of the populations of the world's cities. Next, we review the current information on the effects of air pollution on health and describe our approach to deriving the concentration-response function(s). Finally, we present and discuss our estimates of the attributable burden and their uncertainties.

## 2. Exposure to Urban air pollution from COMBUSTION SOURCES

Combustion of fossil fuels for transportation, power generation, and other human activities produces a complex mixture of pollutants comprising literally thousands of chemical constituents (Derwent 1999; Holman 1999). Exposure to such mixtures is a ubiquitous feature of urban life. The precise characteristics of the mixture in a given locale depend on the relative contributions of the different sources of pollution, such as vehicular traffic and power generation, and on the effects of the local geoclimatic factors. The relative contribution of different combustion sources is a function of economic, social and technological factors, but all mixtures contain certain primary gaseous pollutants, such as sulfur dioxide $\left(\mathrm{SO}_{2}\right)$, nitrogen oxides $\left(\mathrm{NO}_{\mathrm{x}}\right)$ and carbon monoxide (CO), that are emitted directly from combustion sources, as well as secondary pollutants, such as ozone $\left(\mathrm{O}_{3}\right)$, that are formed in the atmosphere from directly-emitted pollutants. The pollutant mixture also contains carcinogens such as benzo( $\alpha$ )pyrene, benzene and 1,3 -butadiene. When petrol contains lead $(\mathrm{Pb})$, as is still the case in many developing countries, this element is a common constituent of the pollution mix, assessed in a separate chapter in this volume (chapter 19).

All combustion processes produce particles, most of which are small enough to be inhaled into the lung either as primary emissions (such as diesel soot), or as secondary particles via atmospheric transformation (such as sulfate particles formed from the burning of fuel containing sulfur). Their concentrations (in micrograms per cubic metre, or $\mu \mathrm{g} / \mathrm{m}^{3}$ ) are generally measured as inhalable and fine particles, $\mathrm{PM}_{10}$ and $\mathrm{PM}_{2.5}$, respectively. ${ }^{3}$ However, the total suspended particle mass (TSP) is still the only particle measurement available in many developing countries (Krzyzanowski and Schwela 1999).

Pollution from the combustion of fossil fuels is largely emitted into the outdoor air, but human exposure occurs both indoors and outdoors (Ozkaynak 1999). An individual's exposure to ambient urban air pollution depends on the relative amounts of time spent indoors and outdoors, the proximity to sources of ambient air pollution, and on the indoor concentration of outdoor pollutants. The indoor concentrations depend on factors such as the circulation of the indoor air and the degree to which constituents of the outdoor combustion mixture penetrate and persist in the indoor environment. Studies conducted largely in Europe and North America have shown that the fine particles generated from combustion outdoors both effectively penetrate and persist in many indoor environments. Gases, such as sulfur dioxide and ozone, may penetrate the indoor environment, but generally do not persist because of their reactivity. In some rural areas of developing countries, indoor cooking on unvented coal- or biomass-burning stoves is the most significant exposure to pollution from combustion sources. The burden of disease caused by
such exposure is addressed in chapter 18. The actual dose delivered to the lung or other organs will further depend on the type of pollutant, the breathing pattern and physical characteristics of the individual that determine the extent and site of deposition.

Governments in many parts of the world monitor ambient concentrations of air pollution as part of regulatory programmes designed to protect public health and the environment (Grant et al. 1999). The most extensive monitoring systems are in the United States and western Europe, where regular monitoring of ambient air quality has been in place since the mid-1970s. The most frequently and routinely monitored air pollutants include sulfur dioxide ( $\mathrm{SO}_{2}$ ), nitrogen oxides ( $\mathrm{NO}_{\mathrm{x}}$, including NO and $\mathrm{NO}_{2}$ ), carbon monoxide ( CO ), ozone $\left(\mathrm{O}_{3}\right)$, lead $(\mathrm{Pb})$, black smoke (BS) or soot, and PM. National monitoring systems also exist in other parts of the world, but access to the data collected by these systems and international standardization of the monitoring methods are limited. The World Health Organization (WHO) Air Management Information System (AMIS) (WHO 2001c) collects the available information, but the reporting from many regions is poor, and for some regions there are no data in the WHO database. The various designs of the networks, differences in monitoring objectives and limited availability of the collected data for the outside users limit access to the information on population exposure in the greater proportion of the world's cities. In some parts of the world (e.g. in most of the countries of the former Soviet Union), the monitoring systems exist but do not provide the data necessary for assessment of the impact on health (Krzyzanowski and Schwela 1999). More details about the data available for this analysis are provided in further sections of this chapter.

These monitoring systems currently provide much of the data on exposure to urban air pollution that have been used in epidemiological research, although some studies establish their own monitoring networks when routinely-collected data are either unavailable or of poor quality, or to measure specific air pollution constituents, such as specific known carcinogens. Typically, monitoring sites are located in the city centre or throughout a given metropolitan area, in order to more accurately reflect the average residential exposure of the population. The data from monitors sited so as to measure emissions from specific sources, such as a local industry or heavy vehicular traffic, are frequently excluded from the data sets, as they may significantly deviate from the average levels of exposure experienced by the population.

Exposure estimates that rely exclusively on data from one or more stationary monitoring sites may provide inaccurate estimates of the short- and/or long-term average personal exposures of study populations (Navidi and Lurmann 1995; Zeger et al. 2000). The direction and magnitude of the errors that will be induced in estimates of the relative risk attributable to exposure to air pollution depend on the precision of the air quality monitoring data (or models used to generate the estimates of
the concentration of pollution), the applicability of one estimate to the entire target population and the correlation of the errors with the health outcome. Generally, such errors will be smaller for pollutants that tend to be uniformly distributed over large urban areas, and that penetrate efficiently indoors, both of these features being the case for fine PM produced by combustion. If the errors in the estimates of exposure are uncorrelated with the risk of the health outcome, then the estimates of relative risk attributable to air pollution will, in most cases, be too low (i.e. biased to the null) (Navidi and Lurmann 1995).

### 2.1 Definition of the air pollution metric for exposure variable

We selected $\mathrm{PM}_{10}$ and $\mathrm{PM}_{2.5}$ as the indicators of exposure to urban air pollution from combustion sources. As noted above, PM is a ubiquitous component of the mixtures emitted into, and formed in, the ambient environment by combustion processes, and indicates the presence of these mixtures in outdoor air. Most importantly, these measures of particulate air pollution have been used in many epidemiological studies from around the world, of both mortality and morbidity of air pollution, and so provide the best overall indicator of exposure for our purposes (see section 3). Although other components of ambient air pollution from combustion sources are associated with these and other effects on health (Anonymous 1996a, 1996b), particulate air pollution has been found to be consistently and independently related to the most serious effects of air pollution, including daily and longer-term average mortality (California Air Resources Board 2002; Health Effects Institute 2001; U.S. Environmental Protection Agency 2002; WHO 2000a, 2003). There is some evidence, although much less than that for PM, linking ozone to premature mortality, particularly during the summer months (Abbey et al. 1999; Health Effects Institute 2000b). However, despite recent progress in developing models to estimate tropospheric (ground-level) ozone on a global scale, it was not currently feasible to derive the subregional estimates that would have been required for this project. In many developing countries, exposure to lead in the ambient air may also be of great consequence, having effects on mortality perhaps via effects on blood pressure. The impacts of lead in outdoor air are dealt with in chapter 19.

PM has been linked to serious effects on health after both short-term exposure (days to weeks), and more prolonged exposure (years), although there remains some uncertainty as to the distribution of induction times with regard to mortality (see below). We chose the annual average concentration(s) of PM as the exposure metric(s) because it corresponds to the time-scales of a priori interest for estimates of attributable and avoidable burden in the Global Burden of Disease (GBD) project, and because it was used to estimate the effects of exposure to PM in the key epidemiological study that provides our estimates of the concentration-response function.

### 2.2 Estimation of annual average concentrations of particulate matter

## Air pollution measurements used in estimating annual AVERAGE CONCENTRATIONS

The availability of measurements of ambient concentrations of PM varies widely across the globe, making estimation of annual average concentrations a considerable challenge (Krzyzanowski and Schwela 1999). To estimate ambient PM concentrations for all 14 subregions, we used a model (Global Model of Ambient Particulates [GMAPS]) recently developed at the World Bank to estimate concentrations of $\mathrm{PM}_{10}$ in cities, on the basis of available measurements of PM at population-oriented monitoring sites (Pandey et al. forthcoming). The model incorporates information on factors such as fuel mix, level of economic development, demographics and weather, in order to predict ambient concentrations of $\mathrm{PM}_{10}$ in urban residential areas. These estimates of $\mathrm{PM}_{10}$ were converted to $\mathrm{PM}_{2.5}$ using available information on geographic variation in the ratio of $\mathrm{PM}_{2.5}$ to $\mathrm{PM}_{10}$. For each PM metric, the population-weighted subregional annual average was derived using the population of each city within each subregion in the year 2000.

The GMAPS model developed at the World Bank can be used to generate estimates of concentrations of $\mathrm{PM}_{10}$ in all world cities with populations of $>100000$, and in national capitals. The estimation model is based on available measurements of $\mathrm{PM}_{10}$ and TSP from population-oriented monitoring stations in cities worldwide for the period 1985 to 1999, retrieved in October 2001. In all cases, data from a monitoring site were included if and only if it was clearly identified as a residential or mixed residential site (see section 2.3 for definition). For instance, city averages reported for many Chinese cities (National Environmental Protection Agency of China 2000) were not included in the model estimation because the location of these sites could not be ascertained.

In principle, the monitoring data used for calculation of annual averages should be collected throughout the year, since seasonal patterns in the data are fairly common. More than $85 \%$ of cities in Europe and the United States collect measurements of PM throughout the year. The representativeness of the data for cities in other parts of the world could not be confirmed. In addition, in many countries where PM was measured throughout the year, it was only measured on every sixth day. The methods for measuring concentrations of PM also varied, both gravimetric and automatic methods (tapered element oscillating microbalance monitors [TEOMS] or beta gauge monitors) being included.

Most of the data on annual average ambient concentrations used in the model come from AMIS (WHO 2001c). This information is submitted to WHO by national environmental agencies and air quality control authorities, which perform these measurements using nationally
approved methods and standards of data quality. The data set contains the annual mean concentration of selected air pollutants, including PM, by monitoring site. Additional data, such as 95 th percentiles of daily means, are also available for some sites. Although WHO requests that all Member States provide data for compilation in the AMIS database, the reported data are still limited because many countries do not have air quality monitoring networks. Additionally, some countries with monitoring networks may not report the data because of poor data quality or limited ability to process and report the data.

The data from AMIS were supplemented with other sources of data on TSP and $\mathrm{PM}_{10}$ from monitoring sites. These included data for European cities collected by WHO/European Centre for Environment and Health (ECEH) for the Health Impact Assessment of Air Pollution (HIAAP) project in 1999 from both national and local environmental agencies (WHO 2001a), data for Canadian cities provided by Environment Canada (www.ec.gc.ca) and statistics Canada (http://www.statcan.ca/english/ads/cansimII/index.htm), and data for cities in the United States from the U.S. Environmental Protection Agency AIRS database (Aerometric Information Retrieval System 2001). Data for Chinese cities were also obtained from the Environmental Quality Reports from China (National Environmental Protection Agency of China 2000), and Mexican cities from the Instituto Nacional de Ecología (INE), SEMARNAP, Mexico (Instituto Nacional de Ecología 2000). Additional data were also obtained from the World Bank URBAIR studies of air pollution in Jakarta and Kathmandu (Grønskei et al. 1997a, 1997b). To limit undue influence of the data from cities in the United States, data used from the United States AIRS database were limited to the years 1996-1999.4

Measured annual average concentrations of $\mathrm{PM}_{10}$ and TSP data from monitoring sites were available for 512 unique locations in 304 cities in 55 countries over the period 1985-1999, and provided 1997 timelocation data points. For some sites and years, data on both TSP and $\mathrm{PM}_{10}$ were available, yielding a total of 2344 individual observations. ${ }^{5}$ The number of cities with measured data on PM from monitoring sites in each subregion and for each year by PM measure is shown in Table 17.1. A total of 304 cities reported either the annual average concentrations of $\mathrm{PM}_{10}$ or TSP for at least 1 year between 1985 and 1999. Of these, 51 cities reported both $\mathrm{PM}_{10}$ and TSP while 165 cities, mostly in North America and western Europe, reported $\mathrm{PM}_{10}$ only, and the remaining 88 cities reported data for TSP only.

Coverage of cities and populations with data from monitoring sites varies significantly across different subregions (Figure 17.1). For instance, data from monitoring were available for fewer than two cities for six of the subregions, AFR-D, AFR-E, AMR-D, EMR-B, EMR-D and SEAR-B. In contrast, data from monitoring sites were available for 218 cities in NAWE, of which 174 report data on $\mathrm{PM}_{10}$. The 304 world cities

with data from monitoring account for $9 \%$ of the total number of cities with a population of $>100000$ worldwide and have a combined population in the year 2000 of around 559 million, or about $28 \%$ of the global urban population (Table 17.2).

## Global Model of Ambient Particulates (GMAPS)

The GMAPS model econometrically estimates a fixed-effect model of the concentrations of urban ambient PM using the latest available data from WHO and other sources, as outlined above. The estimating Equation 1 focuses on the anthropogenic sources of pollution and the capacity of the natural environment to generate, disperse and dissipate pollutants. ${ }^{6}$ Its determinants include the scale and composition of economic activity, the energy mix, the strength of local regulation of pollution, and geographic and atmospheric conditions that affect the transport of pollutants.

$$
\begin{align*}

where
$C_{i j k t}=\log$ of concentration of PM in monitoring station $i$, city $j$, country $k$, at time $t$
$Z_{k}=$ binary variable for country $k$
$E_{f k t}=\log$ of per capita energy consumption of energy source type $f$ for country $k$ at time $\mathrm{t}(\mathrm{f}=1 \ldots F)$
$M_{g j k}=\log$ of meteorological/geographic factor $g$ for city $j$, country $k$ (factors $g=1 \ldots G 1$ affect $\mathrm{PM}_{10}$ concentration in a different way than TSP concentration. Factors $g=G 1+1 \ldots G 2$ do not make a distinction between $\mathrm{PM}_{10}$ and TSP)
$R_{k t}=\log$ of population density of country $k$ at time $t$
$N_{j k t}=\log$ of population of city $j$, country $k$, at time $t$
$D_{j k}=\log$ of local population density in the vicinity of city $j$ in country $k$

Scale $_{j k t}=\log$ of scale of economy (intensity of economic activity) for city $j$, country $k$ at time $t$
$\mathrm{Y}_{\mathrm{kt}}=\log$ of income per capita (1-year lagged 3-year moving average) of country $k$ at time $t$
$\operatorname{Trend}_{\mathrm{ijkt}}=$ time trend $(1985=1,1986=2, \ldots 1999=15)$
$\mathrm{S}_{\mathrm{ijkt}}=$ binary variable for PM type measured at monitoring station $i$, city $j$, country $k$, at time $t,\left(1=\mathrm{TSP}, 0=\mathrm{PM}_{10}\right)$, and
the $\beta_{S}$ and $\theta_{S}$ are the parameters that are estimated by the model.
Equation 1 jointly determines the concentrations of total suspended particulate matter (TSP) and inhalable particulates ( $\mathrm{PM}_{10}$ ) in residential areas. Most cities in developing countries only monitor TSP and not $\mathrm{PM}_{10}$. Adoption of the pooled specification permits use of all available data and provides better information about the concentrations of PM, especially for cities in developing countries. Limiting the estimation sample to $\mathrm{PM}_{10}$ observations is sensible only if knowledge of the concentration of TSP in a city makes no contribution to predicting $\mathrm{PM}_{10}$. Since $\mathrm{PM}_{10}$ comprises the smaller size particles within TSP, this assumption is clearly unreasonable. The pooled specification allows for separate estimation of concentrations of $\mathrm{PM}_{10}$ and TSP for each city by setting the binary variable, $S_{i j k t}$, equal to zero or one, as shown in Equations 2 and 3.

$$
\begin{gather*}
\log \left[P^{\prime 2} 0_{i j k t}\right]=\sum_{k=1}^{K} \beta_{k} Z_{k}+\sum_{f=1}^{F} \beta_{E f} E_{f k t}+\sum_{g=1}^{G 2} \beta_{M g} M_{g j k}+\beta_{R} R_{k t}+\beta_{N} N_{j k t}  \tag{2}\\
\quad+\beta_{D} D_{j k}+\beta_{S c a l e} \text { Scale }_{j k t}+\beta_{Y} Y_{k t}+\beta_{T} \text { Trend }_{i j k t}+\beta_{Y T} Y_{k t} \text { Trend }_{i j k t}

\end{aligned}
$$

To reduce undue influence from extreme values, all of the continuous variables in the model were specified in log form and each exogenous variable in the estimation sample was truncated to the middle $98 \%$ range observed in the estimation sample.

The estimation Equation 1 includes country-specific binary variables, $Z_{k}$, to control for economic, social and natural factors that are not captured by the other explanatory variables. These include differences in the quality of the data on ambient concentration and in collection methods across countries, the degree of regulatory heterogeneity within a country, the relative importance of intercity transport, proximity of and pollution levels in neighbouring cities and the composition of economic activity. The country-specific binary variables measure the average concentration of PM in each country during the 15 -year period 1986-1999, controlling for variations within the country caused by factors accounted for in the remainder of the estimating Equation 1. In contrast, the rest of the estimation model (1) explains the marginal contribution of the included factors to deviations in the ambient concentration in the city from this average.

The primary determinants of the observed variations in the ambient concentrations of PM within a country in the estimation model are:

Energy consumption. The model includes six separate per capita energy consumption categories-coal, oil, natural gas, nuclear, hydroelectric, combustible renewables and wastes-that account for all energy consumed in each country for which data are available from the International Energy Agency's (IEA) Annual Energy Balance database (International Energy Agency 2001a, 2001b). The separate inclusion of each type of energy source accounts for differences in emission factors, variations in economic activity and intensity of fuel use across countries. In addition, the model also includes per capita consumption of petrol and diesel used in the transportation sector, also available from IEA's database, to capture additional detail about one of the most significant contributors to ambient concentrations of PM.

Meteorological and geographic factors. The model includes 22 atmospheric and geographic factors for each city to account for both the dissipative/dispersive capacity of the natural environment and natural sources of particulates, such as desert dust storms, forest fires and sea spray. These include a suite of 18 climatic variables representing the long-
term average climatic conditions related to local atmospheric conditions and transport of PM , consisting of the annual average (average of the monthly data) and seasonal changes (measured as the standard deviation of the monthly data) for the following nine factors: mean temperature, diurnal temperature, mean precipitation, barometric pressure, wind speed, percentage cloud cover and frequency of wet, sunny and frosty days (New et al. 1999). ${ }^{7}$ In addition, two meteorological variables related to energy demand (heating and cooling degree-days) are estimated for each city from the mean monthly temperature. Two topographical variables related to atmospheric transport-distance from the city centre to the nearest point on the coastline, calculated using the geographic information system (GIS), and elevation of the city, derived from a global digital elevation model (USGS 1996)—are also included in the model.

City and national population and national population density. These variables provide measures of the scale and intensity of the pollution problem in each city. The data on population comes from the Demographic yearbook published by the United Nations (UN 2001).

Local population density. The local population density in the vicinity of each city provides a measure of the intensity of pollution. It is estimated from the Gridded Population of the World (version 2), available from the Consortium for International Earth Science Information Network (CIESIN 2000). This data set provides the best available population data for about 120000 administrative units, converted to a regular grid of population counts at a resolution of about 5 km . The local population density in the vicinity of each city is the average population density for all grid cells within a $20-\mathrm{km}$ radius of the city centre.

Local intensity of economic activity. Most cities do not collect data on the amount or composition of economic activity. Instead, the local gross domestic product (GDP) per square kilometre computed as the product of the national per capita GDP and the local population density in the vicinity of each city is used as a proxy for the intensity of economic activity within each city (World Bank 2002).

National income per capita. This variable is used to capture the following national indicators: valuation of the quality of the environment, strength of environmental policy and regulation, the institutional capacity to enforce environmental policies, and the potential use of cleaner fuels along the fuel-use chain as countries develop. It is measured as a 1-year lag of the average of the previous 3 years (World Bank 2002).

Time trends. The model includes two time-trend variables (with $1985=1 \ldots 1999=15$ ) to allow for differential time trends for $\mathrm{PM}_{10}$ and TSP particulate pollution. Both of these variables are in turn interacted with lagged national per capita income to allow trends to vary across countries on the basis of differential valuation and improvements in environmental quality across countries as measured by the level of economic development. These trends measure changes in concentrations of PM
that are caused by factors not already captured in the model, such as technological changes, improvements in knowledge and structural shifts in the composition of economic activity. They do not represent the unconditional aggregate trends in concentrations of PM.

Binary variable to differentiate $P M_{10}$ and TSP. The model includes a binary variable indicating whether PM is measured as TSP or $\mathrm{PM}_{10}$. This binary variable is also allowed to interact in the model with other variables to allow for size class differences in the composition of particulates across cities and countries. It provides a better representation of intercity differences across the world, rather than assuming a uniform relationship across all cities. The $\log$ of the ratio of $\mathrm{PM}_{10}$ to TSP in each city can be estimated by subtracting Equation 3 from 2, as shown in Equation 4. The key determinants of this ratio are the scale of economic activity, differential trends across countries, level of economic development and strength of environmental policy, and the subset of meteorological variables that are directly related to particle size (annual mean and seasonal variations in wind speed, precipitation and frequency of wet days).

$$
\begin{align*}
& \log \left[P M 10_{i j k t}\right]-\log \left[\operatorname{TSP}_{i j k t}\right]=-\theta_{S}-\theta_{\text {Scale }} S_{c a l e_{j k t}}-\theta_{Y} Y_{k t} \\
& \quad-\theta_{T} \text { Trend }_{i j k t}-\theta_{Y T} Y_{k t} \text { Trend }_{i j k t}-\sum_{g=1}^{G 1} \theta_{M g} M_{g j k} \tag{4}
\end{align*}
$$

In order to facilitate predictions for countries not included in the estimation, a secondary model shown in Equation 5 is estimated to explain the average level of ambient PM concentration in each country.

$$
\begin{equation*}
\dot{\beta}_{k}=\sum_{f=1}^{F} \gamma_{E f} \bar{E}_{f k}+\gamma_{R} \overline{\bar{R}}_{k}+\gamma_{R} \bar{Y}_{k}+u_{k} \tag{5}
\end{equation*}
$$

where
$\dot{\beta}_{k}=$ country-specific binary variable coefficient estimated in Equation 1
$\bar{E}_{f k}=\log$ of average per capita energy consumption of energy type $f$ for country $k$ during 1985-1999 ( $f=1 \ldots F$ )
$\bar{R}_{k}=\log$ of average population density of country $k$ during 1985-1999
$\bar{Y}_{k}=\log$ of average national per capita income of country $k$ during 1985-1999 (1-year lagged average of previous 3 years)
This secondary model (5) explains the average level of pollution under reference conditions for a country, on the basis of the scale of the economy, the composition of economic activity as measured by the energy mix, and the strength of local pollution regulations and the institutional capacity for implementing these regulations.

### 2.3 Model outputs

The GMAPS model is designed to obtain the best city-level prediction of concentrations of PM for a wide range of cities on the basis of the limited amount of data from monitoring available, so it focuses on increasing the fit of the model. It is not designed to provide a causal model for ambient concentrations of air pollution. The estimation model (1) explains $88 \%$ of the variation in the observed data from monitoring, indicating a good fit (Pandey et al. forthcoming). The overall correlation between the measured and the predicted data is around 0.9 for both $\mathrm{PM}_{10}$ and TSP observations (see Table 17.3), and is $>0.80$ for all years and for both observations of $\mathrm{PM}_{10}$ and TSP, with the exception of $\mathrm{PM}_{10}$ in 1985. The correlation by subregion is smaller than that over time, ranging between 0.2 and 0.9 for subregions with more than 10 data points. The correlations for subregions with fewer data points are smaller than 0.2 and are less precisely estimated. A negative correlation for EUR-B is driven by a single erroneous observation for Bucharest, Romania, where the observed concentration of $\mathrm{PM}_{10}$ is higher than that of TSP. These results originated from two different monitoring locations; had the model been re-estimated without this particular $\mathrm{PM}_{10}$ observation, the correlation for the subregion would have been 0.32 .

Subregion- and PM type-specific scatter plots of model predictions compared to actual data also show a clustering of points around the solid line drawn at a $45^{\circ}$ angle, indicating that the actual values are close to the predicted values. As would be expected, the predicted values are less extreme than the actual values at both tails, owing to the truncation of all explanatory variables to the middle $98 \%$ range of the estimation sample. F-tests revealed that all of the eight aggregate factors in the model added significant explanatory power to the regression.

The secondary estimation model (5) explains $85 \%$ of the variation in the estimated average level of pollution in a country, indicating that this model provides a good fit. The explanatory power of the secondary model is not as robust to changes in the estimation sample owing to significant uncertainties in the estimated dependent variable.

Out-of-sample predictions were used to validate the model using both statistical and heuristic criteria. The model was re-estimated using subsamples of the data on the basis of different cut-off points for per capita income, to examine the appropriateness of extrapolating from a model primarily based on industrialized cities in North America and western Europe to cities in developing countries. The resulting estimates from the model were used to predict concentrations of $\mathrm{PM}_{10}$ in residential areas in the out-of-sample cities located in developing countries. A second set of estimates was also made comprising income-based subsamples using only the available data on $\mathrm{PM}_{10}$ from monitoring in residential sites. These validation estimates consistently showed that out-of-sample correlations were higher when data on TSP were included in the estimations. Furthermore, the out-of-sample correlations on aggregate ranged

between 0.40 and 0.59 , based on the income cut-off used, and lend support to the modelling approach.

Since cities with data from monitoring are not representative of all cities and account for a small fraction of urban residents in developing countries, the following heuristic criteria were also used to evaluate the predictions of the model.

- Comparison of the relative variation of the predictions within countries and between countries relative to the actual data: The model predictions exhibited significant variations both across countries and across cities within a country. The predicted variations within a country were about $60 \%$ of those between countries and were comparable to the corresponding variations in the actual data.
- Number of cities for which predictions were outside the range of the estimation sample: The predictions for $\mathrm{PM}_{10}$ were within the range observed in the actual data. They continued to be within bounds when the same fractions of values are removed from the tails of the estimated and measured data.
- Magnitude of predictions outside the range observed in the estimation sample: Of the 304 cities with data from monitoring, concentrations of $\mathrm{PM}_{10}$ exceeded $200 \mu \mathrm{~g} / \mathrm{m}^{3}$ in three cities and concentrations of TSP exceeded $400 \mu \mathrm{~g} / \mathrm{m}^{3}$ in 10 cities. The predicted concentrations of $\mathrm{PM}_{10}$ exceeded $200 \mu \mathrm{~g} / \mathrm{m}^{3}$ in only four out of 3226 cities.
- Range of the $P M_{10}: T S P$ ratio: The $\mathrm{PM}_{10}$ :TSP ratio predicted by the model is between 0.24 and 0.98 and spans the middle $95 \%$ of the range observed in the actual data. The mean ratio predicted by the model is 0.49 ; the ratio for half of the cities lies between 0.39 and 0.56 .
- Comparison of the uncertainty in estimates for cities, relative to the amount of available information for neighbouring cities: Bootstrap error estimates of the prediction error for the city showed that the confidence intervals were wider for cities with no data from monitoring and are largest in the countries with no data from monitoring.

The robustness of the model was tested using alternative specifications of the model based on the goodness-of-fit of the model and the heuristic criteria outlined above. The alternative models that were considered were:

- Linear model. The linear model provides undue weight to the extreme values in the explanatory variables, resulting in predictions that are orders of magnitude larger than those for cities with data from monitoring.
- Explanatory variable truncation. The model was re-estimated with four different levels of truncation for the explanatory variables: no truncation, truncation to the actual range for the cities with data from monitoring, truncation to the middle $98 \%$ range of all explanatory variables for these cities, and truncation to the middle $90 \%$ range for these cities. Estimates based on the first two of these were sensitive to some of the extreme data points in the estimation sample, resulting in large variations in the predictions. Estimates from the last truncation were rejected because more than one quarter of the observations were truncated, leading to a poorer model fit.
- Energy consumption variables. The model was re-estimated with three alternative measures for the energy consumption variables: energy consumption per area, total per capita energy consumption and share of each energy type in the total energy mix, and the product of national per capita energy consumption by energy type and city population density. The specification per area resulted in predictions that were unstable and orders of magnitude larger than those observed in any city because of truncation of extreme values in countries with missing data on fuels. The second and third specifications resulted in poorer fits with over-predictions for $>100$ cities with values outside of the observed range of concentrations of $\mathrm{PM}_{10}$.
- Income. The model was estimated using income-squared and incomecubed terms to measure the impact of national per capita income. Higher order terms were unstable and resulted in predictions that were orders of magnitude larger than those observed in any city.
- $P M_{10}: T S P$ ratio. A number of different models were estimated from full interactivity of the binary variable $S_{i j k t}$ with all of the continuous variables, to no interactivity with the continuous variables. The full interactivity model was rejected because it predicted physically implausible $\mathrm{PM}_{10}$ :TSP ratios of 2 for a significant number of cities. The limited model with no interactivity was rejected because it over-predicted the results for many cities in the Middle East and North Africa that contain a larger fraction of wind-blown coarser particles. Other models were estimated that incrementally added groups of variables, such as energy type and the other climate variables. These were all rejected using the heuristic criteria outlined above.
- Location of monitoring sites. The sensitivity of the model predictions to the inclusion of mixed residential sites was examined by reestimating the model using only pure residential sites. ${ }^{8}$ Although estimates for some individual cities change in significant ways, predictions at the subregional level, and for most countries, are not statistically different as compared to when mixed sites are included.
- Inclusion of non-residential sites. A more inclusive model, which jointly estimates concentrations of PM in residential and nonresidential sites indicated that most model parameters were relatively stable and that the model predictions for subregional residential concentrations of $\mathrm{PM}_{10}$ were not significantly different for most subregions.
- Additional monitoring data. The sensitivity of the model was tested to the inclusion of additional monitoring data that became available between October 2001 and July 2002. The aggregate PM predictions were not statistically different for all subregions, except for EMR-B where concentrations of PM increase by nearly $50 \%$. This is primarily owing to the inclusion of data for Kuwait City, which is the only city for which data from monitoring sites are available in this subregion.
- Influential data point. The sensitivity of the model predictions to influential data points was examined using bootstrap error techniques. Variations in the predictions based on different subsamples of the data were used to estimate the degree of uncertainty in the model estimates.

## Estimating ambient concentrations of particulate matter in cities

The average subregional ambient concentrations used in this work are estimated from the city-level model predictions for 1999, the latest year for which all of the explanatory variables were available. The estimates of concentrations of $\mathrm{PM}_{10}$ in each city for 1999 were generated using a three-step approach. First, for all cities located in countries with at least one population-oriented monitoring site, the concentration of $\mathrm{PM}_{10}$ was estimated using the GMAPS model, as specified in Equation 1. The concentration of $\mathrm{PM}_{10}$ cannot be estimated using Equation 1 alone for cities in every country, because the average level of pollution in the country as measured by the country binary variable was not available for countries without monitors. Therefore, in the second step, the secondary Equation 5 was used to predict the country coefficient for countries without monitors. These predictions were combined with estimates from Equation 1 that explain variations around the average level to generate 1999 concentrations of $\mathrm{PM}_{10}$ for these cities in these countries.

Finally, for cities with actual data from monitoring, a best estimate of concentration of $\mathrm{PM}_{10}$ in the city in 1999 was generated by incorporating information on concentrations from previous years. Specifically, an average residual for each city was determined by comparing each yearspecific predicted value generated by the estimation model (1) with the actual monitored value for that year and city. This served to adjust the model predictions for local factors that are known but unmeasured in the model, such as the composition of local economic activity. Given the
large year-to-year variations in the available measured data even at the same monitoring station, correcting for the average residual provides a better representation of long-term average factors affecting concentrations of PM in a city than using the actual monitored value for the last year of data from monitoring alone.

## Estimating subregional ambient concentrations of PARTICULATE MATTER

To avoid extrapolating outside the sample frame, all exogenous variables were truncated to the range used in the estimation sample. When necessary, missing explanatory variables for the country were filled in with the median values for economically similar countries located in the same geographic area. For most subregions, data were available for at least $95 \%$ of the cities, accounting for at least $95 \%$ of the population in each subregion. In contrast, data on either fuel, GDP or gross national product (GNP) were missing for $20-30 \%$ of the cities, accounting for $20-30 \%$ of the population for each of the four subregions AFR-D, AFR-E, EMRB and EMR-D. In all, data on either fuel, GDP or GNP were completed in this way for 176 cities worldwide, accounting for $5 \%$ of the total world urban population.

The estimated annual average concentrations of $\mathrm{PM}_{10}$ in urban areas for world cities with populations of $>100000$ and national capitals are shown in Figure 17.2. Each circle on the map represents a city and is shaded according to the estimated concentrations of $\mathrm{PM}_{10}$ in that city. Standards currently in place in North America and western Europe lie

between $30-60 \mu \mathrm{~g} / \mathrm{m}^{3}$. Therefore, we defined a middle group with concentrations of $\mathrm{PM}_{10}$ in the range of $30-60 \mu \mathrm{~g} / \mathrm{m}^{3}$. Cities with values that fell outside this range were sorted into two groups of cities with higher concentrations and two groups with lower concentrations (thus forming a total of five groups). Worldwide, about $30 \%$ of the urban population live in the less polluted cities while $40 \%$ live in the more polluted cities. The remaining $30 \%$ of people live in cities with concentrations of $\mathrm{PM}_{10}$ in the middle range. However, there are significant regional differences. More than $70 \%$ of the people living in NAWE live in cities with concentrations of less than $30 \mu \mathrm{~g} / \mathrm{m}^{3}$, meeting the most stringent standards. In contrast, more than $70 \%$ of the populations in SEAR-D, WPR-B, EMR-D and SEAR-D live in cities where concentrations exceed even the most lenient standards.

This difference can also be seen in the estimated population-weighted mean concentrations of $\mathrm{PM}_{10}$ for each subregion, which are presented in Table 17.4. These are computed from 1999 estimates of concentrations of $\mathrm{PM}_{10}$ in cities, using the populations of each city in 2000 as weights. We have not directly used data for cities with data from monitoring in computing the subregional averages, to avoid incorporating short-term transitional variations into our exposure estimates. ${ }^{9}$ The mean exposures in the most polluted subregions (EMR-D, SEAR-B, SEAR-D and

WPR-B) are about three times higher than those in the least polluted subregions (AMR-A and EUR-A). The table also shows predictions of population-weighted average concentrations of TSP and the size composition of PM for each subregion. Finer particles account for a larger share of PM in the highly industrialized countries of AMR-A and EURA compared to the other less industrialized subregions.

We quantified the uncertainty in our estimates of the subregionspecific mean concentrations of PM using a bootstrap technique. In this method, the model is re-estimated many times (200 trials) using a randomly repeated sample of the observations used in estimating the model. For each trial, city and population-weighted subregional predictions of PM are generated using the methods described above. The predictions from all trials are sorted from highest to lowest to obtain the percentile distribution of concentrations of $\mathrm{PM}_{10}$ for each subregion and are also shown in Table 17.4. The degree of certainty in the point estimates of concentration of $\mathrm{PM}_{10}$ for each subregion is directly related to the number of observations available from monitoring of PM. For example, the two subregions (AMR-A and EUR-A) with the most frequently monitored cities also have the smallest confidence intervals for $\mathrm{PM}_{10}$ values. In contrast, the five subregions with two or fewer cities that are monitored (AFR-E, AFR-D, EMR-B, EMR-D and SEAR-B) have larger confidence intervals than the other subregions. The width of the confidence intervals for these subregions depends on the geographic and climatic similarity of their cities with monitored data. For example, confidence intervals for AFR-E and EMR-B are about half of those for AFR-D and for EMR-D.

The estimates also show that substantial differences exist in the average concentration of PM within each subregion. The share of the urban population in cities with populations $>100000$ and in national capitals according to estimated concentrations of $\mathrm{PM}_{10}$ is given in Figure 17.3. All cities in AMR-A, EUR-A, EUR-C and WPR-A are estimated to have concentrations of $\mathrm{PM}_{10}$ of $<60 \mu \mathrm{~g} / \mathrm{m}^{3}$. In contrast, $95 \%$ of the urban population in SEAR-B and about $82 \%$ of the urban population in WPRB and EMR-D are exposed to $>60 \mu \mathrm{~g} / \mathrm{m}^{3} \mathrm{PM}_{10}$. We also estimate that a high proportion of the urban population in SEAR-D is exposed to high annual average concentrations of $\mathrm{PM}_{10}$.

Since some of the health outcomes are based on $\mathrm{PM}_{2.5}$, rather than $\mathrm{PM}_{10}$, concentrations for this pollutant had to be estimated. Cityspecific concentration of $\mathrm{PM}_{2.5}$ was estimated as a fixed proportion of $\mathrm{PM}_{10}$. Available measurements indicate that the ratio of $\mathrm{PM}_{2.5}$ to $\mathrm{PM}_{10}$ ranges from 0.5 to 0.8 in many urban areas in developed countries, (California Air Resources Board 2002; U.S. Environmental Protection Agency 2002). Limited evidence suggests that a similar ratio may exist in large cities in other subregions. For example, a recent study from China reports the $\mathrm{PM}_{2.5}: \mathrm{PM}_{10}$ ratio to be in the range of 0.51 to 0.72 in four urban locations (Quian et al. 2001). However, in areas impacted

Figure 17.3 Distribution of the urban population according to estimated concentrations of $\mathrm{PM}_{10}$ in cities with populations of $>100$ and in national capitals, by subregion

by more crustal particles (e.g. arid areas or cities with a significant number of unpaved roads or windy days), the ratios are likely to be much lower. These areas will have a greater proportion of $\mathrm{PM}_{10}$ in the coarse size range of $2.5-10 \mu \mathrm{~m}$. For example, evidence from the Coachella Valley (i.e. the Palm Springs area), an arid range of southern California suggests that the $\mathrm{PM}_{2.5}: \mathrm{PM}_{10}$ ratio is 0.35 (Ostro et al. 1999b). Therefore, we assumed a ratio of 0.5 for our base case and have examined the sensitivity of our results to this assumption. Specifically, for our sensitivity analysis, for cities in AMR-A, EUR-A, EUR-B, EURC and WPR-A (including the United States, Canada, all Europe, Japan, Singapore, Australia and New Zealand), a higher scaling factor of 0.65 was used, assuming relatively more combustion-related particles, while a lower scaling factor of 0.35 was used for cities in all other subregions.

Estimates of the annual average population-weighted concentration of $\mathrm{PM}_{2.5}$ for each subregion were calculated in a similar manner to that for $\mathrm{PM}_{10}$, using the estimated concentration of $\mathrm{PM}_{2.5}$ for the city in 1999 and the population for each city in 2000.

### 2.4 Choice of the theoretical-minimum-Risk exposure

Studies of mortality associated with both short- and long-term exposure to PM, discussed below, have been unable to detect a threshold below
which there is no effect of exposure. For most results presented below, we estimated the burden of disease with respect to a counterfactual concentration of $7.5 \mu \mathrm{~g} / \mathrm{m}^{3} \mathrm{PM}_{2.5}$ ( or $15 \mu \mathrm{~g} / \mathrm{m}^{3} \mathrm{PM}_{10}$ ). This value is close to the lowest concentration observed in the epidemiological study (Pope et al. 2002) from which we derived the concentration-response functions used for the majority of our estimates. This choice avoids extrapolating the concentration-response function(s) below the concentrations actually observed in the epidemiologic studies from which they were derived, although health benefits may well accrue from reductions below those concentrations.

We were aware, however, that for some cities the estimated (and observed) concentrations of PM are lower, e.g. in AMR-A (United States and Canada), and that achieving such concentrations more widely would be not only desirable, but also feasible in some settings (U.S. Environmental Protection Agency 2002). Moreover, previous impact estimates have been sensitive to where this value was set (Künzli et al. 2000). Therefore, we also conducted sensitivity analyses in which the theoretical minimum concentration was halved and doubled (see below).

## 3. Health effects of exposure to urban AIR POLLUTION

The past 10-15 years have seen a rapid increase in research on the health effects of air pollution, and it is now widely accepted that exposure to urban air pollution is associated with a broad range of acute and chronic health effects, ranging from minor physiological disturbances to death from respiratory and cardiovascular disease (Anonymous 1996a, 1996b; Figure 17.4). Recently, a committee of the American Thoracic Society identified effects on respiratory health associated with air pollution, which should be considered adverse, spanning outcomes from death from respiratory diseases to reduced quality of life, and included some irreversible changes in physiological function (American Thoracic Society 2000). In general, the frequency of occurrence of the health outcome is inversely related to its severity, with the consequence that assessing total health impact solely in terms of the most severe, but less common, outcomes, such as mortality, will underestimate the total health burden of air pollution (WHO 2001b).

A large body of epidemiological research, discussed in more detail below, provides evidence that exposure to air pollution is associated with increased mortality and morbidity. The respiratory and cardiovascular systems appear to be the most affected. A growing body of toxicological and clinical evidence currently offers some limited insight into the mechanisms through which exposure to air pollution may produce the effects on respiratory and cardiovascular outcomes observed in epidemiological studies (Anonymous 1996a, 1996b; Health Effects Institute 2002). These mechanisms may involve decrements in pulmonary func-

Figure I7.4 The relative frequencies of health events associated with exposure to air pollution

tion, effects on heart rate variability and inflammatory response. Longterm bioassays and other studies of toxicity provide evidence for the mutagenicity and/or carcinogenicity of some components of urban air pollution, such as emissions from diesel-powered vehicles (Cohen and Nikula 1999; Diesel Working Group 1995).

Air pollution may elicit both acute and chronic biological responses. Acute responses to air pollution in otherwise healthy persons may be confined to reversible physiological adaptations resulting from natural defence mechanisms (e.g. watery eyes, cough or a transient fall in lung function). Acute responses may, however, also increase the severity or duration of an already established respiratory infection or of diseases such as asthma or chronic obstructive lung disease that have already placed the individual in a vulnerable position, and increase the risk of hospital admission or even death. If such vulnerability were temporary, for example, a severe infection of the lower respiratory tract, the individual might have recovered and lived for some time, had it not been for the added factor of exposure to air pollution at the time the individual was most vulnerable because of the infection. On the other hand, if the individual had a terminal chronic condition, such as severe chronic obstructive pulmonary disease or chronic congestive heart failure, exposure to air pollution might advance death by only a short time, this being imminent in any case. There is limited epidemiological evidence to suggest that ambient air pollution may contribute to the development
of diseases such as chronic obstructive pulmonary disease, for which smoking and, in developing countries, indoor air pollution, are also risk factors (Abbey et al. 1999; Pope and Dockery 1999; Tager et al. 1998). Distributions of short-and long-term vulnerability, reflecting the prevalence of acute and chronic cardiorespiratory disease, may well differ across populations worldwide. This will have implications for the transferability of risk functions from studies in populations in NAWE to populations where differences in genetic factors, diet, tobacco smoking, extent of urbanization, distribution of wealth and other factors related to social class, have resulted in different patterns of disease.

For example, recent analyses of two cohorts in the United States (Krewski et al. 2000) showed clearly that the effects of long-term exposure to air pollution on mortality depend on attained educational level, with the largest relative effects observed among the least educated. Recent studies in developing countries have also reported such gradients in the relative risks of mortality (O'Neill et al. 2003). It is not clear what factor(s) might be responsible for these observations (e.g. aspects of occupation or diet), but it is reasonable to expect that they might vary across the globe. Differences in vulnerability to air pollution introduce a source of uncertainty in our estimates that can currently be only partially quantified.

Epidemiological evidence about exposure-response relationships is most directly applicable to the risk assessment of air pollution, because it comes from the direct observation of human populations under relevant conditions (Samet 1999). Epidemiological studies have limitations that are largely a result of their observational nature. These relate to the accurate measurement of exposure, definition of outcomes and interpretation of associations that are observed. Assessing the causality of such associations requires a process of scientific reasoning that considers all evidence, including that from experimental studies (WHO 2000b). While there remain many gaps in our knowledge about the explanations for epidemiological associations, they can provide the best evidence to guide action to reduce the exposure of the population to air pollution, and to undertake health impact assessments, provided the uncertainties are recognized.

The epidemiology of air pollution takes advantage of the fact that concentrations of urban air pollution, and thus human exposure, vary in both time and space. For the most part, current epidemiological research has focused on either one or the other dimension, but infrequently on both within the same population(s). Short-term temporal variation in concentrations of air pollution over days and weeks has been used to estimate effects on daily mortality and morbidity. Spatial variation in long-term average concentrations of air pollution has provided the basis for cross-sectional and cohort studies of long-term exposure.

### 3.1 Studies of short-term exposure

The effects of short-term exposure to air pollution have been extensively studied in time-series studies in which daily rates of health events (e.g. deaths or hospital admissions) in one or more locales are analysed in relation to contemporaneous series of daily concentrations of air pollutants, and other risk factors (e.g. weather) that vary over time periods of months or years. Regression techniques are used to estimate a coefficient that represents the relationship between exposure to pollution and the outcome variable. The usual method of regression models the logarithm of the outcome, and thus arrives at an estimate of the relative risk, a proportional change in the outcome per increment of ambient concentration. There has been a rapid increase in the number of these studies as computing and statistical techniques have improved and as data on outcomes and air pollution have become more extensive and easily accessible from routine sources. It is a strength of these studies that individual cofactors, such as smoking, nutrition, behaviour, genetic factors, etc., are unlikely confounders because they are not generally associated, on a day-to-day basis, with the daily concentration of air pollution. Studies of time series have found associations between concentrations of PM in the air and a large range of outcomes. These have been reviewed by Pope and Dockery (1999) and include daily mortality (all causes, respiratory, cardiovascular), hospitalization for respiratory diseases (all causes, chronic obstructive pulmonary disease, asthma, pneumonia) and for cardiovascular diseases (acute myocardial infarction, congestive cardiac failure). Since this review, associations have also been reported for primary health care visits for disease of the lower respiratory tract, and diseases of the upper respiratory tract of both infective and allergic origin (Hajat et al. 2001, 2002). However, recent methodological studies and re-examination of earlier work indicate that the magnitude of the estimates of relative risk from time-series studies of daily mortality depends on the approach used to model both the temporal pattern of exposure (Braga et al. 2001) and potential confounders that vary with time, such as season and weather (Health Effects Institute 2003).

The acute effects of air pollution have also been studied longitudinally in panel studies, which can provide evidence of physiological effects at an individual level. Small groups, or panels, of individuals are followed over short time intervals, and health outcomes, exposure to air pollution and potential confounders are ascertained for each subject on one or more occasions. Panel studies have generally reported associations of exposure to urban air pollution with increased prevalence of symptoms involving the upper and lower respiratory tract, and increased rates of asthma attacks and medication use. Associations with short-term reduction in lung function and the prevalence of cough symptoms have been reported in studies in the United States (Pope and Dockery 1999), but are not consistently supported by studies in Europe (Roemer et al. 1999).

## Time-Series studies in adults across the world

Studies of time series concerning daily mortality and, to a lesser extent, daily hospital admissions, have been conducted in cities throughout the world. A recent meta-analysis summarized the evidence from $>100$ studies of daily mortality (Stieb et al. 2003). In addition, large studies have now been conducted using uniform methods for assembling and analysing data from multiple cities: APHEA 2 (Air Pollution and Health: A European Approach) (Katsouyanni et al. 1996, 2001) and NMMAPS (National Mortality and Morbidity Air Pollution Study) (Health Effects Institute 2000a, 2000b) in the United States. These multi-city studies have confirmed the findings of earlier studies of individual cities in finding positive associations between daily mortality and hospital admissions and concentrations of PM, and have also attempted to explain the heterogeneity among cities in the relative risks associated with exposure to air pollution. For example, in the APHEA 2 Study, it was found that the effects of PM on mortality were modified by mean concentrations of nitrogen dioxide (Katsouyanni et al. 2001), and in the NMMAPS Study, daily mortality was modified by the long-term average concentrations of $\mathrm{PM}_{10}$. Levy et al. (2000) reported that the effects of $\mathrm{PM}_{10}$ were greater in cities where $\mathrm{PM}_{2.5}$ comprised a higher proportion of $\mathrm{PM}_{10}$.

Most studies of time series are from countries in NAWE, where air pollution is low and decreasing and populations are characterized by western lifestyles and patterns of disease. To examine the epidemiological evidence for other non-NAWE countries, we searched a database of studies of time series and panel studies compiled at St George's Hospital Medical School, for which researchers had systematically ascertained, reviewed, and abstracted results from studies published in the peerreviewed scientific literature (WHO 2003). All studies meeting prespecified quality criteria related to adequacy of confounder control, and which provided estimates of the concentration-response relationship and its statistical precision were included. We classified them by the subregion in which the study was performed and tabulated the results for six outcomes: all-cause mortality, respiratory mortality, cardiovascular mortality, infant and child mortality, reduction in peak expiratory flow rate and cough symptom.

The distribution of time-series and panel studies by outcome and subregion is shown in Tables 17.5(a) and (b). Up to mid-November 2001, the number of studies from AMR-A (71) and EUR-A (75) far exceeded the total for the remaining 12 subregions (42). The next largest contributor was AMR-B (Central and South America), with 18 studies. The table shows the numbers of panel studies presenting usable numerical estimates. Only 14 studies from non-NAWE subregions were identified, compared with 64 from the NAWE subregions. Some of the non-NAWE countries had lifestyles and patterns of disease similar to those in NAWE-those in Australasia, for example.

Figures 17.5 and 17.6 show the results for daily mortality and PM, by subregion, for adults and children, respectively. These estimates were scaled to $\mathrm{PM}_{10}\left(\mathrm{PM}_{2.5}=0.6 \times \mathrm{PM}_{10}, \mathrm{BS}=0.5 \times \mathrm{PM}_{10}, \mathrm{TSP}=2 \times \mathrm{PM}_{10}\right)$. These scaling factors were decided after examining a number of co-located measures, but are likely to be variable across the individual cities. Estimates of random effects and fixed effects are shown because there is heterogeneity.

The pooled estimates are shown in Table 17.6. Most of the studies of mortality showed relative risks of $>1.0$ (i.e. a change of $>0.0 \%$ ), with lower $95 \%$ confidence intervals also $>1.0$. However, the studies showing the largest confidence intervals also tended to have the largest effects, this indicating the possibility of publication bias. There was considerable heterogeneity in the estimates. For this reason, the summary estimate for random effects is more appropriate because it takes into account the greater uncertainty. The estimate for random effects was increased and statistically significant for mortality from all causes, respiratory and cardiovascular diseases. It is remarkable that for daily mortality, the pooled estimate for the non-NAWE subregions of $0.5 \%$ increase in daily mortality per $10 \mu \mathrm{~g} / \mathrm{m}^{3}$ increase in PM was very similar to the estimates produced by the APHEA 2 and NMMAPS studies of 0.6 and 0.5 , respectively. A recent meta-analysis of 109 published studies from around the world reports similar estimates (Stieb et al. 2003).

These results indicate that daily mortality is positively associated with short-term exposure to urban air pollution at time-scales in the order of days, in all subregions where this association has been measured. They also suggest that the relative effect of exposure may also be of similar magnitude in different parts of the world.

## Air pollution and reproductive and child health

Six time-series studies of daily mortality report associations between particulate pollution and adverse effects in children, and all of them are from non-NAWE countries. Their estimates are shown in Figure 17.6. Four were from São Paulo (Conceiao et al. 2001; Gouveia and Fletcher 2000; Pereira et al. 1998; Saldiva et al. 1994), one from Mexico City (Loomis et al. 1999) and one from Bangkok (Ostro et al. 1999a). The Bangkok study was of $\mathrm{PM}_{10}$ and daily mortality from all causes in children aged $<6$ years. The study conducted in Mexico City evaluated the impact of daily changes in concentrations of $\mathrm{PM}_{2.5}$ and total mortality in children aged $<1$ year. Three studies in São Paulo (Conceiao et al. 2001; Gouveia and Fletcher 2000; Saldiva et al. 1994), conducted during different periods of time, all reported an association between PM and mortality from respiratory disease in children aged $<5$ years. The study conducted in São Paulo by Pereira et al. (1998) investigated the association of exposure to urban air pollution with intrauterine mortality. Some of the relative risks reported in these studies were $>1.0$, but only the estimate from Mexico City was statistically significant at the $95 \%$ level.

I study (Awasthi et al. 1996) not included in meta-analysis due to uncommon particle measurement.

Infant mortality from respiratory disease and other adverse perinatal events, such as low birth weight and malformations, have also been associated with more prolonged exposure to air pollution (Bobak and Leon 1999; Wilhelm and Ritz 2003; Woodruff et al. 1997). Woodruff et al. followed a large birth cohort in the United States for one year and estimated the relative risk of mortality associated with residential exposure to $\mathrm{PM}_{10}$ in the first two post-natal months, conditional on a variety of potential confounders, including maternal smoking. They reported an increase in total mortality of $4 \%$ per $10 \mu \mathrm{~g} / \mathrm{m}^{3}$, and $20 \%$ for mortality from respiratory causes. Two studies recently evaluated changes in infant mortality associated with reductions in industrial emissions caused by a recession and mandated reductions in pollution resulting from the United States Clean Air Act Amendments of 1970 (Chay and Greenstone 1999, 2001). Using county-level data, the authors estimated that 4-8 infant deaths per 100000 live births were prevented for each $1 \mu \mathrm{~g} / \mathrm{m}^{3}$ reduction in TSP.

## Studies of acute morbidity

Far fewer studies have been conducted of the association of exposure to urban air pollution with acute morbidity, especially in non-NAWE countries. There were insufficient studies in any one outcome group to allow formal meta-analysis of non-NAWE studies, but most reports suggested a positive association with urban air pollution, consistent with that observed in NAWE countries, especially for hospital admissions (Atkinson et al. 2001; Burnett et al. 1999; Health Effects Institute 2000b). A recent study compared directly the effects of air pollution on hospital admissions in China, Hong Kong Special Administrative Region (Hong Kong SAR) and London. Similar associations were observed for $\mathrm{PM}_{10}$ and gaseous pollutants and hospital admissions for ischaemic heart disease in both locations, and the associations were strongest during seasons of low humidity in both cities, but no association with admissions for cardiac disease was observed in Hong Kong SAR (Wong et al. 2002).

### 3.2 Studies of long-term exposure

COHORT STUDIES OF MORTALITY FROM CHRONIC RESPIRATORY AND CARDIOVASCULAR DISEASE
Cohort studies take advantage of spatial heterogeneity in concentrations of air pollution to compare the incidence of disease and death in populations exposed in the long term to differing levels of pollution. By following large populations for a number of years, cohort studies provide estimates of both attributable numbers of deaths and, more importantly, average reductions in life span attributable to air pollution.

The evidence from cohort studies of populations in Europe and the United States indicates that long-term exposure to urban air pollution
is associated with an increase in total and cardiopulmonary mortality in adults (Dockery et al. 1993; Hoek et al. 2002; Lipfert et al. 2003; McDonnell et al. 2000; Pope et al. 2002). In each of these studies, the effects of potential confounders such as cigarette smoking, occupation and prior medical history were adjusted for in regression analyses. Most studies find the strongest and most consistent associations with exposure to PM , and $\mathrm{PM}_{2.5}$ appears to be more closely associated with mortality than $\mathrm{PM}_{10}$ or TSP (Dockery et al. 1993; Pope et al. 2002). The recently published results of a study conducted in the Netherlands confirm the impacts of long-term exposure to air pollution, and in particular that related to road traffic, on mortality (Hoek et al. 2002).

Unfortunately, the cohort studies provide little information on when exposure to air pollution acts to increase the risk of mortality (i.e. the induction time for mortality attributable to exposure to long-term exposure to air pollution), making it difficult to estimate when the effects of reduction of air pollution might be observed.

Comparable cohort studies have not yet been carried out in developing countries. However, the imposition of restrictions on the sulfur content of fuel for power generation and transportation in Hong Kong SAR, instituted over short time intervals in 1990, provided opportunities for researchers to measure directly the impact of reducing air pollution on long-term average mortality (Hedley et al. 2002). Hedley et al. (2002) documented both changes in ambient air quality subsequent to the imposition of the restrictions, and declines in long-term average rates of mortality from cardiovascular and respiratory diseases associated with those changes. Comparison of changes in mortality in more and less polluted areas of Hong Kong SAR provided limited ability to account for secular changes in other risk factors for mortality that could have produced the observed decrease in mortality following the change in the sulfur content of fuel. A similar study was also published recently by Clancy et al. (2002), who measured decreased long-term average mortality in Dublin after the banning of the sale of bituminous coal in Dublin in 1990.

## The American Cancer Society study

The American Cancer Society (ACS) study (Pope et al. 2002) in the United States is by far the largest cohort study of air pollution and longterm average mortality to date. The ACS study of air pollution and mortality is based in the ACS Cancer Prevention II Study, an on-going prospective cohort of approximately 1.2 million adults from all 50 states (Calle et al. 2002). Friends and neighbours recruited cohort members on behalf of the ACS. Participants were enrolled in 1982, when they were aged $\geq 30$ years, and their mortality has been ascertained through to 1998. Data on a wide range of risk factors for cancer and other chronic diseases were obtained from each participant. The ACS study links the data for approximately 500000 cohort members with data on air pol-
lution from metropolitan areas throughout the United States. The first study of air pollution and mortality in this cohort (Pope et al. 1995) was based on follow-up through to 1990 . That study reported increases in mortality from cardiopulmonary disease for $19.9 \mu \mathrm{~g} / \mathrm{m}^{3}$ fine particulate sulfate (relative risk of $1.26,95 \%$ CI 1.16-1.37), and from lung cancer (relative risk of $1.36,95 \%$ CI 1.11-1.66). These findings were subsequently corroborated in an independent re-analysis (Krewski et al. 2000). A more recent analysis of this cohort extended follow-up through to 1998, and ascertained 40706 deaths from cardiopulmonary disease, and 10749 from lung cancer. Data were analysed using Cox proportional hazards regression models that incorporated both random effects and non-parametric spatial smoothing to adjust for unmeasured factors correlated spatially with air pollution and mortality across the United States. The models also adjusted for age, sex, race, education, marital status, body mass, diet, alcohol consumption, occupational exposures and the duration and intensity of cigarette smoking, all measured via questionnaire at enrolment.

Concentrations of ambient air pollution had, in general, declined across the United States between 1982 and 1998. Measurements of ambient concentrations of fine particulate air pollution $\left(\mathrm{PM}_{2.5}\right)$ in the cities where subjects resided at enrolment were available for periods both briefly preceding enrolment (1979-83) and immediately after follow-up (1999-2000). In separate regression analyses, cohort members were assigned estimates of exposure corresponding to their city-of-residencespecific value for each of those periods, as well as for the average value across the two periods. For a change of $10 \mu \mathrm{~g} / \mathrm{m}^{3}$ in the ambient concentration of $\mathrm{PM}_{2.5}$, the smallest relative increases were observed for the mean concentration of the time period 1979-1983. This estimate was based on data from 61 cities, with a mean concentration of $\mathrm{PM}_{2.5}$ of $21.1 \mu \mathrm{~g} / \mathrm{m}^{3}$, and a range of $10-30 \mu \mathrm{~g} / \mathrm{m}^{3}$. The relative risks for a $10 \mu \mathrm{~g} / \mathrm{m}^{3}$ change in the concentration of ambient $\mathrm{PM}_{2.5}$ were larger when exposure was specified as the average of the ambient concentrations of the two time periods. This may be explained by the fact that the estimates from the earliest periods are more subject to random (and nondifferential) error. However, it also suggests that more recent exposures may be exerting the strongest effects on mortality, an interpretation also offered in the recent re-analysis of the earlier follow-up of the ACS cohort (Krewski et al. 2000). Unfortunately, it was not possible to derive individual time-varying estimates of exposure from the available data (e.g. detailed residence histories were unavailable), precluding direct evaluation of the induction time for mortality attributable to exposure to air pollution.

## Long-term exposure and the incidence of chronic disease

Little evidence is available concerning exposure to air pollution and the incidence of chronic cardiovascular or respiratory disease. One study in
the United States reported an association of long-term exposure to $\mathrm{PM}_{10}$ with the incidence of self-reported physician-diagnosed chronic bronchitis (Abbey et al. 1999). A recent case-control study reported an association between short-term exposure and the incidence of non-fatal myocardial infarction (Peters et al. 2001). Cross-sectional studies have found associations with reduced lung function and increased respiratory symptoms in both adults and children, which might in part represent chronic disease as the result of long-term exposure. Several recent crosssectional studies in large Chinese cities have reported increased prevalence of respiratory symptoms in adults (Qian et al. 2001; Zhang et al. 1999) and elementary school children (Qian et al. 2000; Zhang et al. 2002) exposed to urban air pollution. A cross-sectional study in Delhi observed reductions in pulmonary function in residents of highly polluted areas, but little evidence of increased prevalence of symptoms (Chhabra et al. 2001).

## AIR POLLUTION AND LUNG CANCER

Epidemiological studies over the last 40 years have observed that general ambient air pollution, chiefly composed of the by-products of the incomplete combustion of fossil fuels, is associated with small relative increases in the incidence of lung cancer. The evidence derives from studies of trends in the incidence of lung cancer, studies of occupational groups, comparisons of urban and rural populations, and case-control and cohort studies using diverse exposure metrics. Recent prospective cohort and case-control studies which have controlled for the effects of cigarette smoking, occupation and other risk factors have consistently observed small increases in the relative risk of lung cancer in relation to exposure to particulate air pollution (Abbey et al. 1999; Dockery et al. 1993; Krewski et al. 2000; Pope et al. 2002; Samet and Cohen 1999). A recent Swedish case-control study reported that excess lung cancer was related specifically to exposure to mobile sources of air pollution, with the largest effects observed for exposure occurring 20 years prior to diagnosis (Nyberg et al. 2000).

### 3.3 Choice of outcomes and hazards

## Studies used for hazard estimates

The use of results from time series to estimate the disease burden attributable to urban air pollution is problematic for various reasons. First, data on rates of occurrence, such as hospital admissions, primary health care consultations or asthma exacerbation are not collected in many countries. Thus there is no baseline upon which to develop an estimate of health impact. Mortality is an exception in that data are available from death registration or indirect demographic methods in all subregions.

The application of the time-series concentration-response functions to the assessment of mortality impact, however, is limited. Specifically, it is not possible to use the results of studies of time series to estimate YLL in adults. This is because time-series studies of daily mortality do not in themselves allow the estimation of lost life time, but rather only allow estimation of the number of deaths that have been brought forward by an unspecified amount of time. Recent research has made clear that the time-series estimates reflect deaths that may have been brought forward by as much as several months, rather than simply advancing the time of death in frail people by a few days (Schwartz 2000; Zeger et al. 1999). The design of the time-series study of daily mortality, which requires the control of long-term variation in air pollution, precludes estimation of greater losses (Künzli et al. 2001; Leksell and Rabl 2001; McMichael et al. 1998). Thus, the time-series studies only provide an estimate of the daily number of deaths brought-forward.

Cohort studies include not only people whose deaths were advanced by recent exposure to air pollution, but also those who died from chronic disease caused by long-term exposure (COMEAP 1998; Künzli et al. 2001), thus they provide a more comprehensive estimate of the effects on mortality. Furthermore, because their relative risks can be applied to population life tables, the effects of air pollution on life span can be estimated (Brunekreef 1997; COMEAP 2001; Hurley et al. 2000; Sommer et al. 2000)

The situation may be different for children. In developing countries, the major causes of death, such as acute respiratory disease, are very likely to result from a severe acute infection, which represents a brief window of vulnerability. If the child survives, they might be expected to fully recover and enjoy a full life expectancy. If we assume that death was not otherwise imminent, then these deaths, on average, represent the loss of considerable life years. Under such an assumption, one could use time-series estimates to estimate YLL in children aged $0-4$ years.

In making these estimates, several further considerations should be kept in mind. The first is that the effects of cumulative exposure over several weeks are several times greater than those obtained by using a single day lag and thus underestimate the impacts on health. The second is that other air pollutants in the mixture may be exerting additional effects, may interact with particles or may be confounding the associations of particles. Ozone, for example, is also toxic and while its effects tend to be independent of PM, it also seems to modify the effect of particles on number of hospital admissions (Atkinson et al. 2001).

## Definition and specification of health outcomes

We estimated the burden of disease imposed by mortality from cardiopulmonary disease and lung cancer in adults, and from ARI in children aged 0-4 years. We made this choice despite the fact, discussed above, that other serious health effects of air pollution are well-
documented, and that still others appear from more limited evidence to be of potential concern. Our decision to focus on mortality outcomes was made on the basis of the following considerations.

- Strength of evidence. A large body of research from many parts of the world indicates that ambient air pollution causes increased daily mortality from cardiovascular and respiratory disease. There appear to be comparable effects in the cities of developed and developing countries, on the basis of the limited evidence available. Although no cohort studies of mortality have as yet been conducted in developing countries, the possibility that associations comparable to those observed in the United States would be observed is strengthened by the results of the studies of daily mortality, and the limited results from studies of morbidity.
- Consistent definition of the end-point. Mortality per se is a welldefined event that is registered in most countries. For this reason, epidemiologists have frequently measured the effect of air pollution on total mortality from all natural causes, ascertained from death certificates or other sources of vital statistics. Other outcomes, such as bronchitis and the symptom of wheeze, are subject to very large variations in severity, and without such qualification their impact on health is difficult to assess. The definitions of other possible health outcomes, such as restricted activity days, use of primary health care services, diagnoses and school absences, are likely to vary with national culture and among health care systems.

The cause of death is more problematic because it is not certified medically in many countries, and there are considerable differences between and within countries in terms of diagnostic practice. Nevertheless, we propose to base our estimates primarily on cardiopulmonary, rather than total, mortality. There is strong evidence from both time-series and cohort studies that ambient air pollution specifically increases the risk of death from these causes. Moreover, variations in the relative contribution of non-cardiopulmonary mortality among countries could increase the error in the burden assessment, particularly in countries with lower cardiopulmonary death rates, potentially leading to overestimates of impact. Since considerable cross-coding is likely, we have chosen to use the combined cardiopulmonary group consisting of GBD infectious and chronic respiratory diseases and selected cardiovascular outcomes for adults. In children, death from cardiovascular diseases is rare and the pulmonary group is adequate.

- Availability of baseline occurrence rates. Data on age-specific mortality are collected or estimated using consistent methods for all subregions. This is not the case for some important potential measures of morbidity, such as the frequency of asthma attacks, or measures of
the utilization of health care services outside of Europe and North America.
- Importance of the end-point in terms of health impact. Although the impacts of air pollution on other health end-points must certainly contribute to the global burden of disease, mortality, quantified in terms of either numbers of deaths or reduced survival time, currently plays the most prominent role in impact assessments. We chose these three specific mortality outcomes (mortality from cardiopulmonary causes and lung cancer in adults aged $\geq 30$ years, and mortality from ARI in children aged $0-4$ years) because they allow us to estimate YLL, as discussed above.
- Feasibility within the time constraints of the current work. Given additional time and resources, future efforts might possibly consider, for example, using the evidence from the International Study of Asthma and Allergies in Childhood (ISSAC) (Anonymous 1998), which has data on prevalence from 60 countries as a baseline upon which to estimate the effect of particles on the exacerbation of asthma. Another possibility might be the effect on hospital admissions or primary health care visits.

### 3.4 Developing the concentration-response functions

We derived concentration-response functions for three end-points to produce the estimates of global burden of disease reported in this work: mortality from cardiopulmonary causes and lung cancer in adults aged $\geq 30$ years, and mortality from ARI in children aged $0-4$ years. As discussed earlier, we made no estimates of the impacts of PM on the incidence of disease, so the disability-adjusted life years (DALYs) quantify only YLL.

We assumed a log-linear risk model which leads to the following formula for the relative risk $(R R)$ in a population whose exposure is estimated by an average concentration of pollution $C$ relative to the reference level $C_{0}$ :

$$
\begin{equation*}
R R=\exp \left[\beta\left(C-C_{0}\right)\right] ; \tag{6}
\end{equation*}
$$

where, $C_{0}$, the reference, or theoretical minimum level of exposure, is defined as above and $\beta$ is the estimated effect of PM on the health outcome of interest. We calculated a subregion-specific relative risk for each of the 14 subregions using a population-weighted mean of concentrations for all cities in the subregion calculated as follows:

The subregion-specific relative risk for outcome $i$ in subregion $k$ related to $\mathrm{PM}_{2.5}, R R_{2.5 \mathrm{jk}}$, is:

$$
\begin{equation*}
R R_{2.5 i k}=\exp \left[\beta_{2.5 i} \times\left(C k_{2.5}-7.5\right)\right] \tag{7}
\end{equation*}
$$

where $C_{k 2.5}$ is the subregion-specific population-weighted mean concentration of $\mathrm{PM}_{2.5}$ (calculated from the estimated concentration of $\mathrm{PM}_{10}$ in Table 17.4, as described above), and $\beta_{2.5 i}$ is the slope of the concentra-tion-response function for $\mathrm{PM}_{2.5}$ (Table 17.7).

The subregion-specific relative risk for outcomes quantified in terms of $\mathrm{PM}_{10}, R R_{10 i k}$, is:

Table 17.7 Estimates of relative risk of mortality, coefficients of concentration-response functions and study types

| Health outcome | Data source |  | Relative risk per $10 \mu \mathrm{~g} / \mathrm{m}^{3}$ (95\% Cl), <br> from data source | Concentrationresponse slope ${ }^{\text {a }}$ per $\mu g / m^{3}$ (standard error) |

where $C_{k 10}$ is the subregion-specific population-weighted mean concentration of $\mathrm{PM}_{10}$ (Table 17.4), and $\beta_{10 i}$ is the slope of the concentra-tion-response function for $\mathrm{PM}_{10}$. The city-specific concentrations of $\mathrm{PM}_{10}$ were truncated at 15 and $100 \mu \mathrm{~g} / \mathrm{m}^{3}$ for calculation of subregionspecific population-weighted mean concentrations of $\mathrm{PM}_{10}$.

## Mortality from cardiopulmonary disease and lung cancer IN ADULTS

We used the results of the ACS study of urban air pollution and mortality (Pope et al. 2002) to estimate attributable deaths and YLL from cardiopulmonary diseases and lung cancer in adults aged $\geq 30$ years. In our base-case analyses we used the estimates of the concentrationresponse functions based on the ambient concentrations in 1979-1983, which correspond to increases of $5.9 \%$ and $8.2 \%$ in mortality from cardiopulmonary disease and lung cancer, respectively, for each $10 \mu \mathrm{~g} / \mathrm{m}^{3}$ change in the ambient concentration of $\mathrm{PM}_{2.5}$ (Table 17.7).

Deaths from cardiopulmonary disease and lung cancer in the ACS cohort were defined as persons whose underlying cause of death was coded according to the International Statistical Classification of Diseases, ninth revision, on their death certificates as ICD-9 401-440 and $460-519$, and 162 , respectively. When calculating the attributable fraction, ACS concentration-response functions for cardiopulmonary disease defined in this way were applied to baseline cause-specific rates of mortality in the GBD project. For lung cancer, this corresponded exactly to the definition used in the ACS study. For cardiopulmonary deaths, the GBD groupings of cause of death $(39,40,106-109,111)$ did not include several ICD codes (406-409, 415-417, 423-424, 426-429, 440) that were included in the ACS definition. These codes represent diverse cardiac diseases, including conduction disorders, cardiac dysrhythmias, heart failure and ill-defined cardiac causes. Together they comprise approximately $18 \%$ of all cardiopulmonary deaths in the ACS study (R. Burnett, personal communication).

The ACS study estimated concentration-response functions for $\mathrm{PM}_{2.5}$ over a range that extends from annual average concentrations of $\mathrm{PM}_{2.5}$ of about $5-30 \mu \mathrm{~g} / \mathrm{m}^{3}$ (Pope et al. 2002). The shape of the concentra-tion-response function for fine particulate air pollution outside that range is currently unknown, as noted above, and estimated annual average concentrations of $\mathrm{PM}_{2.5}$ in some subregions are outside that range (Table 17.1). In our base-case analyses we limited the risk of mortality in any city to be no greater than that attained at a concentration of $\mathrm{PM}_{2.5}$ of $50 \mu \mathrm{~g} / \mathrm{m}^{3}$ (Figure 17.7). Thus, for cities with estimated annual average concentrations of $>50 \mu \mathrm{~g} / \mathrm{m}^{3}$, we assigned a maximum concentration, or $\mathrm{C}_{\mathrm{m}}$, equal to $50 \mu \mathrm{~g} / \mathrm{m}^{3}$, regardless of their actual estimated

Figure 17.7 Alternative concentration-response curves for mortality from cardiopulmonary disease, using different scenarios

concentration. This means that the excess risk is constrained to be no greater than that associated with an annual average concentration of $50 \mu \mathrm{~g} / \mathrm{m}^{3}$, regardless of the actual estimated annual average concentration. The counterfactual or theoretical minimum concentration was set at $7.5 \mu \mathrm{~g} / \mathrm{m}^{3}$, as discussed above.

We set the maximum city-specific concentration of $\mathrm{PM}_{2.5}, \mathrm{C}_{\mathrm{m}}$, at $50 \mu \mathrm{~g} / \mathrm{m}^{3}$ to avoid producing unrealistically large estimates of mortality in the most extremely polluted subregions under a linear exposure model. With $\mathrm{C}_{\mathrm{m}}=50$, the subregion-specific attributable fraction was restricted to no more than approximately $25 \%$ of the burden of a given health outcome, while not greatly exceeding the maximum observed annual average concentration in the ACS study. We also examined alternative values for the shape of the concentration-response function for $\mathrm{PM}_{2.5}$ and mortality from cardiopulmonary disease and lung cancer in sensitivity analyses, as described below.

## MORTALITY FROM ACUTE RESPIRATORY INFECTIONS IN CHILDREN AGED 0-4 YEARS

In view of the importance of mortality from ARI among children in developing countries and the suggestion from available evidence of an association with air pollution (Romieu et al. 2002), we decided to make
a summary estimate on the basis of these studies, in spite of their heterogeneity in outcomes and age groups.

To estimate the relationship between exposure to PM and mortality from ARI among children aged $0-4$ years, we computed a summary estimate from the five published time-series studies discussed above (Table 17.6 and Figure 17.6). One study (Pereira et al. 1998) was excluded because the outcome, intrauterine mortality, was clearly unrelated to ARI. The five remaining studies were summarized as a weighted average of the estimates from individual studies (scaled to $\mathrm{PM}_{10}$, as discussed above) with the weights determined by the inverse of the reported variance in the concentration-response function. We estimate that a $10 \mu \mathrm{~g} / \mathrm{m}^{3}$ increase in ambient concentrations of $\mathrm{PM}_{10}$ results in a $1.0 \% ~(95 \% \mathrm{CI}-$ $0.9 \%-3.1 \%$ ) increase in daily mortality from ARI in children aged $0-4$ years (Table 17.7).

When calculating the attributable fraction, this concentrationresponse function was applied to GBD baseline cause-specific rates of mortality from acute respiratory infection (GBD code 38) that includes ICD-9 codes 460-466, 480-487 and 381-382.

## Numbers of deaths from all natural causes caused by short-TERM EXPOSURE TO URBAN AIR POLLUTION IN ADULTS

We also calculated an estimate of the numbers of deaths from all natural (non-injury) causes attributable to short-term exposure to urban air pollution using an estimate of concentration-response derived from international literature on air pollution and daily mortality. This estimate was not included in the total attributable deaths and disease burden because of the conceptual issue in quantifying the effects of short-term exposure discussed above.

Using the St George's Hospital Medical School database, described above, we identified 165 time-series studies of $\mathrm{PM}_{10}$ and daily mortality from all causes at all ages in all languages and countries, up to the end of July 2001. As we were concerned about the possibility of publication bias, we compared the summary estimates from 54 individual studies, a subset of the literature which would be expected to be susceptible to publication bias, with those of the two multi-city studies (Health Effects Institute 2000b; Katsouyanni et al. 2001), which selected cities from a pre-specified sampling frame, used uniform methods of analysis, and published all results. The pooled estimate for the cities of the combined APHEA and NMMAPS studies $(n=111)$ was 1.005 ( $95 \%$ CI 1.004-1.006) with no evidence of publication bias in the funnel plot or on statistical testing. For the 54 studies of individual cities, graphical analysis showed some evidence of publication bias but when formally tested, this was weak $(P=0.12)$. The pooled estimate was $1.007(95 \%$ CI 1.006-1.008) but when adjusted for publication bias using Trim and Fill analysis, it was reduced to 1.006 ( $95 \%$ CI $1.004-1.007$ ). We then examined the results for all 165 studies with results for $\mathrm{PM}_{10}$. There was
no evidence of publication bias on inspection of the funnel plot or on formal testing with Begg's or Eggar's tests (Begg and Mazumdar 1994). We calculated pooled estimates weighted according to the inverse of the variance of the individual study. Random effects models were used, as all showed significant heterogeneity. The pooled estimate was 1.006 ( $95 \%$ CI $1.005-1.007$ ) (Table 17.7). This concentration-response function was applied to all GBD baseline cause-specific rates of mortality except GBD code 148 (injuries). ${ }^{10}$

## 4. Uncertainty estimates: statistical variability and sensitivity analyses

The total uncertainty in our estimates of the burden derives from both the statistical (sampling) variability of the parameter estimates in the models we chose to quantify disease burden, and our uncertainty with regard to those choices vs plausible alternatives, i.e. the form of our models (Morgan and Henrion 1998). We therefore quantified the statistical uncertainty of our estimates in terms of a combined, or propagated, uncertainty estimate, and used sensitivity analyses to quantify model uncertainty.

### 4.1 Statistical (sampling) variability

Our estimate of statistical uncertainty combined the sampling errors from two sources to derive an uncertainty distribution:

- sampling variability in the original concentration-response estimates from the ACS and time-series studies quantified in terms of their standard errors (Table 17.5); and
- sampling variability in the estimates of subregional concentration of PM from the exposure estimation model in terms of estimates of bootstrapped standard error described above (Table 17.4).
When presenting our results we show either the complete uncertainty distribution or the intervals between the 25 th and 75 th and/or 2.5th and 97.5 th percentiles of that distribution, i.e. $50 \%$ and $95 \%$ uncertainty intervals.

### 4.2 Sensitivity analyses

We used sensitivity analyses, described below, to quantify the uncertainty in our base-case estimates, in which the burden of disease was estimated by applying the ACS concentration-response function over the range of 7.5 to $50 \mu \mathrm{~g} / \mathrm{m}^{3}$, as discussed above.

- Cases 2-4: Shape of the concentration-response function for $P M_{2.5}$ and mortality attributable to cardiopulmonary disease and lung cancer. We explored three alternatives to the base-case scenario for extrapolating the ACS concentration-response function beyond
$30 \mu \mathrm{~g} / \mathrm{m}^{3}$, the highest annual average concentration observed in the ACS study (Figure 17.7).
- Case 2: No incremental increase in excess mortality above $30 \mu \mathrm{~g} / \mathrm{m}^{3}$ $P M_{2.5}$. Under this scenario, when calculating the population-weighted subregional average concentration of $\mathrm{PM}_{2.5}$ we give the city-specific $C_{m}$ a value of $30 \mu \mathrm{~g} / \mathrm{m}^{3}$, regardless of the estimated concentration, rather than the base-case concentration of $50 \mu \mathrm{~g} / \mathrm{m}^{3}$. This means that the excess risk is constrained to be no greater than that associated with an annual average concentration of $30 \mu \mathrm{~g} / \mathrm{m}^{3}$, regardless of the actual estimated annual average concentration. The counterfactual or theoretical minimum concentration was set at $7.5 \mu \mathrm{~g} / \mathrm{m}^{3}$. We considered this the estimator that would produce the smallest (i.e. most scientifically conservative) estimate of the impact of mortality consistent with the use of the ACS concentration-response function.
- Case 3: Excess mortality increases linearly above $30 \mu \mathrm{~g} / \mathrm{m}^{3} P M_{2.5}$. Under this scenario, the city-specific concentration of $\mathrm{PM}_{2.5}$ takes its actual estimated value when calculating the population-weighted subregional averages, i.e. in contrast to the base-case and case 2 scenarios. The counterfactual or theoretical minimum concentration was set at $7.5 \mu \mathrm{~g} / \mathrm{m}^{3}$. We considered this the estimator that would produce the largest estimate of mortality impact consistent with the use of the ACS concentration-response function.
- Case 4: Excess mortality increases with the log of concentration of $P M_{2.5}$ across the entire range. Under this scenario, the city-specific concentration of $\mathrm{PM}_{2.5}$ takes the $\log$ of its actual estimated value when calculating the population-weighted subregional averages. Therefore, in contrast to case 3, the slope of the concentration-response function is constrained to decrease at higher concentrations. The counterfactual or theoretical minimum concentration was set at $7.5 \mu \mathrm{~g} / \mathrm{m}^{3}$.

We included this estimator, proposed by an external reviewer after we had made our initial estimates (R. Burnett, personal communication), because it seemed a reasonable way to characterize an excess risk that we believed may: (i) increase directly with ambient levels over the entire range of annual average concentrations that we estimated for the world's cities, but (ii) be smaller at higher ambient concentrations, as has been observed for daily mortality in time-series studies (Daniels et al. 2000; Schwartz et al. 2002).

- Cases 5 and 6: Choice of ACS concentration-response function. In the base-case analyses, we used the ACS coefficients that were based on exposure of the cohort in 1979-1983. These arguably best represented the effects of long-term past exposure that some researchers assume are responsible for the increased mortality attributable to air pollution in that cohort through to 1998. There is, however, consid-
erable uncertainty regarding the timing of exposure with regard to risk of mortality (Krewski et al. 2000), so we calculated alternative estimates using the reported ACS coefficients based on the average of past (1979-1983) and recent (1999-2000) annual average concentrations using both a linear (case 5) and log-linear (case 6) extrapolation (Table 17.7).
- Case 7: Change $P M_{2.5}: P M_{10}$ ratio. In the base-case analyses, we assumed a $\mathrm{PM}_{2.5}: \mathrm{PM}_{10}$ ratio of 0.50 , although higher and lower ratios have been observed in a number of locations, as discussed above. We examined the sensitivity of our base-case analyses by assigning cities in AMR-A, EUR-A, EUR-B, EUR-C and WPR-A a higher scaling factor of 0.65 , while assigning a lower scaling factor of 0.35 to cities in all other subregions.
- Cases 8 and 9: Choice of counterfactual or theoretical minimum concentration. We evaluated the sensitivity of the base-case estimates to two different choices of counterfactual $\mathrm{PM}_{2.5}$ concentration: $3 \mu \mathrm{~g} / \mathrm{m}^{3}$ (case 8) and $15 \mu \mathrm{~g} / \mathrm{m}^{3}$ (case 9). The former is close to the minimum background level of $\mathrm{PM}_{2.5}$ observed in the United States, and the latter is the annual concentration of $\mathrm{PM}_{2.5}$ proposed by the United States National Ambient Air Quality Standard (NAAQS) (U.S. Environmental Protection Agency 2002). Each value was substituted for the base-case concentration of $7.5 \mu \mathrm{~g} / \mathrm{m}^{3}$ in Equation 7 above, when calculating population-weighted subregional relative risks.

## 5. Results

### 5.1 Base-case estimates

We estimated that exposure to particulate air pollution caused approximately 800000 excess deaths and 6.4 million DALYs (consisting only of years of life lost to premature mortality) in the year 2000 worldwide as a result of cardiopulmonary disease, lung cancer and ARI in children aged $0-4$ years, combined (Table 17.8).

The worldwide estimates of attributable deaths and YLL from cardiopulmonary and lung cancer are subject to uncertainty contributed by the estimation of both the relative risks and the ambient concentrations of PM (Figure 17.8).

Cardiopulmonary disease in adults aged $\geq 30$ years contributed $89 \%$ ( 712000 ) and $78 \%$ ( 4.97 million) of attributable deaths and burden, respectively. Lung cancer contributed $8 \%$ and $9 \%$ and ARI in children, contributed $3 \%$ and $7 \%$ of deaths and YLL, respectively, to the total burden (Tables $17.9[\mathrm{a}]-17.9[\mathrm{c}]$ ). The number of attributable deaths from all natural causes estimated from the daily time-series studies was roughly half the total attributable deaths, 378000 vs 799000 (Table

17.9 [d]). The overall and cause-specific burden of disease varies across the 14 subregions, with the preponderance of the burden of air pollution contributed by cities in WPR-B, which includes China, and SEARD , which includes India. The variation in attributable deaths and YLL among the 14 subregions seen in Tables 17.9 (a)-(d) reflects a subregional variation in the attributable fraction of approximately six-fold. For example, for all mortality end-points, EUR-A and WPR-B lie at the low and high ends, respectively, of the subregional distribution of attributable fractions. This largely reflects differences in the estimated populationweighted subregional ambient concentrations of $\mathrm{PM}_{10}$ and $\mathrm{PM}_{2.5}$ ( 89 vs $26 \mu \mathrm{~g} / \mathrm{m}^{3} \mathrm{PM}_{10}$ (see Table 17.4), rather than the proportion of the population that resides in cities. The proportion of the population of WPR-B that lives in cities is, in fact, lower than that in EUR-A ( $34 \%$ vs 39\%).

### 5.2 Sensitivity analyses

Cases 2-4: Shape of the concentration-Response function for PM ${ }_{2.5}$
The estimates of attributable deaths from cardiopulmonary disease and lung cancer and YLL under the base-case and three alternative scenarios for the shape of the $\mathrm{PM}_{2.5}$ concentration-response function are presented in Table 17.10. When the city-specific estimated concentrations

Figure 17.8 Uncertainty distributions for deaths and YLL from cardiopulmonary disease and lung cancer worldwide

of $\mathrm{PM}_{2.5}$ are constrained to never exceed the concentrations observed in the most polluted city in the ACS study (annual average concentration of $\mathrm{PM}_{2.5}$ of $30 \mu \mathrm{~g} / \mathrm{m}^{3}$ ), case 2 , worldwide estimates of the number of deaths from cardiopulmonary disease and lung cancer are reduced by $29 \%$ and $27 \%$, respectively. Extrapolation of the ACS coefficients to the highest estimated city-specific concentrations of $\mathrm{PM}_{2.5}$ on the linear and logarithmic scales, cases 3 and 4, respectively, results in increases of $10 \%$ and $12 \%$ in the estimated number of attributable deaths from cardiopulmonary disease, and $8-24 \%$ increases in the estimated numbers of attributable deaths from lung cancer, relative to the base-case estimates.

These changes in worldwide estimates reflect underlying differences in the subregion-specific estimates (Table 17.11). Truncating the cityspecific annual average concentrations at a given level leaves the burden unchanged in subregions with cities with estimated concentrations of PM that are lower than the truncation point, while reducing the burden in subregions with cities with estimated concentrations of PM that are above that point. Most cities in Europe and North America have

estimated annual average concentrations of $\mathrm{PM}_{2.5}$ of $<30 \mu \mathrm{~g} / \mathrm{m}^{3}$, while estimated concentrations in the cities of developing countries are frequently much greater. More than $95 \%$ of the decrease in the worldwide burden in case 2 and the increase in case 3 occurs in four subregions: WPR-B, EMR-D, SEAR-B and SEAR-D.

Log-linear specification of the concentration-response function, as in case 4 , allows for a more gradual increase in the relative risk at concentrations of PM of $>30 \mu \mathrm{~g} / \mathrm{m}^{3}$ than does the linear extrapolation model of case 3. This specification also means that the relative risk increases more steeply at concentrations of $<30 \mu \mathrm{~g} / \mathrm{m}^{3}$. Since the estimates for burden in both the log-linear case and the base case are measured with reference to a counterfactual annual average concentration of $\mathrm{PM}_{2.5}$ of $7.5 \mu \mathrm{~g} / \mathrm{m}^{3}$, the burden under the log-linear specification is higher than that under the base case at low levels of exposure, but lower than the base case at high levels of exposure. Differences in the subregion-specific estimates for burden under the log-linear specification relative to the base case depend on the subregion-specific distributions of the city-specific concentrations of PM. The burden of disease in subregions where exposure is relatively low (AMR-A, EUR-A, EUR-C and WPR-A) increases by $63 \%$, relative to the base case, while the burden in subregions where exposure is high remains unchanged or is slightly reduced.

Linear extrapolation beyond concentrations of PM of $30 \mu \mathrm{~g} / \mathrm{m}^{3}$ of larger alternative coefficients from the ACS study on the basis of the average of ambient concentrations measured in 1979-1983 and 1999-2000 resulted in increases of $59 \%$ and $63 \%$ in deaths attributable to cardiopulmonary disease and lung cancer, respectively, relative to the base-case estimates. Log-linear extrapolation of the larger coefficients produced increases of $50 \%$ and $69 \%$ in the number of deaths attributable to cardiopulmonary disease and lung cancer, respectively (Table 17.10).

Attributable burdens increased in all subregions (Table 17.11). The differences between the linear and log-linear estimates followed the same subregional patterns as in cases 3 and 4, discussed above.

## Case 7: Choice of PM $_{2.5}:$ PM $_{10}$ Ratio

Allowing limited subregional variation in the ratio of $\mathrm{PM}_{2.5}$ to $\mathrm{PM}_{10}$ produced reductions of $15 \%$ and $7 \%$ in the worldwide estimates of numbers of deaths attributable to cardiopulmonary disease and lung cancer, respectively, relative to the base-case scenario in which this ratio was fixed at 0.50 (Table 17.10).

As one might expect, the burden of disease increases by $57 \%$ in those subregions assigned a ratio of 0.65 , that is, AMR-A, all of Europe, and WPR-B. This increase is more than offset by the rest of the world, assigned a ratio of 0.35 , where the burden of disease falls by $31 \%$ (Table 17.11).

## Cases 8 and 9: Choice of theoretical minimum level of exposure

Halving and doubling the base-case theoretical minimum concentration of $\mathrm{PM}_{2.5}$ of $7.5 \mu \mathrm{~g} / \mathrm{m}^{3}$ resulted in a $24 \%$ increase and a $33 \%$ decrease in the number of deaths attributable to cardiopulmonary disease, and a $29 \%$ increase and a $37 \%$ decrease in deaths attributable to lung cancer, but only minor variations in mortality from ARI (Table 17.10).

All subregions experienced increases in attributable burden when the theoretical minimum concentration was halved, with the largest proportional increases in less polluted subregions (AMR-A, EUR-A and WPR-A). These subregions also experienced the largest reductions in burden when the theoretical minimum concentration was doubled. Highly polluted subregions (WPR-B and SEAR-D) also experienced marked reductions in the estimated burden when the theoretical minimum concentration was doubled (Table 17.11).

## 6. Discussion

Previously, most large-scale estimates of the health impacts of urban air pollution were conducted for countries or regions where data on expo-
sure and estimates of effect required for impact estimation were available (e.g. Brunekreef 1997; COMEAP 1998; Künzli et al. 2000; Ostro and Chestnut 1998). In the few previous global estimates, systematic methods were not applied to extrapolate exposures and exposureresponse functions to other parts of the world (Hong 1995; WHO 1997; Working Group on Public Health and Fossil Fuel Combustion 1997). Although our estimates exceed those reported earlier, the differences are not large, given the variation in the approaches that were taken (Smith and Mehta 2003). The global scope of the present analysis required new approaches for estimating exposure, absent measurements of air pollution in many developing countries, extrapolating the results of epidemiological studies more widely than had previously been attempted, and describing and attempting to quantify, the many uncertainties this entailed. The results indicate that the impact of urban air pollution on the burden of disease in the cities of the world is large and, for a variety of reasons discussed below, have probably underestimated the burden. There is also considerable variation in our estimates among the 14 subregions, with the greatest burden occurring in the more polluted and rapidly growing cities of developing countries.

The availability of actual measurements of outdoor concentrations of PM varied widely across the globe. In order to have estimates for all 14 subregions, models developed by the World Bank were used to estimate concentrations of inhalable particles ( $\mathrm{PM}_{10}$ ) using economic, meteorological and demographic data and the available measurements of PM for 3211 cities with populations of $>100000$, and also capital cities. To allow the most appropriate epidemiological studies to be used for the estimation of the burden of disease, the $\mathrm{PM}_{10}$ estimates were converted to estimates of fine particles $\left(\mathrm{PM}_{2.5}\right)$ using information on geographic variation in the ratio of $\mathrm{PM}_{2.5}$ to $\mathrm{PM}_{10}$. Population-weighted subregional annual average exposure estimates for $\mathrm{PM}_{2.5}$ and for $\mathrm{PM}_{10}$ were obtained using the population of the city in the year 2000.

The estimates of the burden of disease were based on three health outcomes: mortality from cardiopulmonary causes in adults, mortality from lung cancer and mortality from ARI in children aged $0-4$ years. Attributable numbers of deaths and YLL for adults and children (aged $0-4$ years) were estimated using risk coefficients from a large cohort study of adults in the United States (Pope et al. 2002) and a metaanalytic summary of five time-series studies of mortality in children, respectively. Base-case estimates were calculated assuming that the risk of death increases linearly over a range of annual average concentrations of $\mathrm{PM}_{2.5}$ between a counterfactual (or referent) concentration of 7.5 and a maximum of $50 \mu \mathrm{~g} / \mathrm{m}^{3}$. For comparison, an additional estimate of attributable deaths was calculated from time-series studies of daily mortality, on the basis of results of a meta-analysis of the world literature, but was not used in the final calculations. Worldwide and subregion-
specific estimates of attributable deaths and burden of disease in terms of YLL were calculated based on the standard methodology developed for this project (see chapters 1 and 25).

We estimated that urban air pollution, as measured by PM, is responsible for about $3 \%$ of mortality caused by cardiopulmonary disease in adults, about $5 \%$ of mortality caused by cancers of the trachea, bronchus and lung, and about $1 \%$ of mortality caused by ARI in children worldwide in the year 2000. The total burden was about 0.80 million ( $1.2 \%$ of total) premature deaths and 6.4 million ( $0.5 \%$ of total) DALYs. This burden occurred predominantly in developing countries, with $30 \%$ of attributable disease burden occurring in WPR-B and 19\% in SEAR-D. The greatest contributions to the total burden of disease occurred in WPR-B, EUR-B and EUR-C, where urban air pollution caused 0.7-0.9\% of the total burden of disease.

### 6.1 IDENTIFYING AND QUANTIFYING UNCERTAINTY IN THE ESTIMATES

These estimates are subject to considerable uncertainty given the need to estimate exposures and to extrapolate concentration-response relationships. This is almost invariably the case in quantitative risk assessment of complex environmental exposures; and is certainly to be expected in this particular exercise, for reasons discussed above.

We quantified the statistical uncertainty of our base-case estimates by estimating the joint uncertainty in the estimates of annual average concentration and the estimates of the relative risks. Worldwide and most subregional estimates vary by less than two-fold ( $50 \%$ uncertainty intervals (Tables 17.8 and $17.9[\mathrm{a}]-[\mathrm{c}])$. Uncertainty of the model owing to assumptions about the shape of the concentration-response function, the magnitude of the relative risk of disease attributable to urban air pollution, the choice of counterfactual level for PM , and the ratio of $\mathrm{PM}_{2.5}$ to $\mathrm{PM}_{10}$ was assessed in sensitivity analyses. For the most part, the estimated worldwide burdens in the various sensitivity analyses are within the $50 \%$ uncertainty interval for the base-case estimate of worldwide burden. The sensitivity analyses indicate that base-case estimates were most sensitive to choice of coefficient from the ACS study and theoretical minimum concentration.

Although some sources of uncertainty could be quantified, others that were no less important or were perhaps more important, could not. These additional sources of uncertainty arise from the methods we used to estimate annual average exposure of the population and our choice of health end-points and concentration-response functions.

Estimates of exposure to urban air pollution
There are four key uncertainties related to exposure that have not been quantified, and that could affect the estimates of burden of disease.

First, we used PM as the sole indicator of exposure to urban air pollution, although urban air pollution is a complex mixture, as noted above. Other frequently measured pollutants, notably ozone, carbon monoxide, oxides of sulfur and nitrogen, and lead are associated with mortality and morbidity, albeit not as consistently as PM, although the effects of a number of these pollutants may be at least partially captured via the use of a PM metric (Sarnat et al. 2001). Estimating the health impacts of specific components poses challenges for both scientific research and risk assessment, including how to avoid attributing the same burdens to multiple pollutants (i.e. double counting), and how to quantify the effects of possible interactions (i.e. synergistic effects) among pollutants. Nonetheless, there is evidence for an effect of ozone on daily mortality that is independent of PM (e.g. Health Effects Institute 2000b). Future estimates of the burden of disease should include the health impacts of ozone. Unfortunately, lead in petrol remains an important toxic component of air pollution in some cities of the developing world and its contribution to the burden of disease has been estimated elsewhere in this book (see chapter 19). Some combination of the GBD estimates for urban air pollution and lead probably provide the best overall estimate of the burden of disease attributable to urban air pollution.

Second, use of estimated levels of exposure introduces some uncertainties and biases in the predicted levels of exposure that could not be addressed, owing to lack of data. The most important of these is the lack of city-specific data on the structure of economic activity and on fuel consumption. The exposure model uses national average data for these variables as a reasonable proxy, which can lead to bias in unknown directions with regard to city-specific estimates. The net bias in estimates of the aggregate burden at the subregional level is unclear. The use of long-run average climatic conditions instead of time-varying local data may result in biased estimates for specific years, but may not pose a serious problem as we are interested mainly in the long-term average health effects of air pollution. We have also explicitly examined our uncertainty regarding spatial variations in the size composition of PM through sensitivity analysis. The model for the estimation of exposure clearly suggests that coarser particles account for a larger fraction of the TSP in developing countries than in developed countries, all other things being equal. The limited data from monitoring available on $\mathrm{PM}_{2.5}$ also indicate that spatial variations may also exist in the sizes of finer particles. Consequently, we have used conservative estimates for the fraction of $\mathrm{PM}_{10}$ accounted for by finer particles in our overall estimates and further tested the implications of using an even more conservative estimate. The burden estimates should be relatively insensitive to PM size fraction.

Third, misclassification of exposure may have led to underestimation of the burden of disease. Like the epidemiological studies used to quantify the estimates of health impact, we used the annual average ambient
concentration measured from a few stationary sources in each city to estimate average personal levels of exposure. Differences between personal levels of exposure and concentrations measured at fixed points depend on how well the pollutant mixes in the environment and the efficiency with which the pollutant penetrates indoors. The exposure estimates are based on a model developed from population-oriented monitors. Measurements of PM from these sites in well-designed monitoring networks would provide representative city-wide levels of exposure for a pollutant that mixes uniformly in the environment. They would underestimate the actual level of exposure of people living near pollution hotspots, such as busy roads or local sources of pollutant, which can contribute to spatial heterogeneity of exposure within cities (Hoek et al. 2002; Jerrett et al. 2001). This underestimate would probably be more pronounced for cities in developing countries, where nearly one third of the population resides in slums, which are often in heavilypolluted parts of cities, and even larger populations work near pollution hotspots.

Exposure misclassification from using outdoor concentrations to represent personal exposure to urban air pollution also results from differences in the efficiency with which PM penetrates indoors. Use of ambient concentrations as surrogates for exposure tends to underestimate the risk per unit exposure because the penetration of particles indoors, where most exposure occurs, is less than $100 \%$. If average penetration is $66 \%$, for example, actual exposure-response per $1 \mu \mathrm{~g} / \mathrm{m}^{3}$ would be 1.5 -fold that indicated by outdoor concentrations of pollution. However, because of climate and housing, the rates of penetration of pollution in most, but not all, cities in developing countries can be expected to be somewhat greater than those in the average city in the United States where the epidemiology used here has been undertaken. Not being able to consider this factor because of lack of data on penetration of the pollutant would bias estimates of burden downward if actual changes in exposures in developing countries are better indicated by changes in outdoor concentrations than in developed countries.

An additional source of misclassification concerns the time referent of our exposure estimate. The current burden is related to past exposure, but our model estimates current (i.e. 1999) levels only. However, even if we had been able to retrospectively estimate a time series of annual average concentrations for each subregion, the ACS study provides little information as to how the concentration-response function varies over time (Krewski et al. 2000). It is not clear how this source of misclassification would affect our estimates.

Fourth, our estimates do not include the attributable burden of disease among the 800 million additional urban residents living either in suburban areas of some of the cities or in cities with populations of $<100000$ and in the $>3$ billion residents of rural areas. Although lower levels of emissions per area combined with the differences in the built-up envi-
ronment in rural areas probably results in a small average exposure to ambient pollution and a modest increase in the global burden of disease from such pollution in rural areas, the same is not true for the urban residents that were not included in the target population. The magnitude of the missing burden depends on the actual exposures of those living in smaller cities. The target population was identified for the study on the basis of data available from the United Nations, which compiles the data reported by Member States from national censuses and makes projections from them on the basis of expected changes in demographics. In compiling the population statistics, Member States, hence the United Nations, do not use uniform definitions either for city area (the characteristic such as city size that defines an urban area) or the population included for each identified city (whether political boundaries are used or agglomerations of contiguous urban areas are used). For the target population, we have used the population of the city agglomeration when this choice was available. If all of the remaining 800 million residents lived in suburban areas next to a targeted city, exposures and hence, estimates of burden, for these residents could be expected to be similar to those in the identified city resulting in an aggregate underestimate of the attributable fraction of the population of about $28 \%$. The exposure model suggests, however, that concentrations gradually decrease as the local population density decreases, suggesting that levels of exposure and hence estimates of burden are lower for these residents compared to those living in larger cities. The net result is that our focus on residents in cities with $>100000$ inhabitants may underestimate the aggregate burden by between $0 \%$ and $28 \%$.

## Choice of health end-Points and ConcentrationRESPONSE FUNCTIONS

Our base-case estimates of burden in terms of disease burden considered only the impact of air pollution on mortality. This approach is likely to have underestimated the true attributable burden, since there is evidence from studies of both epidemiology and toxicology, to suggest that air pollution may play a role in the incidence of cardiopulmonary disease, and thus contribute to years lived with disability (YLD). Lacking estimates of the concentration-response function for air pollution and the incidence of cardiopulmonary disease, lung cancer, and ARI in children, we calculated disease burden under the assumption that air pollution multiplies both incidence and mortality to the same extent, i.e. the relative risk of unobserved morbidity equals the observed relative risk of mortality (Table 17.12), an approach taken to estimating the attributable burden caused by other factors other than urban air pollution. The total disease burden, including YLD for cardiopulmonary disease, exceeds the YLL by $23 \%$ worldwide in the base-case analyses. The effect on the estimated burden for lung cancer and ARI in children is negligible.

Table 17.12 Attributable YLL and DALYs for cardiopulmonary disease, lung cancer, $\mathrm{ARI}^{1}$ and total mortality

a In children aged 0-4 years.

The estimates of the attributable burden caused by cardiopulmonary disease and lung cancer were derived from a single cohort study in the United States (the largest and most extensively reviewed study suitable for the estimation of the burden of disease). This raises questions concerning whether these results can be generalized to other populations, especially those in developing countries, owing to differences in susceptibility to the effects of air pollution and the nature of the mixture of air pollutants. The apparent qualitative and quantitative similarity of the relative risks of daily mortality in developed and developing countries, discussed above, provides some evidence that these results are generally applicable. In addition, trends in known risk factors for chronic cardiovascular and respiratory disease, such as diet and cigarette smoking, suggest that the populations of cities in developing countries may now be more comparable to populations of cities in Europe and North America with regard to susceptibility to air pollution conferred by preexisting cardiovascular and respiratory morbidity (Reddy and Yusuf 1998). The increasing contribution of mobile sources to urban air pollution in developing countries also increases the similarity with cities in North America and Europe.

Other sources of uncertainty in our estimates cannot be readily quantified for the following reasons:

- Lack of knowledge concerning differences between developed and developing countries in the physicochemical nature of PM produced by different sources. The relative toxicity of PM may well vary according to the type of fuel burned and the type technology used to burn it. Increased burning of refuse outdoors and the prevalence of motor vehicles without emissions controls (e.g. vehicles powered by twostroke engines) are two examples.

Inhalable particles that are not the direct or indirect product of combustion sources may also be important. These particles are mainly of crustal origin and may be important, for example, in desert areas, or where there is disturbance of surface material owing to construction, use of unsurfaced roads, etc. They are largely found in the coarse fraction of inhalable particles, whereas combustion-derived particles tend to be found in the fine and ultra-fine fractions. The evidence concerning the toxicity of this fraction is mixed (Anderson 2000). Data on worldwide variation in the ratio of fine to coarse particles is limited, as discussed above, and our sensitivity analyses, which suggest relatively minor differences with our base-case estimates, may understate the uncertainty.

- Lack of knowledge concerning differences in the susceptibility of the population. Despite the trends discussed above, differences in demography and in the patterns of the incidence and prevalence of disease may be associated with differences in short-term and long-term vulnerability to air pollution. There exists the possibility of effectmodification factors related to health status, and behavioural factors, such as smoking and diet (Katsouyanni et al. 2001). The effects of previous or concurrent exposure to high levels of indoor air pollution may also play a role in determining susceptibility to urban air pollution. Poverty, which is a determinant of the factors just discussed, may also determine susceptibility in other ways. If the effects of air pollution are more severe among the poor, who comprise a large part of the world's population, then the magnitude of the burden would likely be greater than that which we estimated (Krewski et al. 2000; O’Neill et al. 2003).
- The shape of the exposure-response relationship may differ between developing and developed countries in ways that were not captured in the sensitivity analyses. For example, a recent time-series study of daily mortality in Mexico City did not observe a flattening of the $\mathrm{PM}_{10}$ concentration-response curve until $175 \mu \mathrm{~g} / \mathrm{m}^{3}$ (the daily mean) (Tellez-Rojo et al. 2000). These concentrations are measured in many mega-cities in developing countries.

We did not know which form of the concentration-response relationship should be used in extrapolating the results of the ACS study to the much higher concentrations observed in cities in India and China, for example. For this reason, we examined the sensitivity of the estimates to a range of scenarios, presenting a "base case", which we thought was a reasonable compromise between the conditions of the ACS and those of the rest of the world. Cohort evidence has recently been reported from Europe, although unfortunately it was unable to estimate concentrations of PM (Hoek et al. 2002). This study provides evidence that long-term exposure to urban pollution is associated with health effects elsewhere in developed countries, but we still lack cohort evidence from developing countries.

## Mortality from acute respiratory infections in children aged 0-4 YEARS

Despite limited evidence, discussed above, linking mortality from ARI to exposure to urban air pollution, we used the results from the small number of time-series studies in developing countries to estimate attributable deaths and YLL in children aged 0-4 years. In our view, most of these deaths are likely to be among children with temporary vulnerability owing to chest infections which would resolve eventually, and therefore represent, on average, the loss of many potential years of life, but this view is largely speculative.

Several studies that we used to derive the concentration-response function for ARI mortality actually reported results for all causes mortality in the $0-4$ years age group (Ostro et al. 1999a), or total mortality in the first year of life (Loomis et al. 1999). We have assumed that the relationship between $\mathrm{PM}_{10}$ and mortality from ARI in children aged $0-4$ years is similar to that for all-cause mortality. To some extent this is justified by the knowledge that mortality from ARI is an important component of all-cause mortality in developing countries.

### 6.2 Generalizability of our results

As a consequence of the uncertainties in this global assessment, its quantitative results cannot be confidently extrapolated to smaller geographic areas, such as specific countries or cities. The methods for estimation of exposure and extrapolation of concentration-response functions were developed specifically for estimating burdens for large geographic regions, often in the absence of essential data on exposure and response. Where better data exist, as they currently do in some parts of the world, they can, of course, be used.

Differences between our estimates and those of other groups may reflect other differences in methodology. For example, a tri-national European assessment recently estimated that some 40000 deaths per year were attributable to exposure to ambient air pollution in a population of approximately 72 million, whereas the burden in EUR-A, in an urban
population of 80 million, was estimated to be 23000 deaths per year, despite similar estimates of the concentration of ambient pollution (Künzli et al. 2000). The difference is largely owing to the different assumptions regarding the exposure reference level of $15 \mu \mathrm{~g} / \mathrm{m}^{3} \mathrm{PM}_{10}$ in this work vs $7.5 \mu \mathrm{~g} / \mathrm{m}^{3}$ in the European study. In addition, the concentration-response functions were slightly higher in the tri-national project, which used estimates of total mortality from both the first ACS publication and the Harvard Six City estimates (Dockery et al. 1993; Pope et al. 1995).

### 6.3 Avoidable disease burden

We did not attempt to estimate the avoidable burden of disease, despite this being a specific objective of the project. Estimating the avoidable burden would have required making projections of concentrations of ambient air pollution and providing a model for the exposure time-response function for PM and mortality. Time constraints did not allow us to undertake the former task, although it is feasible. The latter information is not currently available from the existing cohort studies, although there is limited evidence that the induction time for mortality from lung cancer attributable to exposure to urban air pollution is in the order of decades (Nyberg et al. 2000), and that it is perhaps in the order of years for mortality from cardiovascular disease (Krewski et al. 2000). Evaluations of both "natural experiments" (Heinrich et al. 2000; Pope 1989), and regulatory interventions (Clancy et al. 2002; Hedley et al. 2002) provide further support for relatively rapid improvements in cardiovascular and respiratory outcomes. The latter studies also suggest that although rates of mortality may decrease after the successful implementation of air pollution reductions, the long-term benefits may extend well beyond that observed during the first years after the intervention is implemented.

### 6.4 How could a future risk assessment exercise PROVIDE BETTER ESTIMATES?

There is a critical need for more information on the health effects of air pollution in developing counties. Research on exposure should aim to provide better estimates not only of ambient concentrations of pollutants, but also the characteristics of urban air pollution, including the contribution of various sources and the size distribution of PM. Epidemiological studies of mortality should be designed to provide ageand disease-specific estimates of the effects of air pollution, as well as identifying factors that confer susceptibility to air pollution. There is an obvious need for epidemiological studies of the effect of air pollution on the incidence of chronic cardiovascular and respiratory disease, and on the growth and development of children. Future estimates of the burden of disease attributable to urban air pollution should include morbidity outcomes, such as asthma exacerbation, which most certainly contribute to morbidity.

Estimates of uncertainty distributions should more fully incorporate model uncertainties, such as those related to the choice of concentra-tion-response function. This could be accomplished via the elicitation and weighting of expert opinions in the context of a Bayesian approach to quantifying model uncertainty (Morgan and Henrion 1998; National Research Council 2002).

## Notes

1 Throughout the chapter we refer to urban air pollution using the terms "ambient air pollution" or "urban air pollution". For our current purposes, these terms are fully interchangeable.
2 See Preface for an explanation of this term.
3 Ambient particles fall into a trimodal size distribution, according to their aerodynamic diameter: coarse particles ( $>1 \mu \mathrm{~m}$ ), fine particles $(0.1-1 \mu \mathrm{~m})$, and ultrafine particles $(<0.1 \mu \mathrm{~m})$. Ultrafine particles constitute a small percentage of the total mass of PM, but are present in very high numbers. Because of health concerns, the ambient concentrations (mass) of both coarse and fine PM are regulated by the United States Environmental Protection Agency (EPA) through the National Ambient Air Quality Standards for $\mathrm{PM}_{10}$ (PM $<10 \mu \mathrm{~m}$ ) and $\mathrm{PM}_{2.5}(\mathrm{PM}<2.5 \mu \mathrm{~m})$ (USEPA 1997), and by the European Union through limit values for $\mathrm{PM}_{10}$. $\mathrm{PM}_{2.5}$, which includes only fine and ultrafine particles, is dominated by emissions from combustion processes; $\mathrm{PM}_{10}$, which includes coarse as well as fine and ultrafine particles, has a much higher proportion of particles generated by mechanical processes from a variety of noncombustion sources. It is currently not clear how much particles of different sizes and composition differ in the effects on health that they cause.
4 Cities in the United States account for about $40 \%$ of the observations in the estimation model, even after this exclusion.
5 Data from monitoring were available for one additional city/country, Skopje in The former Yugoslav Republic of Macedonia, but were not used in the estimation model because of missing explanatory variables. In addition, 150 observations primarily from Germany (94), Lithuania (30) and other eastern European states (26) made during the early 1990s were excluded because of uncertainties in defining appropriate explanatory variables.

6 The model presented here is one of several versions of the GMAPS model developed at the World Bank. An alternative model jointly estimates concentrations of $\mathrm{PM}_{10}$ and TSP at residential and non-residential sites.

7 The climatic variables have been constructed from a global mean monthly climatology map with a resolution of $0.5^{\circ}$ latitude $\times 0.5^{\circ}$ longitude developed by researchers at the Climate Research Unit of the University of East Anglia. These data are available at http://ipcc-ddc.cru.uea.ac.uk/cru_ data/examine/have_index.html. All of the climate variables are based on the conditions for the city centre.
8 Residential monitoring sites are located in residential areas but do not include pollution hotspots, such as locations that are immediately adjacent to industrial and commercial pollution sources or high traffic corridors. In contrast, mixed residential sites are characterized by both high population densities and the presence of some pollution sources that may result in elevated concentrations of PM in the immediate vicinity of the pollution source. Neither site includes areas of high pollution activity located in sparsely populated areas.
9 Had we instead included data from monitoring for cities with measured data for 1999 , there would be an insignificant difference in the subregional average concentration, because a small fraction of the population in each subregion lives in monitored cities and most of the monitored cities are located in North America and western Europe, where the estimates of PM are more precise.
10 After these estimates had been made, investigators in the United States and Canada discovered several problems with the statistical software that had been used to estimate the relative risks associated with air pollution in the time-series studies (Health Effects Institute 2003). Correcting these problems reduced the magnitude of estimated relative risks and increased their standard errors.

## Chapter I 8

# INDOOR AIR POLLUTION FROM HOUSEHOLD USE OF SOLID FUELS 

Kirk R. Smith, Sumi Mehta and<br>Mirjam Maeusezahl-Feuz

## Summary

This chapter summarizes the methodology used to assess the burden of disease caused by indoor air pollution from household use of solid fuels. Most research into and control of indoor air pollution worldwide has focused on sources of particular concern in developed countries, such as environmental tobacco smoke (ETS), volatile organic compounds from furnishings and radon from soil. Although these pollutants have impacts on health, little is known about their global distribution. Thus, we focus solely on indoor smoke from household use of solid fuels, the most widespread traditional source of indoor air pollution on a global scale.

In order to be consistent with the epidemiological literature, binary classifications of household use of solid fuels (biomass and coal) were used as a practical surrogate for actual exposure to indoor air pollution. Specifically, household solid fuel use was estimated at the national level using binary classifications of exposure to household fuel use, i.e. solid fuel and non-solid fuel (gas, kerosene, electricity). We estimated exposure to smoke from solid fuel by combining a number of national surveys of household fuel use into a regression model that predicts use according to independent, development-related variables, such as income and urbanization. Although this method was necessary owing to the current paucity of quantitative data on exposure, we acknowledge that it overlooks the large variability of exposure within households using solid fuels. As pollution emissions from the use of solid fuel may not always indicate high exposures, we have adjusted exposure estimates by a second term, the ventilation factor, which is based on qualitative measures of ventilation.

Estimates of relative risk obtained from epidemiological studies were combined in meta-analyses for three disease end-points for which there is strong evidence of an association with use of solid fuels: acute lower respiratory infections (ALRI) in children aged $<5$ years, chronic
obstructive pulmonary disease (COPD) and lung cancer (estimates for lung cancer are only for use of coal).

More than 1.6 million deaths and over 38.5 million disability-adjusted life years (DALYs) were attributable to indoor smoke from solid fuels in 2000. Cooking with solid fuels is thus responsible for a significant proportion, about $3 \%$, of the global burden of disease. Although trends are highly uncertain, attributable risks are likely to be greater than avoidable risks.

Several potentially important health outcomes, including tuberculosis, cardiovascular disease, and adverse pregnancy outcomes, were not included, owing to insufficient epidemiological evidence. In addition, there was insufficient evidence to assess the associated health effects for children aged $5-14$ years. The burden of disease caused by use of solid fuel is thus likely to be underestimated.

## 1. Introduction

The use of solid fuels for cooking and heating is likely to be the largest source of indoor air pollution on a global scale. Nearly half the world continues to cook with solid fuels such as dung, wood, agricultural residues and coal. When used in simple cooking stoves, these fuels emit substantial amounts of toxic pollutants. These pollutants, called solid-fuel "smoke" in this chapter, include respirable particles, carbon monoxide, oxides of nitrogen and sulfur, benzene, formaldehyde, 1,3butadiene, and polyaromatic compounds, such as benzo $(\alpha)$ pyrene (Smith 1987). In households with limited ventilation (as is common in many developing countries), exposures experienced by household members, particularly women and young children who spend a large proportion of their time indoors, have been measured to be many times higher than World Health Organization (WHO) guidelines and national standards (Bruce et al. 2000; Smith 1987).

Most research into and control of indoor air pollution worldwide has focused on sources of particular concern in developed countries, such as ETS, volatile organic compounds from furnishings and radon from soil (Table 18.1) (Spengler et al. 2001). Although these pollutants have impacts upon health, little is known about their global distribution.

In an initial attempt to estimate the burden of disease and death caused by indoor sources of air pollution, this chapter focuses solely on the burning of solid fuels. Studies of the health effects of exposure to emissions from the two major sources of energy used for cooking in developed countries, gas and electricity, have been inconsistent, although small but statistically significant increased risks of childhood respiratory disease and other effects associated with use of gas have emerged from meta-analyses (Basu and Samet 1999). This is in contrast to the growing quantity of literature reporting reasonably consistent and strong relationships for a number of health end-points in households burning solid

Table 18.I Major toxic pollutants of indoor air

| Pollutant | Major indoor sources |
| :---: | :---: |
| Fine particles | Fuel/tobacco combustion, cleaning, fumes from food being cooked, e.g. from cooking oil |
| Carbon monoxide | Fuel/tobacco combustion |
| Polycyclic aromatic hydrocarbons | Fuel/tobacco combustion, fumes from food being cooked, e.g. from cooking oil |
| Nitrogen oxides | Fuel combustion |
| Sulfur oxides | Coal combustion |
| Arsenic and fluorine | Coal combustion |
| Volatile and semi-volatile organic compounds | Fuel/tobacco combustion, consumer products, furnishings, construction materials, fumes from food being cooked, e.g. from cooking oil |
| Aldehydes | Furnishing, construction materials, cooking |
| Pesticides | Consumer products, dust from outside |
| Asbestos | Remodelling/demolition of construction materials |
| Lead ${ }^{\text {a }}$ | Remodelling/demolition of painted surfaces |
| Biological pollutants | Moist areas, ventilation systems, furnishings |
| Free radicals and other short-lived, highly reactive compounds | Indoor chemistry |
| Radon | Soil under building, construction materials |
| Lead-containing dust from deteriorating paint is an important indoor pollutant for occup many households, but the most critical exposure pathways are not usually through air. S chapter 19. |  |

fuels (biomass or coal), particularly those with poorly-vented stoves and homes, which are common throughout developing countries. In many circumstances, it is difficult to distinguish use of solid fuels for cooking from use for heating the home. There may also be effects associated with the use of kerosene, a common cooking fuel in many parts of the world, for which emissions and exposures are intermediate between those for solid and for gaseous fuels (Smith 1987), but on which few studies of health effects seem to have been conducted.

## 2. Estimating risk factor levels

### 2.1 Exposure variables

One way to determine the health effects of indoor smoke from solid fuels would be to apply the well-established exposure-response relationships from epidemiological studies of outdoor, or ambient, concentrations of
the same pollutants (see chapter 17) to the household exposures, called here the "pollutant-based approach" (Smith and Mehta 2003).

There are a number of potential problems with such an approach, however, including:

- Differences in pollutant mixtures: Although particles are often used as an indicator pollutant, the composition of particles (size, chemical composition, etc.) as well as that of other pollutants varies from source to source, and also changes with dispersion (Rossi et al. 1999).
- Differences in exposure patterns: The daily pattern of indoor air pollution sources varies from that of ambient sources, with large peaks corresponding to cooking and heating schedules (Naeher et al. 2000b).
- Differences in exposure levels: Concentrations of particulates from the indoor combustion of biomass have been measured at levels that are 10-50 times greater than in urban areas of developed countries, where the main epidemiology of pollutants has been performed. Extrapolating exposure-response relationships by such a large factor is problematic, particularly as there are indications that the relationship becomes more shallow at higher exposures (Bruce et al. 2000).
- Relevance of health outcomes addressed: Most studies of outdoor air pollution have attempted to associate short-term changes in exposure with acute health outcomes. This does not address the long-term impact on chronic health outcomes, nor does it necessarily focus on the health outcomes that are responsible for the bulk of the burden of disease. In particular, ALRI, mostly in the form of pneumonia, are likely to be responsible for the largest burden of disease caused by exposure to indoor air pollution.
- Data on concentrations of particulate matter (PM) in indoor air ${ }^{1}$ are sparse. In addition, most measurements have been made for concentrations of total particulates, which are less reliable indicators of risk than smaller particles $\left(\mathrm{PM}_{10}\right.$ or $\left.\mathrm{PM}_{2.5}\right)$.

An alternative approach, consistent with that used in most epidemiological studies in developing countries, is to divide the population into categories of people that are exposed or not exposed to smoke from solid fuel, on the basis of fuel use and ventilation. Although necessary here, owing to the current lack of exposure data, this method overlooks the large variability of exposure within each of these groups (Naeher et al. 2000a). Furthermore, the method based on use of fuel is affected by the first of the shortcomings listed above, as the same broad category of fuels may produce different mixtures of pollutants in different settings. We also recognize that exposures from cooking and heating
can differ considerably because of different conversion technologies. It was not possible to distinguish between the two end-uses in most cases, however.

To account for differences in other factors (e.g. housing) that would affect levels of pollution (Mehta and Smith 2002), we included a second component in the exposure variable, which we refer to as the "ventilation factor". The final exposure variable in the population was defined as:

## Household-equivalent solid-fuel exposed population = (Population using solid fuel $) \times($ Ventilation factor $)$

We compiled a database of household use of solid fuel, from which the prevalence of household use of solid fuel was estimated for each subregion. ${ }^{2}$ Using known values from this database, a statistical model was developed to predict national use of solid fuel for countries without data. Ventilation factors were assigned on the basis of qualitative evidence, to account for differences in types of cooking and heating appliances and housing.

### 2.2 ThEORETICAL-MINIMUM-RISK EXPOSURE DISTRIBUTION

The theoretical minimum for this risk factor is clearly no use of solid fuels for the production of household energy; this has already been achieved in many populations. In reality, of course, there would still be exposure to pollution from liquid and gaseous fuels, which might be further reduced through a switch to use of electricity or of very wellventilated cooking conditions.

### 2.3 A database of household use of solid fuel

A database of households using solid fuel, expressed as a percentage of all households, was compiled for 52 countries in 10 subregions, in order to estimate global household use of solid fuel (see Table 18.2). Although the data were acquired from studies conducted at different times in the past decade, fuel-use patterns are unlikely to have changed drastically within this time frame (International Energy Agency 2002; World Resources Institute 2000). Out of necessity, the data were gathered from various sources using different and, at times, non-validated methodology. We thus had to make many assumptions in order to facilitate subregional comparison and data manipulation associated with solid fuel use. No households were reported to be using solid fuels for cooking in AMR-A, EUR-A, EUR-C and WPR-A, presumably because countries in these subregions have already shifted to cleaner fuels.

In many countries where large proportions of the population cook with solid fuels, data on household energy are widely, although not
Table I8.2 Estimates of data for the database of households using solid fuels

universally, available. In some cases, the data come directly from national census information or energy use statistics, which state explicitly the number or fraction of households that rely predominantly on solid fuels for their energy needs (Government of Botswana 1991; Government of Brazil 1991; Government of Ecuador 1990b; Government of Ethiopia 1998; Government of India 1991b; Government of Mexico 1990b; Government of Nigeria 1990; Government of Zimbabwe 1992). For example, information on the main fuel used for cooking is collected during the house listing of the census of India each decade (Government of India 1991b). These data, disaggregated into urban and rural sectors, are available at the district level (in India, a district contains about 2 million people).

In some countries, where censuses are infrequent and/or data on residential energy use are not collected, household surveys are an important source of information. Some of these household surveys, such as the widely conducted Demographic Health Surveys are repeated, while others may be conducted only once. For example, primary household energy estimates for 22 countries in Africa, based on household surveys with sample sizes ranging from 1000 to $>14000$ households, are included in a database of development indicators for Africa, compiled by the World Bank (2000). In China, data are available in the form of aggregate annual residential fuel consumption at the provincial level, disaggregated by urban and rural areas (Government of China 1996). Cooking and heating energies were distinguished using a simple model that accounted for the average number of "heating days" in each province, based on a 30 -year average from 1951-1980 (Lin 1995). A small amount of energy ( 2 kg -coal equivalent per household per heating day) was considered to be heating fuel and subtracted from the mix of solid fuels in each province. The remaining heating-adjusted cooking fuel was then normalized to "useful energy" using typical conversion efficiencies for each fuel-stove combination reported (Zhang et al. 2000). The proportion of useful cooking energy attributed to each fuel type per household in each province was taken to represent the number of households using that fuel. This analysis was repeated for each of the provinces in China ${ }^{3}$ and aggregated to give a national total. It was estimated that in 1996 nearly $80 \%$ of the households in China used solid fuels.

Many countries produce national estimates of solid-fuel use, but only a minority collect specific information on fuel use at the household level. Evidence from 10 countries (Bangladesh, Ecuador, Indonesia, Mexico, Myanmar, Nepal, Pakistan, the Philippines, Thailand and Viet Nam) indicates that national and household levels of solid-fuel use are highly correlated ( $\mathrm{R}^{2}=0.75$ ). It should be noted, however, that this relationship holds true when solid fuels are not heavily used in industry. This correlation was used to estimate use of solid fuel by households in nine coun-
tries (Afghanistan, Algeria, Egypt, the Islamic Republic of Iran, Lebanon, the Libyan Arab Jamahiriya, Morocco, Tunisia and Turkey) where only information on national use of solid fuel was available. For three countries (Angola, the Democratic Republic of the Congo and the Sudan), in which a large fraction of the total national energy consumed ( $>70 \%$ ) comprised biomass fuels (World Resources Institute 2003), household use of solid fuel was assumed to be $100 \%$. In other countries, including Bangladesh, Indonesia, Myanmar, Nepal, the Philippines, Thailand, Viet Nam and Pakistan (FAO 1997a, 1997b; Government of Indonesia 1995, 1996a; Government of Pakistan 1997), aggregate data on annual residential fuel consumption are available. In these cases, the percentage of households using solid fuels was estimated according to the quantity of fuel consumed.

The fraction of the population of each subregion covered by the countries for which some data were available, and the prevalence of solid-fuel use according to these data are given in Table 18.3. Data on specific types of solid fuel (i.e. use of coal vs biomass) are limited to India and China, but this factor is also likely to be important in other countries in which no estimates were made, including South Africa and Pakistan.

### 2.4 A model to predict national use of solid fuel

Using known values from the database of households using solid fuel, a statistical model was built to predict national use of solid fuel according to a number of development parameters. The model was then applied to countries where no data on household fuel use existed. This method also allowed for the estimation of statistical uncertainty (i.e. excluding uncertainty in available data and the validity of model) surrounding each prediction. ${ }^{4}$

As a country develops, households gradually switch from using solid fuels to using cleaner liquid and/or gaseous fuels. Although the picture is often more complex at local and household levels, it is assumed here that this generally holds true over the long term on a subregional scale, a trend well-established by current, albeit cross-sectional, international comparisons. After a certain level of economic growth has been achieved, it is assumed that countries will shift away from cooking entirely with solid fuels. The use of solid fuel for heating may continue, however, especially in areas that are rich in coal and wood.

For countries for which data were not available, a model based on the parameters described in Table 18.4 was used with stepwise linear regression. With a gross national product (GNP) of US\$ 4420 per capita

Table 18.4 Parameters in the fuel use prediction model ${ }^{2}$

| became insignificant with inclusion of additional variables were removed. Missing values were replaced |  |
| with mean values for each variable. |  |

## Table 18.5 Models to predict fuel use: GNP per capita vs use of traditional fuel as a predictor variable

| Model | Predictors $^{\mathrm{a}}$ | $R$ | $R^{2}$ | ${\text { Adjusted } R^{2}}^{\prime 2}$ |
| :--- | :--- | :---: | :---: | :---: |
| I | Use of traditional fuel, EMR, <br> bapita, rural population, constant |  |  |  |
| 2 | GNP per capita, EMR, petroleum use per capita, <br> rural population, constant | 0.869 | 0.756 | 0.735 |
|  |  | 0.746 | 0.724 |  |

${ }^{\text {a }}$ Dependent variable in both models is the percentage of households using solid fuels.
b Each subregional dummy variable was entered separately into the model. EMR was the only subregional dummy variable that was significant in the final model, perhaps because of a combination of low biomass resources and high access to petroleum fuels in some countries in these subregions.
in 1999, Brazil was the richest country in the database to have significant levels of cooking with solid fuels ( $27 \%$ of households). To avoid extrapolating the model to areas where it may be inappropriate, estimates were made only for countries with a GNP of $<$ US $\$ 5000$ per capita in 1999. All countries with a GNP of $>$ US $\$ 5000$ per capita in 1999 were assumed to have made a complete transition to clean household-cooking systems, either with cleaner liquid or gaseous fuels, or electricity or, where solid fuel was still used for cooking or heating, to fully ventilated appliances.

As use of traditional fuel (as a percentage of national energy use) is highly correlated with GNP per capita, stepwise linear regression eliminates GNP per capita when both variables are entered together. If use of traditional fuel is not entered, it is essentially replaced by GNP per capita in the model, with little impact on model fit or standard error (Table 18.5). Two models to predict fuel use were assessed, one employing GNP per capita and the other use of traditional fuel (as a percentage of national energy use) as predictor variables. Use of traditional fuel, which includes use of fuel-wood, bagasse (biomass remaining after processing sugar-cane), charcoal, animal wastes, agricultural residues, and other vegetable biomass wastes, is expressed as a percentage of total fuel use at the national (as opposed to the household) level, on an energy-equivalent basis. Like household use of solid fuel, use of traditional fuel at the national level is highly correlated with GNP per capita (Figures 18.1 and 18.2).

Information on GNP per capita is more reliable, is updated more routinely, and is available at the national level for nearly all countries. Therefore, we used the model including GNP per capita as a predictor, rather than the model using use of traditional fuel. The final model is shown in Table 18.6 and includes percentage of the rural population, GNP per capita (log-transformed), petroleum use per capita, and location within the EMR subregions (entered as a dummy variable). Other

| :--- | :---: | :---: | :---: | :---: | :---: | :---: | :---: |$)$

[^63]Figure 18.2 Relationship between use of traditional fuel at the household level and GNP per capita

potential variables were dropped from the model in stepwise linear regression.

This model was used to predict percentages of households using solid fuel in all countries where these values were unknown (see Figure 18.3). In order to force the percentage of households using solid fuel to lie between $0 \%$ and $100 \%$, estimates for the 23 countries with predicted values of $<0$ or $>100$ were converted to 0 and 100 , respectively.

Known (for all countries in the household fuel-use database) and predicted estimates of use of solid fuel at the country level were aggregated into subregional estimates of household solid-fuel use (Table 18.7). The subregions with the least coverage are those that have the highest levels of economic development, i.e. those subregions that are least likely to have high proportions of household solid-fuel use because people have, for the most part, already shifted to cleaner fuels and cooking technologies.

We assumed that the fraction of the population exposed is the same as the fraction of households using solid fuel. This assumption is likely

Figure 18.3 Household use of solid fuel, at the national level, 2000

Note: Household solid fuel use estimates are predictions in areas without striations.

Table 18.7 Estimated household use of solid fuel, by subregion

| Subregion | Subregional population (000s) | Total population covered by fuel use prediction and by available data |  | Household use of solidfuel (\% of population) |

| SEAR-D | 1238808 | 1 236398 | 99.8 | 83.5 (78.3-88.3) |
| WPR-A | 153357 | 328 | 0.2 | 0.2 (0.1-0.2) |
| WPR-B | 1528144 | 1479669 | 96.8 | 78.1 (73.0-82.8) |
| World | 6036664 | 5003510 | 82.9 | 56.5 (51.7-61.5) |

to underestimate exposure since solid-fuel-using households are more likely to be rural and of low socioeconomic status, and are thus likely to have more members than the subregional average.

### 2.5 Assigning ventilation factors

Since people in different parts of the world use different cooking and heating appliances and have different types of housing, ventilation must also be taken into account when estimating exposure. Here, the term "ventilation" encompasses both ventilation-related characteristics of the stove (such as the presence of a chimney that vents to the outside of the house) and characteristics of the kitchen (building material, architectural features that influence indoor air quality, location of the kitchen with relation to living area, etc.).

Although we had no data on ventilation conditions according to subregion, we hypothesized that ventilation was a function of climate and development (UNCHS 1996). As described above, countries with a GNP per capita of >US $\$ 5000$ were essentially assigned an estimated exposure of 0 , that is, any use of solid fuel in the household was assumed to be undertaken in fully-vented appliances, with no re-entry of the pollution into the household. In the absence of further information (as described below), all other countries were assigned a ventilation factor of 1.0.

In countries of eastern Europe and the former Soviet Union, a long history of household use of solid fuel under cold climatic conditions and relatively high standards of living, before the recent economic decline, led to the development of energy technologies with far fewer indoor emissions and, consequently, less exposure per unit of solid fuel burned. Therefore, we set the ventilation factor at 0.2 for EUR-B and EUR-C.

In China, the widespread national improved-stove programme has disseminated cooking stoves with chimneys to three-quarters of rural households using solid fuel since 1981 (Goldemberg et al. 2000; Smith et al. 1993), resulting in decreased effective exposure. The ventilation factor for China was set at 0.25 for child health outcomes, because even welloperating, improved biomass stoves with chimneys are still responsible for some exposure (Sinton et al. 1995). We set China's ventilation factor at 0.5 for adult health outcomes, as current disease patterns for adults partly reflect exposure before the introduction of improved stoves. India, the only other country with a long-term national stove-improvement programme, has had only mixed success, with relatively low stove lifetimes and national coverage (NCAER 2002). The ventilation factor was therefore maintained at 1.0 for India.

Tables 18.8 and 18.9 detail estimated exposures as defined above for children aged $<5$ years and for adults. Separate estimates of exposure resulting from use of coal are presented in Table 18.10 for adults only, as adults are affected by chronic health outcomes (see section 3 ).

Table 18.8 Exposure of children (aged <5 years) to indoor smoke from solid fuels

| Subregion | Household solid-fuel <br> use (\%) | Ventilation factor | Exposure (\% population) <br> Point estimate (95\% Cl) |

### 2.6 Quantitative and Qualitative sources of uncertainty

Estimates of use of solid fuel for countries in the household fuel-use database were arbitrarily assigned an uncertainty range of $5 \%$. The exposure classification system used here is binary (exposed to solid fuels or not exposed), which is consistent with the available epidemiological literature. In reality, exposure to indoor air pollution from use of solid fuel results in a wide range of exposures, which vary according to different types and quality of fuel and stove housing characteristics (e.g. ventilation and size), cooking and heating methods, differences in timeactivity patterns (time spent within the household and in close proximity to the pollution source) and season (Saksena et al. 1992). Since the distribution of exposures is continuous, exposures would best be characterized as a continuous outcome, or at least better characterized by multiple categories. As a result, the above binary categorization and uncertainty values significantly underestimate the true uncertainty in levels of exposure. In addition, the need to use the fuel-prediction model for countries without data obviously introduces uncertainty, only part of which may be reflected in the variance of the results obtained from the model.

## 3. Estimating Risk Factor-Disease RELATIONSHIPS

### 3.1 Health outcomes: EVIDENCE FOR CAUSALITY and INCLUSION CRITERIA

Health outcomes caused by indoor exposure to smoke from use of solid fuel were chosen after a review of the epidemiological evidence available for each end-point, using electronic databases, including Medline and TCMLARS (Traditional Chinese Medical Literature Analysis and Retrieval System, an electronic database of Chinese journals). In addition, given that a large body of evidence comes from developing countries, literature was also obtained from other researchers and reputable developing-country journals not currently indexed in international databases. Only articles written or abstracted in English were used, except for articles on lung cancer, for which both the Chinese and the English

Table 18.1I Diseases associated with use of solid fuels and populations affected that were included in the analysis

| Disease | Population affected |
| :--- | :--- |
| Acute lower respiratory infections (ALRI) | Children aged $<5$ years |
| Chronic obstructive pulmonary disease (COPD) | Females and males aged $\geq 30$ years |
| Lung cancer (coal use only) | Females and males aged $\geq 30$ years |

literature were accessed, since, to our knowledge, only in China has there been significant use of coal in unvented household devices in recent decades.

## GENERAL ASSESSMENT OF CAUSALITY

The strength of the evidence for each end-point was determined on the basis of a structured assessment of causality, using Bradford Hill's criteria for causality, including temporal relationship, strength of association, specificity, the presence of a dose-response relationship, biological plausibility, coherence, the existence of experimental evidence and consistency of association.

As specificity, dose-response relationships, and experimental evidence are often difficult to assess for environmental exposures and health outcomes with multiple causes or long latency periods, we used the epidemiological evidence in conjunction with available information on emissions, exposures and mechanisms for indoor air pollution (Smith et al. 2000; Zelikoff et al. 2003). Three health outcomes were determined to have strong enough evidence to be included: ALRI, COPD and lung cancer (Table 18.11). Information on assessing causality for these outcomes is given in section 3.3 and excluded outcomes are discussed in section 3.2.

Children aged $>5$ years (of school-age) were excluded as they spend less time in the house than women and children aged $<5$ years; this is a conservative assumption as there is some exposure of this group, although levels are unknown on a global scale (Ezzati and Kammen 2001; Saksena et al. 1992). Because of the limitations of the available epidemiological studies, only risks in young children (aged $<5$ years) and adults were included. Available data indicate that men are also affected by those outcomes considered for women, but presumably at lower risks than women because of lower exposures. Adults aged 15-30 years were excluded because the chronic diseases of concern (COPD and lung cancer) have not yet become manifest in this group. Obviously, however, development of these diseases in later years is partly caused by exposures at these and younger ages.

### 3.2 Excluded health outcomes

## OUTCOMES WITH INSUFFICIENT EVIDENCE

A number of important diseases that are potentially associated with use of solid fuels have not been included in this analysis owing to insufficient or lack of direct evidence on causality. Lack of inclusion does not necessarily imply inconclusive findings. Rather, it refers to a relatively small set of findings, suggesting that additional, carefully conducted studies are needed to strengthen the evidence base.

## Asthma

On the basis of the usual measures (concentrations of small particles, $\mathrm{PM}_{2.5}$ ), typical exposures to indoor smoke from use of solid fuels are much higher than those for urban outdoor pollution (García-Marcos et al. 1999) and ETS (Strachan and Cook 1998), with which asthma has been frequently associated. In addition, a study of children aged $<5$ years in Malaysia found increased risk associated with the burning of mosquito coils, another important indoor source of $\mathrm{PM}_{2.5}$ (Azizi et al. 1995). Studies in China (Xu et al. 1996a) and Kenya (Mohamed et al. 1995) have quantitatively associated asthma in children of school age and in adults with various measures of indoor pollution from solid-fuel use. As the reported background rate is low in most developing countries, however, asthma contributes relatively little to the total burden of deaths or DALYs from indoor air pollution.

## Cataracts and other visual impairments

Two case-control studies in India have found an increased risk of cataracts among people using biomass fuel; Mohan et al. (1989) determined an odds ratio of 1.6; Zodpey and Ughade (1999) found an adjusted odds ratio of 2.4. Evaluation of the National Family Health Survey of India (NFHS 1995) found a somewhat lower rate for partial blindness (odds ratio of 1.3; Mishra et al. 1999a), but no significant difference for total blindness. There is also evidence that exposure to ETS is associated with cataracts (West 1992) and animal studies show that cataracts can be caused by wood smoke (Rao et al. 1995; Shalini et al. 1994).

Indoor air pollution may also be linked to blindness through trachoma (Prüss and Mariotti 2000). Two unadjusted studies in the United Republic of Tanzania found such a link (Taylor and West 1989; West and Lynch 1989) although another in Ethiopia found cooking in a central room to be protective, perhaps through reduction of flies (Sahlu and Larson 1992).

## Perinatal effects

One study in India found an adjusted excess risk of stillbirth of $50 \%$ among women using biomass fuels during pregnancy (Mavalankar et al. 1991), and two Chinese studies of urban ambient pollution, from the
same group of researchers, also found a strong relationship between concentrations of particulates and pre-term delivery ( Xu et al. 1995) and low birth weight (Wang et al. 1997). Low birth weight was also found to be associated with household exposure to biomass smoke in Guatemala (Boy et al. 2002). Intrauterine mortality, low birth weight, prematurity, and early infant death have been significantly associated with urban outdoor pollution at much lower concentrations than those typically found in households that use biomass (Bobak 2000; Loomis et al. 1999; Pereira et al. 1998; Ritz and Yu 1999; Scram 1999; Woodruff et al. 1997). Exposure of non-smoking pregnant women to ETS has been associated with low birth weight in a meta-analysis of 17 studies (Windham et al. 1999a), with low cognitive development (Johnson et al. 1999), but not with spontaneous abortion (Windham et al. 1999b).

Low birth weight is a risk factor for a number of childhood (Walsh 1993) and, probably, adult (Barker 1997) diseases, not just those of the respiratory system. The potential pathways by which indoor cooking smoke may cause low birth weight are given in Figure 18.4. Although this mechanism seems likely to be important in some parts of the world,

Figure 18.4 Possible mechanisms for indoor air pollution and low birth weight

[^64]at present it is difficult to provide a quantitative estimate of the potential burden, and it is not attempted here.

## Tuberculosis

Recent studies in India and Mexico have suggested that indoor air pollution from use of solid fuel may be a risk factor for active tuberculosis. A statistically significant relationship has been found between reported use of biomass fuel and incidence of tuberculosis in 260000 adults aged $>20$ years. Indeed, women in households using biomass fuels were found to be 2.7 ( $95 \%$ CI 1.9-4.0) times more likely to have tuberculosis than women in households using cleaner fuels, even after correction for a range of socioeconomic factors (Mishra et al. 1999b). In addition, an unadjusted but significant odds ratio of 2.5 has been reported for clinically-confirmed tuberculosis in adult male and female householders aged 16-60 years using wood or dung cakes as fuel (Gupta and Mathur 1997). Although these studies were not able to address smoking as a possible confounder, two studies in Mexico City have found an association between exposure to wood smoke and incidence of tuberculosis, after taking smoking into account (Perez-Padilla et al. 1996, 2001). A study in China also found exposure to outdoor air pollution to be associated with tuberculosis (Xu et al. 1995). Animal studies have shown that wood smoke causes immune suppression in the respiratory system (Thomas and Zelikoff 1999; Zelikoff 1994).

## Other health effects not included

- Interstitial lung disease has been associated with long-term exposures in several studies (Dhar and Pathania 1991; Gold 2000; Ramage et al. 1988; Sandoval et al. 1993).
- Early studies in Africa seemed to implicate wood smoke as a cause of nasopharyngeal cancer, but this association was not borne out by later studies in Asia (Smith 1987; Smith and Liu 1994).
- Two studies in Brazil have shown increased risk of upper aerodigestive tract cancers, with adjusted odds ratios of 2.7 (Pintos et al. 1998) and 2.5 (Franco et al. 1989).
- An association has been shown with cervical neoplasia among HPVinfected women in Honduras, with an adjusted odds ratio of 5.7 after 35 years or more of cooking over an open fire (Velema et al. 2002).
- Ischaemic heart disease has been associated with exposure to outdoor particulate air pollution (Ponka and Virtanen 1996; Pope et al. 1992; Schwartz 1993; Schwartz and Dockery 1992; Schwartz and Morris 1995) and ETS (Steenland et al. 1998) in some studies, both at much lower levels of exposure than for indoor air pollution (see chapter 17).

## EXCLUDED OUTCOMES ASSOCIATED WITH USE OF SOLID FUEL, BUT NOT CAUSED BY EXPOSURE TO AIR POLLUTION

The use of solid fuels for household cooking and heating involves a range of activities with potential health implications that are separate from those involving the pollution created. The most important involve the harvesting of the two major types of fuel.

- The harvesting of biomass in rural settings in developing countries may involve regular carriage of heavy loads for long distances, with consequent physical strain and food energy demands, along with exposure to such hazards as snake-bite, leeches and assault (crime). Women and children typically bear the greatest burden of such harvesting, although there is much variation across the world.
- Coal mining is one of the most hazardous occupations in the world, particularly in developing countries in small mines from which much household fuel is obtained.

In addition, the extra time taken to harvest, store, and prepare solid fuels is time that is potentially deducted from other pursuits that are associated with health benefits, such as child care or the generation of the household income.

Considering that the counterfactual distribution is cooking with nonsolid fuels (rather than no cooking at all), there are also categories of health risk that are avoided by the use of solid fuels:

- fires and explosions related to household use of liquid and gaseous fuels;
- poisoning caused by ingestion of household kerosene;
- risk inherent in the operation of the national and international petroleum fuel cycles required to provide liquid and gaseous fuels;
- risks involved in providing electricity for household cooking, such as coal mining, air pollution from power plants, accidents involving nuclear and hydroelectric dams, etc.; and
- additional risk of mosquito-borne diseases owing to absence of repellence from household smoke produced by solid fuel.

In its current form, the system limits of this comparative risk assessment (CRA) do not encompass any of these health effects, positive or negative, that are not directly caused by exposure of humans to pollution in the household.

EXCLUDED OUTCOMES ASSOCIATED WITH SPECIALIZED AIRBORNE PRODUCTS OF INDOOR COMBUSTION

There are several related sources of indoor pollution not covered by this analysis that may be locally important in some countries. However, too
few data are available regarding exposures to extrapolate these risks to global burdens, although we suggest that these sources represent potential research topics, as well as priorities for determining exposure distributions, in order to improve the estimated burden of indoor air pollution.

- Smoke from cooking oil: studies in China (including the Province of Taiwan) show relative risks for lung cancer of 3-5 for Chinese-style cooking in a wok with certain cooking oils (Ko 2000; Zhong et al. 1999b).
- Exposures to trace quantities of toxic elements resulting from indoor use of coal in China and elsewhere: significant and widespread impacts from exposures to fluorine and arsenic have been reported in China (Finkelman et al. 1999) and can be expected to occur wherever coal fuels are contaminated with such toxic elements.
- Smoke from incense and mosquito coils, which have been associated with ill-health in some Asian studies (Azizi et al. 1995).

### 3.3 Evidence and exposure-Risk relationships

The estimates of relative risk ${ }^{5}$ and confidence intervals used for ALRI, COPD and lung cancer were derived through formal meta-analyses of the available literature.

Searches of the scientific literature were conducted using the Medline computerized bibliographic database, review of bibliographies from previously-retrieved articles and personal communications. In some cases, the authors of articles that were lacking data that were of interest for this analysis were contacted and asked for clarification, and specific requests for information were sent to researchers in this field.

Medline searches were conducted using the following key words:

- For ALRI: indoor air pollution, household fuel, smoke, acute respiratory infections (ARI), pneumonia and ALRI
- For COPD: indoor air, fuel, COPD, chronic obstructive lung disease (COLD) and chronic bronchitis
- For lung cancer: indoor, air, fuel and lung cancer

To be eligible for inclusion in the meta-analysis, studies had to fulfil the following criteria:

- to be a primary study, not a re-analysis or review;
- to examine some proxy for exposure to indoor smoke from the use of solid fuels for cooking and/or heating purposes;
- to report an odds ratio and its variance, or sufficient data with which to estimate them; and
- to be written or abstracted in English. Additionally, for lung cancer only, a Chinese colleague assisted in a comprehensive search of the Chinese literature, extraction of the relevant data and translation.

We considered both fixed- and random-effects models for the metaanalysis. As the results from both were similar, we used those from the fixed-effects model only. Owing to heterogeneity within studies, we performed sensitivity analyses by stratifying the studies by potential sources of heterogeneity, including assessment of exposure and adjustment for confounders. We did not use a random-effects model, even when statistical significance for heterogeneity was present, for the following reasons.

- Random-effects models assume that studies are selected from a population with a single underlying variance. This would be violated given the heterogeneity among the studies in measuring exposure.
- Random-effects models assign the same weight to small and large studies. This would be problematic for the studies of this analysis because the number of cases ranged from 45 to 500 .

Smoking is an important risk factor for the diseases associated with indoor smoke from use of solid fuel, especially lung cancer and COPD. At present, information on the combined effects of smoking and use of solid fuel is rare. To avoid possible overestimation of the burden of disease, therefore, attributable fractions for lung cancer and COPD caused by use of solid fuel were applied to disease burdens remaining after removal of the burden attributable to smoking. This is conservative in that some of the effect attributable to smoking could also be attributed to use of solid fuel. To ensure internal consistency within the CRA project, burdens attributable to smoking were obtained from chapter 11. Globally, about $51 \%$ and $62 \%$, for men and women respectively, of the total burden of COPD is not attributable to tobacco.

## ACUTE LOWER RESPIRATORY INFECTIONS

A number of studies in developing countries (Argentina, Brazil, the Gambia, India, Kenya, Nepal, Nigeria, South Africa, the United Republic of Tanzania and Zimbabwe) have quantified the relative risk of ALRI for children in households that burn biomass (Armstrong and Campbell 1991; Campbell 1997; Cerqueiro et al. 1990; Collings et al. 1990; de Francisco et al. 1993; Ezzati and Kammen 2001; Johnson and Aderele 1992; Kossove 1982; Mtango et al. 1992; O’Dempsey et al. 1996; Pandey et al. 1989b; Shah et al. 1994; Victora et al. 1994). Some work has also been done to identify possible mechanisms in the developing countries (Verma and Thakur 1995).

Studies among native Americans (Navajos in the south-western United States of America) show a strong and significant association between ALRI and use of wood stoves, at much lower levels of indoor pollution than found in developing countries (Morris et al. 1990; Robin et al.
1996). There is a larger group of studies that show various childhood respiratory symptoms (e.g. cough, wheezing) to be associated with exposure to smoke from solid fuel, but do not provide sufficient evidence to calculate odds ratios of ALRI itself.

As all studies included here used either ARI or ALRI, or death caused by ARI or ALRI, in children aged $<5$ years as a health outcome, we only estimated the burden of disease for children in this age group. A recent study in Kenya (Ezzati and Kammen 2001) found associations between use of solid fuels and ARI in adults (both men and women), suggesting that, once time-activity patterns and spatial dispersion of smoke have been taken into account, men and women may have similar patterns of exposure-response.

A single statistical analysis of all 15 studies identified (Table 18.12) was not appropriate because of the heterogeneous exposure variables and the diverse analytical strategies used by the investigators, especially with respect to potential confounding factors. To address this diversity, different subgroups of these studies were used to conduct several metaanalyses, the results of which were remarkably consistent; pooled relative risk estimates increased with improved precision of exposure measure. ${ }^{6}$

## Characteristics of excluded studies

Of the 15 studies identified (Table 18.12), we excluded the study by Kossove (1982), which had an inappropriately-small comparison group. Two studies in South America focused on use of solid fuels in urban populations (Cerqueiro et al. 1990; Victora et al. 1994). The study in Buenos Aires, Argentina, was excluded owing to a very low prevalence of households using solid fuels and, in one of the case groups, missing data on exposure to heating fuelled by charcoal (Cerqueiro et al. 1990). In the study in Brazil (Victora et al. 1994), only a small proportion of the study population was exposed $(6 \%)$ and exposure was defined loosely, encompassing a wide range of sources of pollution, from open fires to enclosed metal heating stoves and vented fireplaces. The study by Shah et al. (1994) was excluded because its definition of nonexposure (use of stove with chimney provided by the government improved-stove programme) has been shown to produce concentrations of indoor pollutants that were not statistically different from those produced by open fires at that time in India (Ramakrishna et al. 1989) and no observations of direct pollution were made. The study by Mtango et al. (1992) was excluded because, as the study focused on mortality from all causes, no information was given on exposure status for the proportion of deaths caused by ALRI (in this case, pneumonia). Two studies reported on the same study population (Armstrong and Campbell 1991; Campbell et al. 1989). We chose to include the older report by Campbell, which included the odds ratio for girls and boys combined. A recently-published longitudinal study examining rates of episodes of

| South Africa | Kossove (1982) Excluded | Case-control (132-18) Children aged $\leq 1$ year | Questionnaire: does the child stay in the smoke? | ALRI hospital cases, clinical signs and X-ray | None | 4.8 (1.7-13.6) |
| United <br> Republic of Tanzania | Mtango et al. (1992) <br> Excluded | Case-control (456-II60) Children aged <5 years | Questionnaire: child sleeps in room where cooking is done | Death from all causes, by verbal autopsy and physician | Village, age, questionnaire respondent, maternal education, parity, water source, child eating habits | 2.8 (1.8-4.3) |
| USA |  |  |  |  |  |  |
| Arizona | Morris et al. (1990) | Case-control (58-58) Children aged <2 years | Questionnaire: primary source for heating and cooking | ALRI hospital cases, clinical signs and X-ray | Family history of asthma, recent respiratory illness, dirt floor, running water | 4.9 (1.7-12.9) |
| USA |  |  |  |  |  |  |
| Arizona | Robin et al. (1996) | Case-control (45-45) Children aged <2 years | Questionnaire: household uses wood for cooking | ALRI hospital cases | No. of siblings, electricity, running water, difficulty in transport to clinic, ETS, housing | 5.0 (0.6-42.8) |
| Zimbabwe | Collings et al. (1990) | Case-control (244-500) <br> Children aged <3 years | Questionnaire: household uses open wood-fire for cooking | ALRI hospital cases, clinical signs and X-ray | ETS, crowding, housing, number of siblings | 2.2 (1.4-3.3) |

ALRI in a range of age groups across several categories of exposure to smoke from combustion of biomass in Kenya (Ezzati and Kammen 2001) was excluded from the formal meta-analysis because the outcome, expressed as "fraction of weeks with illness", could not be translated into an odds ratio in a manner consistent with the other epidemiological studies. This study did provide strong collaborative evidence, nevertheless, for it showed effects in older children and women as well as in young children and demonstrated a statistically significant trend in the exposure-response relationship. In a subsequent analysis, the authors reported an odds ratio of 2.14 for children exposed to $\mathrm{PM}_{10}$ concentrations of $>1000 \mu \mathrm{~g} / \mathrm{m}^{3}$ (Ezzati 2002).

## Estimating risk factor-disease relationships

After the exclusions noted above, there remained eight studies that reported relative risks of acute respiratory illness for young children exposed to indoor smoke from use of solid fuel (Campbell et al. 1989; Collings et al. 1990; de Francisco et al. 1993; Johnson and Aderele 1992; Morris et al. 1990; O’Dempsey et al. 1996; Pandey et al. 1989b; Robin et al. 1996). Of these, the majority were case-control studies. One study used the outcome "pneumococcal infection", which includes meningitis and septicaemia (O’Dempsey et al. 1996). However, $80 \%$ of patients in this study were diagnosed with pneumonia. Although most of the studies were conducted in developing countries, two were carried out in populations of Navajo and Hopi Indians in the United States (Morris et al. 1990; Robin et al. 1996). The populations in the United States are likely to differ in socioeconomic characteristics from the rest of the studies, thus potentially influencing the rates of incidence of ALRI. As the overall odds ratio did not change substantially with the exclusion or inclusion of these studies, all subsequent analyses included these two studies.

## Exposure assessment used in the studies

The studies provide relatively little information on the indoor concentrations of or exposures to specific pollutants produced by use of solid fuels, or on the baseline concentrations within similarly-constructed households that do not use solid fuels. All but one study used binary classifications of exposure (Table 18.12). On the basis of evidence for an exposure-response relationship between ARI and exposure to smoke from solid fuels (Ezzati and Kammen 2001; Pandey et al. 1989a), we attempted to analyse the studies according to the precision of the exposure measure used and the likely intensity of exposure. Exposure measures used were grouped in three major categories, in what was assumed to be an increasing order of precision: type of fuel used, duration of exposure to smoke from solid fuels, and using solid fuel and carrying the child on the mother's back (Table 18.13). Although it is generally true that concentrations of pollutants are likely to be lower in households using cleaner fuels, such as kerosene or gas, there is a wide variation in con-

Table 18.13 The risk of ALRI associated with use of solid fuels, in children aged $<5$ years: subgroup analyses

| Children aged $<2$ years old | Campbell et al. (1989); de Francisco et al. (1993); Morris et al. (I990); Pandey et al. (1989b); Robin et al. (1996) | 2.5 (2.0-3.0) |
| Children aged <5 years old | Collings et al. (1990); Johnson and Aderele (1992); O'Dempsey et al. (1996) | 1.8 (1.3-2.5) |

centrations reported in households using solid fuels (Mehta and Smith 2002). Some studies report whether or not children remained indoors when the mother was cooking, but, for reasons noted above, all of these studies were excluded (Awasthi et al. 1996; Kossove 1982; Mtango et al. 1992). Only one study reported the average time that the child spent near the cooking fire (Pandey et al. 1989b). We assumed that carrying the child on the mother's back during cooking represented the most precise measure of exposure, as this suggests that the child was in close proximity to the fire, where exposures are generally higher (although the type of fuel used in control households in these studies was not specified).

We performed separate analyses for each category of exposure, as summarized in Table 18.13. Cooking with wood or other biomass was associated with an odds ratio of $2.0,95 \%$ CI 1.4-2.8. The Pandey study reported an intermediate estimate of relative risk of $2.3,95 \%$ CI 1.8-2.9, for children spending more than two hours near the cooking fire each day. The highest odds ratio was found to be associated with the child being carried on the mother's back during cooking (odds ratio of 3.1, 95\% CI 1.8-5.3).

In only three of the studies were the results adjusted for nutritional status in multivariate analyses, an important confounding variable for

ARI in young children (Victora et al. 1999). The odds ratio found by those studies that did adjust was $3.1,95 \%$ CI 1.8-5.3, whereas the effect was slightly smaller in the studies that did not adjust, with an odds ratio of $2.2,95 \%$ CI $1.8-2.6$. This may be explained, however, by the fact that the studies that controlled for nutrition also used a different exposure proxy (child was carried on mother's back during cooking).

Age is another potential confounding variable because younger children are more likely to remain close to their mothers and are therefore also more likely to be exposed to indoor smoke from cooking or heating, and because age is independently associated with ALRI, with younger children being more susceptible than older children. Most case-control studies adjusted for age by matching controls to cases. When the analysis was restricted to include only studies in children aged $<2$ years, the risk of ALRI was found to be slightly higher (odds ratio of $2.3,95 \%$ CI 1.9-2.7) than that obtained from studies in children aged $\leq 5$ years (odds ratio of $1.6,95 \%$ CI 1.2-2.2). Armstrong and Campbell (1991) noted that, in their study population, girls were more likely to be carried on their mothers' backs than boys and were thus exposed to higher concentrations of pollutants for a longer duration of time. This study found that girls who were carried on the mother's back during cooking had an increased risk of ALRI; no association was observed for boys. The risk in girls was much higher (odds ratio of 6.0 vs odds ratio of 1.9 ) when only the first episode of ALRI (rather than all episodes) was included in the analysis, although the confidence interval was also much wider, owing to the smaller sample. Data were not disaggregated by sex in any of the other studies (although several did control for sex in the multivariate analyses).

As we could not separate the effects of measures of exposure from adjustment for nutritional status, we used the combined odds ratios for all eight studies remaining after exclusions. The results of this approach are similar to those that would be produced if the difference between the most and least precise exposure measures were to be used as the range, i.e. 2.0-3.1 (geometric mean, $\mathrm{GM}=2.4$ ). This is also consistent with the differences in the odds ratios for the two age groups, that is, 1.8 for children aged $<5$ years and 2.5 for children aged $<2$ years. The overall estimate, from all eight studies, of the risk of ALRI in young children exposed to indoor air pollution caused by use of solid fuels was 2.3 , CI 95\% 1.9-2.7.

## Chronic obstructive pulmonary disease

Globally, the most important risk factor for COPD is thought to be smoking of tobacco (NHLBI/WHO 2001) (see also chapter 11). A number of studies have examined various symptoms of chronic respiratory ill-health in women who cook with open stoves burning biomass (Smith 2000). Eight studies in six countries-Bolivia (Albalak et al. 1999), Colombia (Dennis et al. 1996), India (Gupta and Mathur 1997;

Malik 1985), Mexico (Perez-Padilla et al. 1996), Nepal (Pandey 1984b; Pandey et al. 1988) and Saudi Arabia (Døssing et al. 1994)—have quantified the association between indoor air pollution and COPD. Although there are no comparable studies reporting odds ratios in China, the high rates of COPD in non-smoking Chinese women argue that this risk can be related to exposure to coal smoke (Liu et al. 1998).

Cor pulmonale, a heart condition that is secondary to COPD and that is also found among non-smoking rural women in south Asia (Smith 1987), has long been attributed to long-term exposure to smoke from biomass (Padmavati and Pathak 1959). Other studies have attributed silicosis (Norboo et al. 1991; Saiyed et al. 1991), reductions in lung function, cough and various other respiratory conditions to exposure to smoke from biomass, in women, ${ }^{7}$ but were not however included here, owing to limited evidence and the relatively small burden of disease associated with these conditions.

Studies that were included in the meta-analysis used a specific definition of COPD or chronic bronchitis, such as cough and sputum on every day for at least three consecutive months for two successive years, and/or a forced expiratory volume in first second/forced vital capacity (FEV1/FVC) ratio of $<70 \%$ or a FEV1 of $<70 \%$ of the predicted value. We identified 11 studies reporting the relative risks of chronic airway disease in adults exposed to indoor smoke (Albalak et al. 1999; Behera et al. 1991; Dennis et al. 1996; Døssing et al. 1994; Dutt et al. 1996; Gupta and Mathur 1997; Malik 1985; Menezes et al. 1994; Pandey 1984a; Perez-Padilla et al. 1996; Qureshi 1994). Of these, one was a cohort study (Dutt et al. 1996) and three were case-control studies (Dennis et al. 1996; Døssing et al. 1994; Perez-Padilla et al. 1996). The remaining six studies were cross-sectional (Table 18.14).

Where studies reported exposure as a continuous variable, categories were constructed post hoc to be consistent with studies that presented the same exposure or a similar exposure as a categorical variable (e.g. average time spent daily near the stove, $<2$ hours and $>2$ hours). More than half of the study populations in Table 18.14 originated from rural areas where cooking on an open fire in ill-ventilated huts was common. Five study sites, however, were in urban or peri-urban settings where a mixture of fuels might be used (see Table 18.14) and where exposure to indoor smoke is likely to be lower than for women living in rural areas.

## Estimating the relationship between risk factor and disease

Smoking is an important potential confounding variable for COPD and particularly so if men are included in the analysis, given the higher prevalence of smoking in men than in women in developing countries. Only two studies adjusted for smoking (Dennis et al. 1996; Menezes et al. 1994). Of the studies that did not adjust for smoking, two included nonsmokers only (Behera et al. 1991; Dutt et al. 1996), another reported an overall prevalence of smoking of $<1 \%$ in the entire study population
Table 18.14 Studies on the risk of chronic obstructive pulmonary disease associated with use of solid fuels

(Albalak et al. 1999). Pandey (1984a) reported the data stratified by smoking status and finally, the study by Perez-Padilla et al. (1996) reported that $70-80 \%$ of the subjects indicated that they had never smoked.

Two studies (Døssing et al. 1994; Gupta and Mathur 1997), which included men and women and reported a relatively high prevalence of smoking in their study populations (not equally distributed between COPD cases and controls), did not adjust for smoking. The combined estimate of risk from the group of studies that accounted for smoking, and excluding the Døssing et al. and Gupta and Mathur studies, was $2.5,95 \%$ CI 1.9-3.3. The combined estimate of relative risk for the studies by Døssing et al. and Gupta and Mathur that did not adjust for smoking, and which is thus likely to be an overestimation, was substantially higher at $10.8,95 \%$ CI 5.4-21.8. Another major confounding variable in the association between risk of COPD and exposure to indoor smoke is age, with absolute risk increasing with age. Most studies adjusted for age by matching, stratified sampling (Dutt et al. 1996), or by adjustment in the analysis; two studies (Malik 1985; Qureshi 1994) reported the mean age to be similar in the exposed vs unexposed subjects. A potential problem of confounding by age remains with the studies by Pandey (1984a) and Behera et al. (1991), which showed no data on the age distribution. The combined estimate of the relative risk excluding these two studies was $2.9,95 \%$ CI 2.2-3.6.

This analysis primarily included women as they comprise the population that is most frequently exposed to smoke from wood during cooking and which is thus at greatest risk of developing chronic airway disease. Therefore, we included estimates for women or the combined estimate adjusted for sex, if available. With two exceptions (Døssing et al. 1994; Gupta and Mathur 1997), all studies reported the data separately for men and women, or combined the data while adjusting for sex. The overall estimate of relative risk for all studies included was 2.9 , $95 \%$ CI $2.2-3.8$. For men, it was $2.8,95 \%$ CI $1.4-5.7$, but this was based on only two studies, one of which did not correct for age (Døssing et al. 1994; Qureshi 1994). See Table 18.15 for details.

All three case-control studies were hospital-based; control groups consisted of visitors to patients other than the study subjects (Døssing et al. 1994), patients with illnesses other than those of the respiratory tract (Dennis et al. 1996) and a mixture of visitors, patients diagnosed with tuberculosis or interstitial lung disease and patients with otolaryngological problems (Perez-Padilla et al. 1996). Bias could have been introduced by the choice of visitor controls if exposure to indoor smoke was related to the likelihood to come to the hospital to visit a patient, or by the selection of inpatient controls, if exposure to indoor smoke made the patients with the control diseases less or more likely to be referred to the hospital (e.g. tuberculosis).

Table 18.15 The risk of chronic obstructive pulmonary disease associated with use of solid fuels: subgroup analyses

|  | Subgroup analyses | Studies included | Odds ratio (95\% Cl) |
| :---: | :---: | :---: | :---: |
| Males and females | Rural population | Too few studies available to allow odds ratio to be calculated | NA |
|  | Urban population | Too few studies available to allow odds ratio to be calculated | NA |
|  | Adjusted for smoking | Albalak et al. (1999); <br> Menezes et al. (1994); <br> Pandey (1984a) | 2.51 (1.76-3.56) |
|  | Not adjusted for smoking | Qureshi (1994); Døssing et al. (1994); Gupta and Mathur (1997) | 5.8 (3.74-8.99) |
|  | Adjusted for age | Albalak et al. (1999); <br> Døssing et al. (I994); <br> Gupta and Mathur (1997); <br> Menezes et al. (1994) | 3.3 (2.32-4.69) |
| Females only | Adjusted for smoking but not for age | Behera et al. (1991); Pandey (1984a); Qureshi (1994) | 2.56 (1.75-3.75) |
|  | Adjusted for smoking and age | Dutt et al. (1996); Perez-Padilla et al. (1996); Dennis et al. (I996); Malik (I985) | 2.83 (2.0-3.97) |
| Males only | Not adjusted | NA, too few studiesDøssing et al. (1994) adjusted for age; Qureshi (1994) adjusted for none | NA, see also text |
|  | Adjusted for smoking and age | None of the studies in males adjusted for both age and smoking | NA |

[^65]The final model for women excluded the three studies that did not adjust for age and/or smoking status. The overall risk of COPD in women exposed to indoor air pollution from use of solid fuels was estimated as $3.2,95 \%$ CI $2.3-4.8$. There is much less evidence available about the impact on men, but the risk seems to be lower, $1.8,95 \%$ CI $1.0-3.2,{ }^{8}$ presumably because of lower exposure.

## LUNG CANCER

Lung cancer in women has been associated with cooking with open coal stoves in China on the basis of a number of studies. In China, there is also evidence that lung cancer is caused by use of certain cooking oils
(Zhong et al. 1999a, 1999b) as well as by exposures to known carcinogens contained in coal smoke, such as arsenic (Finkelman et al. 1999). There is limited evidence available for an association between lung cancer and use of biomass fuels in women, but not in men (Gao et al. 1987; Liu et al. 1993; Sobue 1990), although several pollutants in biomass smoke are known or suspected human carcinogens (Smith 1987).

The majority of the internationally published studies on lung cancer and indoor air pollution that we were able to locate were conducted in China. One took place in Japan (Sobue 1990) and one in the United States (Wu et al. 1985). Two eligible studies were published in Chinese only (Huang 1999; Wu et al. 1999). All 19 studies identified were case-control studies, including either newly-diagnosed cases of lung cancer at a hospital or using death registries, and of these, 14 studies were hospital-based. Inherent in the choice of this design is Berkson's bias, referring to the possibility that controls (men and women hospitalized with other diseases) are not selected independently of exposure in the source population. With two exceptions (Ko et al. 1997; Sobue 1990), all studies used population controls, which minimizes such bias (Table 18.16).

## Characteristics of excluded studies

Of the 19 studies identified, we excluded three (Du et al. 1988; Xu et al. 1996b; Yang et al. 1990). The ecologic study by Yang et al. (1990) neither adjusted for smoking or other risk factors nor provided sufficient information to calculate odds ratios. Of two articles which reported on the same study population (Du et al. 1988, 1996), we included the more recent, which provided $95 \%$ CIs for the relative risk. More than one article reported on a collaborative study that included men and women of two major cities in the Province of Liaoning (Wu-Williams et al. 1990; Xu et al. 1996b); we included only the study by Wu-Williams et al. (1990), which combined all female lung cancer cases from the death registries of the two cities. The study by Xu et al. (1996b) considered cases in males and females from one city only.

## Estimating risk factor-disease relationship

Although the 16 studies included in this analysis were all case-control designs, measurement of exposure to indoor air pollution was carried out by a multitude of methods. Seven studies assessed exposure to indoor air pollution in terms of years of exposure (Dai et al. 1996; Ko et al. 1997; Lei et al. 1996; Liu et al. 1991; Sobue 1990; Wu et al. 1999; Wu-Williams et al. 1990). The remaining eight studies merely determined whether coal and/or bio-fuel were generally used for cooking or heating (Du et al. 1996; Gao et al. 1987; Huang 1999; J. Liu and H. Hu, unpublished data, 1996; Liu et al. 1993; Shen et al. 1996; Wang et al. 1996; Wu et al. 1999). In order to explore the characteristics responsible for

heterogeneity found in the results of a meta-analysis of all studies, several subgroup analyses were conducted, in which stratification by type of fuel used (mostly coal and some wood) and sex was used. The variability of exposure categories was too great and the number of studies too small to be grouped for duration of exposure. If a study reported an estimate of relative risk for several exposure categories, the odds ratio for the category representing the longest period of exposure was used (Lei et al. 1996; Wu-Williams et al. 1990). Two studies (Luo et al. 1996; Wu et al. 1985) reported separate estimates for adenocarcinoma and squamous cell carcinoma; these were entered as separate studies as we were unable to achieve a combined estimate. Whenever possible, separate estimates for men and women were extracted and entered as individual studies (Du et al. 1996; Liu et al. 1991).

In a recent review of the literature on indoor air pollution and several health outcomes (Bruce et al. 2000), the most prominent concern voiced was regarding the lack of control for confounders. Therefore, we conducted stratified analyses based on studies that accounted for the most common potential confounders, such as smoking and the presence of a chronic respiratory disease. All studies included in the meta-analysis either adjusted for smoking or included only non-smokers. It has been suggested that chronic respiratory diseases such as chronic bronchitis, tuberculosis, asthma and emphysema that originate from infections or other predispositions may increase the probability of developing lung cancer later in life (Luo et al. 1996). We examined the effect of indoor air pollution from coal smoke on men and women separately. Nine studies either only included women or presented risk estimates for men and women separately (Dai et al. 1996; Du et al. 1996; Gao et al. 1987; Ko et al. 1997; Liu et al. 1991; Sobue 1990; Wang et al. 1996; Wu et al. 1985, 1999). The overall estimate for females was 1.17, $95 \%$ CI 1.02-1.35. The analysis restricted to studies that adjusted for smoking and chronic respiratory disease indicated a substantial increase in risk for women of almost two-fold (odds ratio of 1.94, $95 \%$ CI 1.09-3.47).

Five studies presented a combined risk estimate for men and women (Huang 1999; Lei et al. 1996; Liu et al. 1993; Luo et al. 1996; Shen et al. 1996), producing a summary odds ratio of 1.86 ( $95 \%$ CI 1.48-2.35). Restricting the analysis to the three studies that controlled for smoking and chronic respiratory disease showed a substantial increase in risk (odds ratio of $2.55,95 \%$ CI 1.58-4.10).

Only three studies either included males only (Wu et al. 1999) or presented sufficient data to extract a separate estimate for males (Du et al. 1996; Liu et al. 1991). The risk associated with coal use for the male population was $1.79,95 \%$ CI 1.18-2.72, and slightly lower when taking into account confounding by smoking and chronic airway disease (odds ratio of $1.51,95 \% \mathrm{CI} 0.97-2.46)$. Although the results of the two studies

Table 18.17 Summary of results of subgroup meta-analyses

|  | Odds ratio (95\% CI) |  |
| :--- | :---: | :---: |
| Subgroup analyses | Not adjusted | Adjusted for smoking and chronic <br> airway disease |
| Males and females—coal use | $1.86(1.48-2.35)$ | $2.55(1.58-4.10)$ |
| Males only—coal use | $1.79(1.18-2.72)$ | $1.51(0.97-2.46$ |
| Females only-coal use | $1.17(1.02-1.35)$ | $1.94(1.09-3.47)$ |

comprising this model were not quite statistically significant (lower confidence limit was 0.97 ), the pattern of significance of the five studies assessing risks for men and women combined, give confidence that there is likely to be a real effect on men. Odds ratios are shown in Table 18.17.

### 3.4 Sources of uncertainty

Uncertainty estimates were generated through the use of meta-analyses for all the disease end-points included. A critical problem with extrapolating the results of epidemiological studies from one subregion to another, particularly between developed and developing regions, is the difference in other potentially interactive risk factors, such as malnutrition, which are not addressed by the methodology. That all the studies used for the calculations of solid-fuel use were done in developing countries, however, does provide some confidence that differences in competing risks were not excessive. Meta-analytical confidence intervals probably underestimate true uncertainty because of variations in the way different studies dealt with measures of exposure, adjustment for confounding, and outcome definitions, as well as the need to extrapolate results across populations.

### 3.5 Risk Reversibility

There are few studies on the reversibility of the health effects of smoke from solid fuel. For acute outcomes (ALRI), evidence from risk factors for other childhood infectious diseases may provide some guidance (Jones et al. 2003). For the chronic conditions, COPD and lung cancer, the timing is less clear, however, since the increased risk presumably results from many years of exposure. A retrospective cohort study in China, however, did find a statistically significant drop in lung cancer rates associated with introduction of improved stoves with flues in around 1980 (Lan et al. 2002). The delay between intervention and a discernible reduction in lung cancer incidence was about 10 years, consistent with that observed after smoking cessation (see chapter 11).

## 4. Results

### 4.1 Attributable burden of disease

As shown in Table 18.18, the burden of disease attributed to use of household solid fuels is dominated by that caused by ALRI in young children, which accounts for $59 \%$ of all attributed premature deaths and $78 \%$ of DALYs. COPD accounts for nearly all the remainder, with the burden from lung cancer a relatively minor contributor, owing to the concentration of estimated use of coal in two subregions only. Because ALRI in children does not cause many years lost due to disability, however, COPD is responsible for a much larger portion of the total disability.

As shown in Table 18.18, five subregions account for nearly all deaths ( $94 \%$ ) and DALYs ( $93 \%$ ) attributable to indoor air pollution from solid fuel. The subregions with the largest numbers of DALYs, in descending order, are SEAR-D, WPR-B, AFR-E, AFR-D and EMR-D. When the subregions are ranked according to numbers of deaths, the relative positions of SEAR-D and WPR-B shift, because there are more deaths in SEAR-D in a younger age group (ALRI-related deaths in children) compared to WPR-B (mortality is dominated by COPD in adults).

As shown in Figure 18.5, because of differences in baseline rates of disease, not exposure or risk from use of solid fuel, effects on mortality

Table 18.18 Burden of disease from use of solid fuel, 2000

Figure 18.5 Deaths from acute lower respiratory infection attributable to indoor smoke from use of solid fuels, 2000

attributable to ALRI are larger for males than females in AFR-D and AFR-E, similar in EMR-D and WPR-B, and greater for females in SEAR-D.

As shown in figure 18.6, the vast majority of attributable deaths from COPD and lung cancer appear to be experienced by the women of SEARD and WPR-B. This is partially because lung cancer deaths associated with solid fuel use were only estimated in these two subregions, due to lack of information on coal use in the other subregions. In addition, women appear to bear a higher proportion of the burden not only because they are likely to be more exposed, but because smoking attributable deaths (which are a higher proportion of male deaths) have been removed.

## 5. Discussion

### 5.1 Sources of uncertainty

Of a large number of sources of uncertainty, four major factors dominate these estimates.

- The choice of exposure variable, which, although necessary to match with current epidemiological studies, only roughly captures the population distribution of exposure and its variability in different populations.

Figure 18.6 Deaths from chronic obstructive pulmonary disease and lung cancer attributable to indoor smoke from use of solid fuels, 2000

- Distribution of the ventilation factor worldwide, i.e. what fractions of solid-fuel-using households do so in ways that vent some or all of the smoke outside and away from the householders.
- The different patterns of competing and confounding risks for ALRI in different circumstances, particularly those related to the severe forms affecting mortality.
- The relationship between the risks of indoor pollution and tobacco smoking, particularly for COPD and lung cancer in China where tobacco smoking is an important contributor (Liu et al. 1998).

### 5.2 Possible interventions

Although not included in the primary calculations here, as previously noted, there is growing evidence that other important health end-points can be attributed to exposure to indoor air pollution. Three of these, in particular, are of increasing concern worldwide: tuberculosis (because it is so closely related to the HIV epidemic); ischaemic heart disease (because of the shift in age and diet occurring in developing countries); and asthma (because of rising trends in diagnosed asthma in many parts of the world) (ISAAC 1998). There is some urgency that the associations of all potentially policy-sensitive risk factors (including use of solid household fuels) with these diseases be investigated.

There are four general categories of interventions that have been identified to reduce the health impacts of household use of solid fuel (Barnes et al. 1993; Ezzati and Kammen 2002; NCAER 2002; Smith and Desai 2002; Smith 1987, 1989).

- Behavioural changes to reduce exposure, for example, encouraging women to keep their young babies away from the fire.
- Changes in household ventilation, such as increasing the number of window openings in the kitchen, providing gaps between roof and wall, and moving the stove out of the living area.
- Improvements in stoves, either through venting by use of flues or hoods and/or improvements in stove combustion efficiency that reduce the emissions of toxic pollutants, nearly all of which are products of incomplete combustion.
- Shifts to higher-quality, low-emission liquid or gaseous fuels, such as kerosene and liquefied petroleum gas (which are based on petroleum) or biomass-based alcohol and biomass-based gaseous fuels derived either from biological processes (bio-gas) or thermochemical processing (producer gas).

Most research has focused on improvements in stoves and shifts to higher-quality, low-emission liquid or gaseous fuels; it seems that the efficacy of the interventions listed above generally increases as one moves down the list. The extent to which they can be successfully applied varies across different populations depending on income, housing, biomass availability, cultural factors and climate. It seems possible, however, that programmes can be designed to encourage many urban and peri-urban solid-fuel-using populations to move to using liquefied petroleum gas or kerosene, at lower incomes (i.e. sooner) than would occur without intervention. On the other hand, the poorest rural populations with nearly no cash income, but with access to wood and/or agricultural waste, are unlikely to move to clean fuels or use significantly improved stoves without large subsidies, which are usually not sustainable. There do seem to be large populations between these extremes, however, that can be targeted by efforts to introduce improved stoves. Although the fraction of improved-stove programmes that have succeeded is small, the total number of stoves successfully introduced is impressive because of the remarkable achievement of the Chinese programme, which has apparently been responsible for the introduction of nearly 200 million stoves since the early 1980s (Goldemberg et al. 2000; Smith 1993). More research and development work is needed, however, to learn how to successfully translate the lessons learned in China and elsewhere to other parts of the world in a sustainable cost-effective manner.

## 6. Exposure projections

The use of solid fuel will probably slowly decrease in absolute, as well as relative, terms, as economic development proceeds. This shift is occurring most rapidly in China and Latin America, at interim rates in south Asia, and slowest or not at all in sub-Saharan Africa (World Resources Institute 2000). Cooking outdoors, on the other hand, is likely to decrease with development, but as the number of separate kitchens may increase, it is not clear how exposures will change overall. Current trends in vented stoves are less certain outside China. The Indian national stove programme, for example, had mixed success (NCAER 2002) and was dismantled in 2002 (Mahapatra 2003). In China, however, nearly 90\% of the rural population seems to have adopted higher-efficiency vented stoves in recent years.

Table 18.19 Use of solid fuel and exposure to its smoke: estimates for 2000 and predictions for 2010

| Subregion | Estimated fuel use ${ }^{\text {a }}$ |  | Estimated exposure of adults ${ }^{\text {b }}$ |  |
| :---: | :---: | :---: | :---: | :---: |
|  | 2000 | 2010 | 2000 | 2010 |
| AFR-D | 73.4 | 69.0 | 55.1 | 52.0 |
| AFR-E | 85.8 | 83.0 | 64.3 | 62.0 |
| AMR-A | 1.5 | 1.0 | 1.1 | 1.0 |
| AMR-B | 24.6 | 20.0 | 18.4 | 15.0 |

| WPR-B ${ }^{\text {c }}$ | 78.1 | 70.0 | 41.8 | 23.0 |

[^66]Some insight can be gleaned about the potential for reduction in exposure by application of the model of solid-fuel use employed in this chapter. Estimates of income growth and shift of the population from rural to urban areas have different impacts on use of solid fuels in different subregions. Economic growth and urbanization over the next 10 years, for example, might substantially reduce the fraction of households that use solid fuel in the subregions that currently have the largest burdens. We examined changes that might occur over a 10 -year period in two major model parameters: GNP per capita and rural-urban population shift (World Bank 2001). Estimates based on changes in income and urbanization beyond 2010 would be highly unstable, since current trends are unlikely to be sustained over several decades. Countries for which data are lacking are assigned the global average values for GNP per capita (equivalent to a $1.3 \%$ annual growth rate) and global rate of urbanization (rural population decreases from around $58 \%$ to $51 \%$ of the total population. Among many other assumptions, of course, such an extrapolation supposes that the structure of the model remains valid over this period. Table 18.19 shows how predicted changes in GNP per capita and urbanization affect predictions of future household use of solid fuel and of future exposure in each subregion. The net impact of shifts in these factors seems to indicate that, globally, exposure to indoor smoke from use of solid fuel is likely to decrease. There are subregional variations in the pattern, however, with continuing large exposures in sub-Saharan Africa and south-east Asia (Indian subcontinent).

## Acknowledgements

We appreciate the excellent comments of many anonymous reviewers; assistance with extracting information from Chinese-language literature from Linwei Tian; advice on meta-analysis from Daniel Mäusezahl, Jack Colford and the Berkeley Meta-analysis Group; and the patience and thoughtfulness of the book's editors, particularly Majid Ezzati. The authors would also like to recognize the millions of poor women and children around the world who are exposed daily to toxic indoor air pollution produced by smoke from solid fuel, as well as to a range of other risks. We hope that these results will help to generate recognition of the potential magnitude of this problem and spark commensurate efforts to ameliorate the situation.

## Notes

1 Particulate matter, often abbreviated as PM, is categorized by size, specifically by aerodynamic diameter in microns (millionths of a meter or $\mu \mathrm{m}$ ). For example, $\mathrm{PM}_{2.5}$ refers to particulate matter with a diameter of less than $2.5 \mu \mathrm{~m}$. In general, small particles are thought to be more damaging to health.
2 See preface for an explanation of this term.

3 Seven urban and three rural areas were omitted because of missing data or likely errors in the government statistical publications, which suggested improbable levels of energy consumption per household (i.e. in provincial households, average levels of consumption that were more than one standard deviation from the mean).
4 All analysis was done using SPSS Version 8.0 (SPSS Inc., USA) and STATA 7.0 (Stata Corporation, USA).

5 Cross-sectional studies report odds ratios rather than relative risks. These terms are used interchangeably in this chapter.
6 Two hospital-based case-control studies in India came to our attention too late for inclusion in the meta-analysis. In New Delhi, Broor et al. (2001) found an adjusted odds ratio of 2.5 ( $95 \%$ CI 1.5-4.2) for ALRI in children aged $<5$ years in homes not using liquefied petroleum gas. In Calcutta, Mahalanabis et al. (2002) found an adjusted odds ratio of 4.0 ( $95 \%$ CI $2.0-7.9$ ) for pneumonia in children aged 2-35 months living in homes using solid fuels.
7 For further discussions, see reviews by Bruce et al. (2000), Chen et al. (1990) and Smith (1987).
8 For males, it did not seem appropriate to use the unadjusted estimate of risk, particularly when the adjusted estimates for both sexes were lower than either the unadjusted estimate for males only or the adjusted estimates for females only. Simple averaging of the risk chosen for males, 1.8, with the adjusted risk for females, 3.2 , results in the combined mean risk of 2.5 observed when analyses included both sexes. The lower bound of the confidence interval was set at 1.0 (no effect) and the higher bound only at the unadjusted risk for males, 3.2.

## Chapter I9

LEAD EXPOSURE<br>Annette Prüss-Üstün, Lorna Fewtrell, Philip J. Landrigan and José Luis Ayuso-Mateos

## Summary

Exposure to lead causes a number of diseases, including mild mental retardation resulting from loss of IQ points, as well as increased blood pressure, anaemia, and gastrointestinal effects. Several other disease outcomes have been associated with exposure to lead, but evidence is considered insufficient at this time for a quantitative assessment of their impact on health to be made here.

The exposure variable used was the population distribution of bloodlead concentrations. We compiled data on concentrations of lead in blood from general population samples in countries around the world, as reported in more than 700 published studies. Only recent studies (published in or after 1995) were considered, because of changes in lead exposure that have taken place since the 1970 s, mainly as a result of the implementation of lead reduction programmes (e.g. the phasing out of leaded petrol). Where current data were not available, we applied an adjustment of $39 \%$ reduction in blood-lead concentrations to allow for the effects of implementation of five-year lead reduction programmes. For countries for which data were not available, exposure reduction due to existing lead reduction programmes was accounted for by extrapolation.

Blood-lead concentrations of about $0.016 \mu \mathrm{~g} / \mathrm{dl}$ have been measured in pre-industrial humans, indicating that the contribution of natural sources of lead to human exposure is minimal. Estimates published recently suggest that the theoretical-minimum-risk of health effects may occur at blood-lead concentrations as low as $0-1 \mu \mathrm{~g} / \mathrm{dl}$.

The association of increased blood-lead concentrations with loss of IQ points has been described in a meta-analysis by Schwartz (1994). Hazards for blood lead and blood pressure were from a meta-analysis by Schwartz (1994) and a published analysis of data from the second National Health and Nutrition Examination Survey (NHANES II).

Hazards for anaemia and gastrointestinal effects were based on a large review of toxicological and epidemiological data (ATSDR 1999). Based on the results of a study by Schwartz et al. (1990), as a consequence of individual variation we considered that only $20 \%$ of the people with blood-lead concentrations above those indicated by the Agency for Toxic Substances and Disease Registry (ATSDR) would actually develop symptoms.

The number of people with mild mental retardation as a result of IQ loss was determined on the basis of a standardized intelligence curve. To account for the higher prevalence of other mild mental retardation risk factors (e.g. malnutrition) in some subregions, ${ }^{1}$ the prevalence of leadinduced mild mental retardation was adjusted for the known ratio of mental retardation caused by other factors. A number of health outcomes and social consequences of lead exposure (e.g. increased risk of violence and drug abuse) could not be quantified owing to insufficient evidence on hazard size.

In 2000 , an estimated 120 million people around the world had bloodlead concentrations of between 5 and $10 \mu \mathrm{~g} / \mathrm{dl}$, and about the same number had concentrations of $>10 \mu \mathrm{~g} / \mathrm{dl}$. Forty per cent of all children had blood-lead concentrations of $>5 \mu \mathrm{~g} / \mathrm{dl}$ and half of these children had blood-lead concentrations of $>10 \mu \mathrm{~g} / \mathrm{dl}$; of these children, $97 \%$ were living in developing countries. The burden of disease caused by mild mental retardation attributable to exposure to lead resulted in 9.8 million disability-adjusted life years (DALYs), and the burden from cardiovascular diseases caused by elevated blood pressure resulted in 229000 premature deaths and 3.1 million DALYs. In total, these two outcomes alone account for about $0.9 \%$ of the global burden of disease. Several health outcomes resulting from exposure to lead could not be quantified in this analysis, in particular, increased delinquent behaviour and its impact on injuries. Health impacts from anaemia and gastrointestinal effects caused by exposure to lead were relatively small. People affected by exposure to lead were concentrated mainly in developing countries. The burden of disease associated with exposure to lead could be virtually eliminated through interventions that have proven successful in developed countries, most importantly, the removal of lead from petrol.

## 1. Introduction

The toxic nature of lead has been recognized for millennia, with the earliest published reports dating back to 2000 BC (Needleman 1999). However, the range of health effects that exposure to lead can cause and the low concentrations of lead in blood at which these effects can occur is only now being fully appreciated. It is now understood that lead is toxic, especially to children, at levels that were previously thought to be safe.

Lead, due to its multiplicity of uses (e.g. leaded petrol, lead in paints, ceramics, food cans, make-up, traditional remedies, batteries), is present
in air, dust, soil and water to varying degrees. Each of these media can act as a route of human exposure, through ingestion or inhalation and, to a small degree for organic lead compounds, dermal absorption. Human exposure can be assessed directly, through body burden measurements (lead in blood, teeth or bone) or indirectly, by measuring levels of lead in the environment (air, dust, food or water).

Multiple health effects have been associated with lead exposure, including systemic effects (e.g. gastrointestinal effects, anaemia, hypertension and hearing loss), effects on the nervous system (e.g. on behaviour and cognition), on development, and on the reproductive system, as well as genotoxicity, carcinogenicity and social effects (ATSDR 1999). The strength of evidence supporting the association of these health effects with exposure to lead varies, and not all of these effects have been investigated sufficiently to permit quantification of their consequences in terms of disease burden.

### 1.1 Risk factor definition

In this analysis, exposure was characterized by the population mean and the population distribution of blood-lead concentrations. Occupational exposures or "hot spots" (i.e. areas of local relevance where lead levels are unusually high, such as around smelters) were excluded, unless they were assessed within general population samples.

### 1.2 ThEORETICAL-MINIMUM-RISK EXPOSURE DISTRIBUTION

The definition of an elevated concentration of lead in the blood according to the Centers for Disease Control and Prevention (CDC 1991) is $10 \mu \mathrm{~g} / \mathrm{dl}$. However, evidence indicating that some health effects can occur below this threshold is accumulating. Recent analyses suggest that health effects may become apparent at concentrations of $<5 \mu \mathrm{~g} / \mathrm{dl}$ (Lanphear 2000) and, indeed, that no evidence exists for a threshold, even at $1 \mu \mathrm{~g} / \mathrm{dl}$ (Schwartz 1994). For the purpose of this analysis, the concentration of blood-lead incurring the lowest population risk was considered to be $0-1 \mu \mathrm{~g} / \mathrm{dl}$, in the absence of scientific consensus and pending further investigation. The measurement of blood-lead concentrations in preindustrial humans has shown that the contribution of natural sources of lead to human exposure is small; Flegal and Smith (1992) have estimated that pre-industrial humans had blood-lead concentrations of only $0.016 \mu \mathrm{~g} / \mathrm{dl}$.

## 2. Estimating Risk Factor levels

### 2.1 Choice of exposure variable

The concentration of lead in blood was chosen as the measure of exposure of the population because:

- it is an objective physiological measure, which can be measured accurately;
- it is directly related to health outcome and can be expected to reflect exposure more closely than estimates derived from measurement of the concentration of lead in air, soil, dust or food; and
- it is the only parameter for which measurements are available from many parts of the world, thus making it preferable to other physiological measures, such as the concentration of lead in bone.

Blood-lead concentrations are indicative of recent lead exposure (within the preceding few weeks) rather than of cumulative long-term exposure. However, as exposure to lead varies relatively little over a time span of a year (WHO 1998), this measure can also be a sign of longerterm exposure.

### 2.2 Data on blood-lead concentrations

## Data sources

Exposure data were obtained from studies identified principally through Medline searches. The primary database used was compiled by the CDC (1999) and contained exposure data from over 700 articles published between 1965 and 1998. The search strategy used was the term "lead" paired with any of the following keywords: newborn, cord, adult, pregnancy, occupation, blood, tooth, hair, milk, placenta, urine, smelter, ceramics, pottery, petrol, cosmetics, kohl, surma, medicine, neurological deficit, cognitive function, pregnancy outcome, fertility and birth defect. Initial queries were followed up using the "related-articles" option of Medline and further searches on the basis of author. The reference list of each relevant article was also examined. Additionally, the authors conducted searches of the databases LILACS (Latin American and Caribbean Information System of Health Sciences), IMEMR (Index Medicus of the World Health Organization's [WHO] Regional Office for the Eastern Mediterranean-EMRO) and African Index Medicus, using the same keywords. Medline was also re-consulted to ensure coverage of the most recent publications (up to the end of 2000).

## Compilation and presentation of Data

Blood-lead concentrations in the population generally have a log-normal distribution, as reported in numerous countries and populations (Al-Saleh et al. 1999; Baghurst et al. 1995; Brody et al. 1994; CDC 2001; Harlan et al. 1985; Hense et al. 1992; Molla et al. 1997; Pocock et al. 1988; Schwartz 1991; Tong et al. 1998). Geometric means with standard deviations were therefore compiled to represent population exposures.

A few studies reported small differences (typically $<10 \%$ ) between blood-lead concentrations in males and females (e.g. CDC 2001; Nielsen et al. 1998; Omokhodion 1994; Paolielo et al. 1997). We therefore com-
bined exposure data for men and women in this analysis. Exposure data were compiled separately for children and adults where this information was available.

### 2.3 Country estimates and subregional aggregation

## AdJustments for data from countries currently phasing out lead

 IN PETROLBlood-lead concentrations can change dramatically over a few years in response to programmes to eliminate the use of lead in petrol. Therefore, data which were more than one year old from countries that had reduced exposure to lead required downward correction to avoid overestimating exposure.

Decreases in blood-lead concentrations correlate well with the removal of lead from petrol (Thomas et al. 1999). Therefore, progress in phasing out lead was used to adjust exposure levels. Although leaded petrol is not the only source of lead in the environment, it is a good indicator of reduction in exposure to lead (Landrigan et al. 2000). Multiple studies have shown reductions in blood-lead concentrations in parallel with decreases in levels of lead in petrol (Thomas et al. 1999). Full implementation of lead reduction programmes has produced decreases in blood-lead concentrations in children of $\geq 90 \%$ over 25 years (CDC 1997, 2000).

Figure 19.1 shows changes in population blood-lead concentrations in the United States of America over a five-year period, during the early stages of a lead reduction programme (Annest 1983; Annest et al. 1983). During this period, the mean blood-lead concentration dropped by $37 \%$. Other studies conducted in various countries have shown very similar results (Elinder et al. 1986; Schuhmacher et al. 1996; Wietlisbach et al. 1995), with decreases ranging from $30-48 \%$ over a five-year period. We chose the midpoint of $39 \%$ as a reduction factor for data that had been collected 5 years before the initiation of a leaded petrol phasing-out process or, for shorter periods, $7.8 \%$ decrease per year. Data which were $>6$ years old were not used. Only the most recent data were selected, provided that they were consistent with trends observed in older data.

Use of leaded petrol and the timing of any changes in the concentration of lead in petrol were assessed using data derived from the World Resources Institute (WRI 1998), the Earth Summit Watch (UNEP 2000), Car Lines (Walsh 2001) and M.P. Walsh (personal communication, 2002). A summary of the global situation with regard to reducing exposures to lead in petrol is provided in Figure 19.2 and below.

- AFR-D and AFR-E: With the exception of South Africa, countries in these subregions have not implemented lead reduction programmes.
- $A M R-A$ : Blood-lead concentrations are likely to be significantly higher in Cuba than in Canada or the United States, as Cuba started lead reduction programmes more recently.

Figure 19.1 Decrease in mean population blood-lead concentrations in relation to reduction of lead in petrol, ${ }^{a}$ in the United States

Source: Annest (1983).

Figure 19.2 Sales of leaded petrol as a percentage of total petrol sales, by country, end of 2001

[^67]- $A M R-B$ and $A M R-D$ : Most countries have now phased out leaded petrol. However, other sources, such as battery recycling and leadglazed ceramics, are of importance in these subregions. Some countries, including Mexico and Peru, are major producers of lead.
- EMR-B and EMR-D: Some countries have now started a lead reduction programme. Egypt and Saudi Arabia are almost lead-free with regard to petrol.
- EUR-A: Most countries have phased out lead in petrol, and lead reduction programmes have been in place for a considerable period of time.
- EUR-B and EUR-C: While lead reduction programmes in some countries are relatively advanced, the great majority of countries have made little progress. EUR-C is less advanced than EUR-B in terms of phasing out leaded petrol.
- SEAR-B and SEAR-D: While Thailand has phased out lead in petrol, significant amounts of leaded petrol are still used in other countries. Sources other than leaded petrol (especially lead-containing cosmetics and local medications) greatly contribute to exposure in certain parts of these subregions.
- WPR-A: All countries have undertaken lead reduction programmes, most of which have been fully implemented. Japan began implementing lead reduction programmes at a very early stage.
- WPR-B: Some countries in this subregion, such as China and the Philippines, have made considerable efforts to phase out leaded petrol. Other countries have made little or no progress.

## EXPOSURE IN RURAL POPULATIONS

Where leaded petrol is still in use, blood-lead concentrations in rural populations are generally lower than those in urban populations (Nriagu et al. 1997a; Piomelli et al. 1980; Rhainds and Levallois 1993; Vasilios et al. 1997).

Thomas et al. (1999) showed that soon after the elimination of leaded petrol, population blood-lead concentrations tend to converge on an average of $3.1 \mu \mathrm{~g} / \mathrm{dl}$ ( $\mathrm{SD} 2.3 \mu \mathrm{~g} / \mathrm{dl}$ ). This value is similar to the mean, $3.0 \mu \mathrm{~g} / \mathrm{dl}$, of the data from rural areas available from countries in which lead has not been totally or partially phased out $(3.4 \mu \mathrm{~g} / \mathrm{dl}$, Grobler et al. $1985 ; 2.3 \mu \mathrm{~g} / \mathrm{dl}$, Khwaja 2002; $3.8 \mu \mathrm{~g} / \mathrm{dl}$, Nriagu et al. 1997a; $3.4 \mu \mathrm{~g} / \mathrm{dl}$, Piomelli et al. 1980; $2.1 \mu \mathrm{~g} / \mathrm{dl}$, Vasilios et al. 1997). We therefore selected $3.1 \mu \mathrm{~g} / \mathrm{dl}$ as the mean blood-lead concentration for rural populations in countries where concentrations of blood-lead in urban areas were higher than this value. In Latin America and the Caribbean, however, it was assumed that rural populations would have higher concentrations of blood-lead as other sources, such as ceramics and recy-
cling of batteries, contribute significantly to lead exposure in these areas (Romieu 2001a). The mean of the most recently-reported blood-lead concentrations in urban Latin American countries that have phased out lead is $4.3 \mu \mathrm{~g} / \mathrm{dl}$ (Garcia and Mercer 2001; Sepulveda 2000), and we also used this value to represent rural blood-lead concentrations in this subregion.

After the complete phasing-out of leaded petrol, blood-lead concentrations continue to decrease, mainly as a result of additional efforts to reduce other sources of lead in the environment. Recent assessments from the United States have reported mean blood-lead concentrations of $1.6 \mu \mathrm{~g} / \mathrm{dl}$ for the total population and $2.0 \mu \mathrm{~g} / \mathrm{dl}$ for children aged $<5$ years (CDC 2001). In such cases, the same values were used to characterize urban and rural populations, as assuming higher exposures in urban environments did not seem justifiable.

## CALCULATING SUBREGIONAL MEANS

For each country with more than one source of data for blood-lead concentrations, geometric means were calculated (weighted by sample size) after the above adjustments. Means for urban and rural populations were estimated separately. Subregional means were calculated by weighting the mean for each country by the size of its urban population. For subregions with countries at different stages of lead phase-out (all subregions except EUR-A and AFR-D), urban means were estimated separately for countries which had made different degrees of progress in eliminating lead. In summary, we superimposed two or three log-normal distributions for each subregion to characterize the distribution of bloodlead concentrations in the population, each of which was weighted by the size of the population they represent. The urban/rural breakdown was based on data from UNDP (2000).

Fewer data on standard deviations were available than on mean blood-lead concentrations. In order to estimate standard deviations for areas for which data were sparse, we grouped subregions according to economic and lead-use patterns and calculated the average standard deviation for each grouping (AMR-A; EUR-A and WPR-A; AMR-B and D; remaining B and C subregions; remaining D and E subregions). Country averages (weighted by sample size) were estimated, and then averaged into the subregional standard deviations by weighting for the size of the urban population. For the grouping of D and E subregions, we did not weight by population size because the large countries contained within these two groupings were not representative of other countries. Table 19.1 shows the urban means for children and adults, the standard deviations, and the distribution of the population into categories of blood-lead concentration. As mentioned above, mean blood-lead concentrations in rural populations are assumed to be $3.1 \mu \mathrm{~g} / \mathrm{dl}$, or equal to blood-lead concentrations for urban populations in which levels have declined after lead reduction programmes.
Table I9.I Blood-lead concentrations in children and adults, by subregion

| Subregion | AFR-D ${ }^{\text {a,c }}$ | AFR-E ${ }^{\text {ac. }}$ | AMR-A | AMR-B | AMR-D | EMR-B | EMR-D | EUR-A | EUR-B | EUR-C | SEAR-B | SEAR-D | WPR-A | WPR-B |

Table 19.1

Based on these methods, we estimated that globally 120 million people had blood-lead concentrations of between 5 and $10 \mu \mathrm{~g} / \mathrm{dl}$ in the year 2000, and about the same number of people had blood-lead concentrations of $>10 \mu \mathrm{~g} / \mathrm{dl}$. Forty per cent of all children had blood-lead concentrations of $>5 \mu \mathrm{~g} / \mathrm{dl}$, and $20 \%$ had concentrations of $>10 \mu \mathrm{~g} / \mathrm{dl}$, and $97 \%$ of the latter were living in developing countries. Nine per cent of children had blood-lead concentrations of $>20 \mu \mathrm{~g} / \mathrm{dl}$, and $99 \%$ of these children were living in developing countries.

## 3. Estimating Risk FACTOR-DISEASE <br> RELATIONSHIPS

### 3.1 Health outcomes

Exposure to lead affects multiple health outcomes and physiological systems (ATSDR 1999), including the following: hypertension, the gastrointestinal system, anaemia, nephropathy, vitamin D metabolism, decreased growth, the immune system, the nervous system, behavioural/cognitive/IQ effects (and as a result, multiple social effects, including increased risk of violence and drug abuse), nerve conductive effects, hearing loss, effects on reproduction and development and death from encephalopathy.

Evidence relating exposure to lead and various health effects has been reviewed extensively (ATSDR 1988, 1993, 1999; International Programme on Chemical Safety 1977, 1995; National Research Council 1993; Pocock et al. 1994; Schwartz 1994). The most recent comprehensive review of the evidence on the risk factor-disease relationship was conducted by ATSDR in the United States (1999). Health effects considered in this review included systemic effects (e.g. raised blood pressure, gastrointestinal effects and anaemia) and nervous system effects (IQ reduction). Nephropathy and encephalopathy were not included as they rarely occur after environmental exposures but rather as a result of highlevel exposure, such as ingestion of lead or lead salts, e.g. from local medication (Woolf 1990) or occupational exposure. A number of suggested health outcomes (e.g. developmental, reproductive and social effects) were not considered because of difficulties in quantifying the level of exposure at which a health outcome occurs, inadequate evidence of causality, or lack of information regarding baseline disease levels.

### 3.2 Evidence and exposure-Risk relationships

## GENERAL NERVOUS SYSTEM EFFECTS

The central and peripheral nervous systems are considered to be the principal targets affected by toxicity caused by the absorption of lead (Tsuchiya 1986; WHO 1996). Proposed mechanisms of toxicity (reviewed in ATSDR 1999) are based on the ability of lead to inhibit or mimic the action of calcium, and to interact with proteins. In terms of
general effects on the nervous system, the key mechanism is likely to be the substitution of lead for calcium as a "second messenger" in neurons. Lead blocks voltage-regulated calcium channels, inhibiting the influx of calcium and release of neurotransmitters and thus inhibiting synaptic transmission.

The most severe neurological effect of exposure to lead is encephalopathy. However, neurotoxic effects are apparent at much lower blood-lead concentrations than those that cause encephalopathy (i.e. $\leq 90 \mu \mathrm{~g} / \mathrm{dl}$ for children, $\leq 140 \mu \mathrm{~g} / \mathrm{dl}$ for adults, depending on the individual). Studies investigating occupational exposure to lead have reported symptoms such as loss of appetite, malaise, lethargy, headache, fatigue, forgetfulness and dizziness in workers with blood-lead concentrations of $40-120 \mu \mathrm{~g} / \mathrm{dl}$.

In the 1940s, Byers and Lord (1943) reported that children who had previously suffered from lead poisoning made poor progress at school, had a shorter attention span and exhibited behavioural disorders. Such observations were followed by epidemiological studies to determine the effects of low-level exposure to lead on children's intellectual abilities and behaviour. Low-level exposure to lead has been associated with failure to complete schooling, reading disability, longer reaction times, delinquent activity and other signs indicating effects on the central nervous system (Needleman et al. 1990, 1996). A large cohort study (Burns et al. 1999) showed that children exposed to relatively low levels of lead experienced an array of emotional and behavioural problems. Similarly, children who had experienced prenatal and postnatal exposure to lead were found to have an increased risk of cognitive deficit (Bellinger et al. 1990), problem behaviour and other dysfunctions, such as inappropriate approaches to tasks, or difficulty with simple directions and sequences of directions (Bellinger et al. 1994; Leviton et al. 1993). Nevin (2000) reported that long-term trends in population exposure to lead (indexed through use of leaded petrol and paint) were remarkably consistent with changes in violent crime; these findings are consistent with the reported link between IQ and social behaviour. Although it has been suggested that neurophysiological changes may be reversible (Ruff et al. 1993), the results of numerous studies indicate that this is unlikely (Schwartz et al. 2000b; Stokes 1998; Tong et al. 1998).

Effects on the nervous system other than loss of IQ and consequent mental retardation could not be quantified at the population level. This was either because of insufficient evidence linking effects to blood-lead concentrations, or because the outcome was not, in the strict sense, a quantifiable health effect (e.g. behavioural problems).

## Loss of IQ POINTS

Analyses of the body of evidence regarding the link between exposure to lead in early childhood and decrease in IQ score suggest that the relationship is causal (International Programme on Chemical Safety 1995;

Pocock et al. 1994; Schwartz 1994). In a meta-analysis, Schwartz (1994) estimated that a mean loss of 2.6 IQ points was associated with an increase in blood-lead concentration from 10 to $20 \mu \mathrm{~g} / \mathrm{dl}$. This result was robust to the inclusion or exclusion of the results of the strongest individual studies. This meta-analysis included eight cross-sectional and longitudinal studies, the largest longitudinal study being the Port Pirie cohort study in Australia (Baghurst et al. 1992) with about 500 participants and a follow-up of several years. Other meta-analyses report similar findings (International Programme on Chemical Safety 1995; Pocock et al. 1994). We selected the analysis by Schwartz (1994) to define the outcome as this study quantified the loss of IQ points and provided a point estimate with a confidence interval. At blood-lead concentrations of $>20 \mu \mathrm{~g} / \mathrm{dl}$, we assumed a loss of $2-5 \mathrm{IQ}$ points (midpoint of 3.5 IQ points) on the basis of the conclusions of the ATSDR report, which were derived from evidence from two studies (de la Burde and Choate 1972; Rummo et al. 1979).

Schwartz (1994) also reported that loss of IQ points is likely to be found between 5 and $10 \mu \mathrm{~g} / \mathrm{dl}$, with an even steeper relationship than in higher concentrations. For comparison, CDC currently defines bloodlead concentrations in excess of $10 \mu \mathrm{~g} / \mathrm{dl}$ as elevated, although acknowledging Schwartz' analysis as evidence for subtle effects at lower concentrations (CDC 2000). The existence of such effects has recently been confirmed by Lanphear et al. (2000), whose analysis of data from about 5000 children showed that children with blood-lead concentrations of between 5 and $10 \mu \mathrm{~g} / \mathrm{dl}$ had poorer cognitive skills.

In summary, to quantify IQ loss in the population, we assumed a linear relationship of 1.3 IQ points lost per $5 \mu \mathrm{~g} / \mathrm{dl}$ increase in blood lead, for blood-lead concentrations of between 5 and $20 \mu \mathrm{~g} / \mathrm{dl}$ (according to the analysis of Schwartz 1994, which showed a loss of 2.6 IQ points for an interval of $10 \mu \mathrm{~g} / \mathrm{dl})$. This linear relationship was divided into three segments, or increments, of $5 \mu \mathrm{~g} / \mathrm{dl}$, and the mean loss of IQ points in each increment was assigned to its mean blood-lead concentration-that is, 0.65 points for the increment $5-10 \mu \mathrm{~g} / \mathrm{dl}$ with a mean of $7.5 \mu \mathrm{~g} / \mathrm{dl}$; 1.95 points for the increment $10-15 \mu \mathrm{~g} / \mathrm{dl}$ with a mean of $12.5 \mu \mathrm{~g} / \mathrm{dl}$; and 3.25 points for the increment $15-20 \mu \mathrm{~g} / \mathrm{dl}$. The mean loss of IQ points is $0.65(1.3 / 2)$ for the first increment, $1.95(0.65+1.3)$ for the second, and $3.25(1.95+1.3)$ for the third. This is illustrated in Figure 19.3. A loss of 3.5 IQ points was assumed for blood-lead concentrations of $>20 \mu \mathrm{~g} / \mathrm{dl}$.

## Mild mental retardation as a consequence of loss of IQ points

As loss of IQ points per se is not considered to be a disease by the international classification of disease (ICD) system, we converted IQ loss into mild mental retardation. Although loss of IQ potentially increases the risk for other diseases, injuries and adverse outcomes, such as violence (Needleman et al. 1996; Nevin 2000), no quantification could be made

Figure 19.3 Decrease in IQ points per increment increase in blood-lead concentration ("best estimate")

Figure 19.4 Loss of IQ points resulting in mild mental retardation

owing to the very heterogeneous nature of these relationships in different populations. For the purpose of this study, a reduction in IQ points was considered to be a disease burden when resulting in mild intellectual impairment, which was defined as having an IQ score of 50-69 points (see Figure 19.4). Intelligence in human populations approximates a normal distribution (Lezak 1995), except for an excess below IQ 50 (representing brain damage and disorder). To estimate the incidence of mild mental retardation resulting from IQ reduction attributable to lead exposure, we first estimated the proportion of children who would have

Table 19.2 Proportion of the population having an IQ score of between 70 and 73.50, assuming a normal distribution ${ }^{2}$

| IQ (points) | \% of the population (assuming <br> a normal IQ distribution) |
| :--- | :---: |
| $70-70.65$ | 0.24 |
| $70-71.95$ | 0.80 |
| $70-73.25$ | 1.45 |
| $70-73.50$ | 1.59 |

a Mean IQ score of 100 , standard deviation of 15 .
Source: Lezak (1995).

IQ scores close to the threshold defined and for whom the loss of a few IQ points would result in a total score of $<70$ points. This included the fractions of the child population with IQ scores of between 70 and 70.65, $71.95,73.25$ and 73.5 points (i.e. the intervals of interest defined by the loss of IQ points as specified above, representing increments of 0.65 , $1.95,3.25$ and 3.5 points), assuming a normal distribution for IQ according to Lezak (mean IQ score of 100, standard deviation of 15; see Table 19.2).

The proportion of mild mental retardation attributable to exposure to lead was estimated as the proportion of children losing a number of IQ points (i.e. ratio of children with blood-lead concentrations within intervals $5-10 \mu \mathrm{~g} / \mathrm{dl}, 10-15 \mu \mathrm{~g} / \mathrm{dl}$ or $15-20 \mu \mathrm{~g} / \mathrm{dl}$; see Table 19.1), multiplied by the fraction of children within the interval $70+x$ IQ points (Table 19.2), for whom a loss of $x$ points results in a final IQ score of $<70$ points (Figure 19.4). This is similar to the method used by INSERM (1999).

This standard IQ distribution does not include additional risk factors for IQ loss, which may be more common than exposure to lead. Several diseases that occur more frequently in developing countries result in cognitive impairment or mental retardation. The detailed estimates of the global burden of disease listed in the World health report 2001 (WHO 2001) provide prevalences of cognitive impairment and mental retardation as a consequence of anaemia, meningitis and pertussis, Japanese encephalitis, ascaris, trichuriasis and infection with hookworm, as well as prevalences of cretinoidism and cretinism caused by iodine deficiency, for the 14 subregions studied here (Murray and Lopez 1996; WHO/EIP, unpublished data, 2001). The literature confirms that there are differences in the prevalence rates of mild mental retardation in developed countries compared to developing countries (Roeleveld et al. 1997), most of these differences being explained by noncongenital causes.

As the normal distributions of IQ scores were established on the basis of data from developed countries, the number of additional cases of mild
mental retardation that are likely to be observed in developing countries because of the additional risks mentioned above had to be estimated. This adjustment was based on the assumption that congenital causes of impaired cognitive function were separable and additive as compared to other risk factors. We thus assumed that the increase in the incidence of mild mental retardation (defined as an IQ score of $50-69$ points) caused by factors other than exposure to lead was proportional to the increase in frequency of the IQ scores of slightly more than 70 points (i.e. between 70 and 73.5 points).

The prevalence of mild mental retardation and cognitive impairment resulting from known, noncongenital causes (see above) was estimated, values from developed and developing countries were compared, and an "adjustment ratio" to account for the increased risk of mental retardation in developing countries was estimated:

$$
A R=\frac{P_{R}-P_{\text {bascline }}+P_{M R} \text { standard }}{P_{M R} \text { sandard }}
$$

AR Adjustment ratio
MR Mild mental retardation
$\mathrm{P}_{\mathrm{R}} \quad$ Region-specific prevalence of MR from known causes from the Global Burden of Disease (GBD) database (WHO/EIP, unpublished data, 2001)
$\mathrm{P}_{\text {bascline }} \quad$ Prevalence of MR from known, noncongenital causes in developed countries
$\begin{array}{ll}\mathrm{P}_{\text {MR standard }} & \begin{array}{l}\text { Prevalence of MR according to the standard distribution of } \\ \text { IQ score }\end{array}\end{array}$
The baseline prevalence of mild mental retardation caused by known, noncongenital factors of 420 per 100000 population (typical in developed countries), and the total rate of mental retardation of 2270 per 100000 population, as taken from the standard distribution, were used. The resulting subregion-specific adjustment ratios are summarized in Table 19.3. We assumed that the same adjustment ratio applied for the

Table 19.3 Adjustment ratios to account for excess prevalence rates of mild mental retardation caused by communicable diseases and iodine deficiency as compared to standardized rates

| Subregion | AFR-D | AFR-E | AMR-A | AMR-B | AMR-D | EMR-B | EMR-D | EUR-A | EUR-B | EUR-C | SEAR-B | SEAR-D | WPR-A | WPR-B |

| Adjustment ratio | 2.05 | 2.01 | 1.00 | 2.71 | 2.64 | 1.90 | 1.90 | 1.00 | 1.53 | 1.19 | 3.25 | 2.06 | 1.00 | 3.03 |

considered ranges of IQ (i.e. 70-73.5) in an attempt to take into account additional risks prevailing in certain developing subregions. It should be noted, however, that protein-energy malnutrition, potentially the most important risk factor for mild mental retardation, could not be taken into account here. The estimated prevalence rates per 1000 people affected by lead-induced mild mental retardation were multiplied by the subregion-specific adjustment ratios given in Table 19.3.

Lower mental ability has been associated with lower life expectancy. For example, a longitudinal cohort study of childhood IQ score and survival (Whalley and Deary 2000) found lower survival probabilities at age 76 for people who had a 15 -point disadvantage in IQ score at age 11 years $(\mathrm{RR}=0.76,95 \%$ CI $0.75-0.84)$. Various mechanisms to explain this association were proposed, including childhood IQ as a record of bodily insult (e.g. antenatal care), as an indicator of "system integrity" (the availability of a cerebral reserve capacity to deal with other risks of cognitive decline), as a predictor of healthy behaviour and of entry into safer environments. All but the first mechanism would be relevant in relating the lead-induced loss of IQ points to additional adverse health effects or to reduced life expectancy, rather than considering mild mental retardation in isolation. Additional evidence, however, is needed to quantify this association.

## Increased blood pressure

Schwartz (1995) conducted a meta-analysis examining the relationship between blood-lead concentration and systolic blood pressure in adult males (see Table 19.4). This analysis showed a significant association, with a reduction in blood-lead concentration from $10 \mu \mathrm{~g} / \mathrm{dl}$ to $5 \mu \mathrm{~g} / \mathrm{dl}$ being correlated with a decrease in blood pressure of $1.25 \mathrm{mmHg}(95 \%$ CI 0.87-1.63). It has been suggested that lead exerts an influence on calcium metabolism, which is linked to modulation of blood pressure through vascular tone. In vitro studies have reported increased blood pressure in isolated tail arteries and increased responsiveness to alphaadrenergic stimulation in response to exposure to lead. Raised blood pressure has been associated with increases in risk of cardiovascular and cerebrovascular disease.

A more recent meta-analysis by Nawrot et al. (2002) of data from 32000 men estimated that a two-fold increase in blood-lead concentration was associated with a 1.2 mmHg increase in systolic blood pressure. While this analysis considered a two-fold increase in blood-lead concentration as the measure of exposure, most of the studies in the metaanalysis fell within the interval of $5-10 \mu \mathrm{~g} / \mathrm{dl}$ considered by Schwartz (1995). The analysis of data from the second National Health and Nutrition Examination Survey (NHANES II) revealed decreases in blood pressure of 2 mmHg associated with a reduction in blood-lead from $20 \mu \mathrm{~g} / \mathrm{dl}$ to $15 \mu \mathrm{~g} / \mathrm{dl}$ and also from $15 \mu \mathrm{~g} / \mathrm{dl}$ to $10 \mu \mathrm{~g} / \mathrm{dl}$ (Pirkle et al. 1998; Schwartz 1988).

Source: Adapted from Schwartz (1995).

As a conservative estimate, we used the same change of 1.25 mmHg in systolic blood pressure for all three intervals in blood-lead concentration. The relationship was assumed to be linear between 5 and $20 \mu \mathrm{~g} / \mathrm{dl}$, with a 1.25 mmHg rise in blood pressure for each incremental increase of $5 \mu \mathrm{~g} / \mathrm{dl}$. As with loss of IQ points, we converted the linear increase into three equal increments, using the midpoints of the increments with the corresponding increase in blood pressure.

In women, the association between systolic blood pressure and bloodlead concentrations is weaker and less well documented. The most recent and comprehensive estimate, using data from 24000 women suggests that an increase of 0.8 mmHg in systolic blood pressure is associated with a doubling in blood-lead concentration (Nawrot et al. 2002). The association was not different from that of men in a statistically significant manner. We used an increase of 0.8 mmHg in systolic blood pressure for each $5 \mu \mathrm{~g} / \mathrm{dl}$ increase in blood-lead concentration for women, for the interval between 5 and $20 \mu \mathrm{~g} / \mathrm{dl}$.

The disease burden caused by exposure to lead and mediated through increased blood pressure was based on the method used in chapter 6.

## ANAEMIA

Absorbed lead inhibits the activity of a number of enzymes involved in haem biosynthesis. Several studies have shown that the activity of ALAD ( $\delta$-aminolevulinic acid dehydratase) is affected at very low blood-lead levels, with no apparent threshold (International Programme on Chemical Safety 1995). Typically, lead-induced anaemia arises from a combination of reduced haemoglobin formation (caused either by impaired haem synthesis or globin chain formation) and reduction in erythrocyte survival because of haemolysis (National Research Council 1993).

Adverse effects start to appear following decreases in concentrations of haemoglobin, which occurs at blood-lead concentrations of approximately $50 \mu \mathrm{~g} / \mathrm{dl}$ in adults and $40 \mu \mathrm{~g} / \mathrm{dl}$ in children, although there is increasing evidence that effects in children may occur at lower concentrations. Schwartz et al. (1990) studied the relationship between various levels of exposure to lead and anaemia in 579 children aged between 1 and 5 years living close to a primary lead smelter. The analysis related blood lead and hematocrit concentrations, and observed an increase in anaemia in children with blood-lead concentrations of $>20 \mu \mathrm{~g} / \mathrm{dl}$. However, ATSDR (1999) defines children with blood-lead concentrations of $\geq 70 \mu \mathrm{~g} / \mathrm{dl}$ and adults with $\geq 80 \mu \mathrm{~g} / \mathrm{dl}$ to be at risk of anaemia, and we chose these thresholds for estimating disease burden. The number of studies looking at more severe health effects and issues of individual variability is relatively limited; however, results suggest that only a proportion of those exposed become ill. In the study conducted by Schwartz et al. (1990), $20 \%$ of children with a blood-lead concentration of $\geq 60 \mu \mathrm{~g} / \mathrm{dl}$ exhibited signs of anaemia. This value was used in the present analysis to estimate the proportion of those exposed who became ill.

## GASTROINTESTINAL EFFECTS

Abdominal pain, constipation, cramps, nausea, vomiting, anorexia and weight loss, collectively known as colic, are early symptoms of lead poisoning in both adults and children. In adults, such symptoms occur at blood-lead concentrations of $>80 \mu \mathrm{~g} / \mathrm{dl}$ (International Programme on Chemical Safety 1995) and typically at concentrations of $100-200 \mu \mathrm{~g} / \mathrm{dl}$, while concentrations of $60-100 \mu \mathrm{~g} / \mathrm{dl}$ are more typical for children (ATSDR 1999). No dose-response relationship for blood-lead and gastrointestinal effects has been published, so the same correction factor $(20 \%)$ as that assumed for anaemia was used.

## OTHER HEALTH EFFECTS

A number of health effects, such as nephropathy and encephalopathy, are associated with higher exposures to lead. These effects were not quantified as they occur in extreme cases for which population-based data from assumed distributions are highly uncertain.

Other health effects associated with lead exposure, such as hearing loss, cognitive deficits and reproductive effects, were not included in this
estimate. Exclusion was based on a number of factors, including difficulty in determining the threshold at which an effect could be expected to occur, inadequate causal evidence, or an outcome that fell outside of those for which the disease burden had been estimated in the GBD project.

## SUMMARY

Table 19.5 summarizes blood-lead concentrations at which the population is considered to be at risk of the health outcomes discussed here and the quantitative relationship between exposure and outcome. The values given in this table do not necessarily indicate the lowest levels at which lead exerts an effect.

## Use of absolute versus relative risk ratios

The majority of studies investigating the relationship between lead exposure and disease have assessed incidence rates of disease for exposed and unexposed individuals in developed countries. These two rates are then generally combined into a relative risk. The exposure-risk relationships could therefore be applied to the populations of developing countries by transferring either the relative risks of disease, or the absolute disease

Table 19.5 Summary of health risks associated with blood-lead concentrations considered in this analysis

|  | Blood-lead concentration <br> threshold $(\mu \mathrm{g} / \mathrm{dl})$ |  |
| :--- | :---: | :---: | :--- |
| Outcome | Children | Adults |$\quad$| Description of relationship |
| :--- |

[^68]rates for those exposed at equivalent levels. A transfer of relative risk rates to a country with higher baseline rates of the considered disease would result in a higher burden of disease for lead-induced illness than if absolute rates were transferred.

In the case of lead-induced outcomes occurring at high concentrations of blood-lead, including gastrointestinal symptoms and anaemia, it may be argued that lead poisoning acts independently of the baseline rates of disease and the presence of other risk factors in the population. We therefore determined incidences for gastrointestinal symptoms and anaemia on the basis of absolute risks rather than of relative risks. However, the risk of anaemia from exposure to lead may be magnified by other risk factors, and therefore a relative risk approach may be envisaged when more solid exposure-risk relationships become available.

With regard to the effects of lead on cognitive functions, data reported in the literature mainly provide mean decreases in IQ points, rather than relative risks for selected decreases. However, exposure to lead may interact with other risk factors, resulting in a magnifying effect, as previously mentioned.

As the exposure distribution relies on a database containing limited information concerning very high concentrations of blood-lead, the estimation of the percentage of the population that experiences extreme levels of exposure becomes very uncertain. Although the number of individuals with lead-induced nephropathy and encephalopathy could, in principle, be estimated, calculating disease burden would be misleading.

### 3.3 Estimation of the number of people affected bY EXPOSURE TO LEAD

To estimate the number of people whose health was affected by exposure to lead, the exposure-risk relationships described in section 3.2 were applied to the fraction of the population having the blood-lead concentrations at which these health effects occur. Figure 19.5 shows schematically how this was applied to the distribution of blood-lead concentrations in a population.

## 4. Sources of uncertainty

We estimated upper and lower uncertainty bounds for the best estimates by selecting upper and lower values for those parameters which were most likely to contribute significantly to uncertainty and which could be quantified.

### 4.1 UnCERTAINTY IN EXPOSURE ASSESSMENT

Standard deviation of blood-Lead concentrations
Fewer data are available for standard deviations of population bloodlead distributions than for mean blood-lead concentrations. We selected

Figure 19.5 Schematic diagram of the distribution of blood-lead concentrations in the population and the number of individuals who are at risk of selected health effects

upper and lower values for the standard deviation by recalculating subregional values after eliminating the upper and lower $20 \%$ of the reported standard deviations. The calculated values varied by approximately $13 \%$.

## TEMPORAL CHANGE IN BLOOD-LEAD CONCENTRATIONS

Population blood-lead concentrations drop rapidly in countries that make substantial efforts to reduce exposure to lead, including the phasing-out of leaded petrol. Although we examined comprehensive sources documenting such efforts, and adjusted blood-lead concentrations to account for changes in exposure since the most recent assessment, uncertainty remained due to differences in the period of time needed to reduce the use of lead and the lack of data on timing of lead reduction programmes for some countries. In addition, lead reduction programmes other than the phasing-out of leaded petrol may have influenced blood-lead concentrations in the population since the year in
which the data were collected. The exposure level may therefore not always exactly correspond to the year 2000, but to a short time span around that year. To account for uncertainty in the timing of lead reduction, mean blood-lead concentrations were varied by $\pm 16 \%$, reflecting a two-year difference in progress in lead reduction programmes, assuming that blood-lead concentrations would change by $39 \%$ over a five-year period. Although not strictly applicable to the subregions in which leaded petrol has already been phased out for some time, we maintained this variation around the mean blood-lead concentration in these subregions to account for other factors that may have contributed to uncertainty.

## EXTRAPOLATION TO DATA-POOR COUNTRIES

Recent exposure information representative of parts of the general population was available for 41 countries. Many countries (or age groups) were, however, not represented. Exposure to lead in these countries was assumed to be similar to that in countries within the same subregion and which shared socioeconomic characteristics and similar implementation of lead reduction programmes.

## MEASUREMENTS OF CONCENTRATIONS OF BLOOD LEAD

Uncertainty in the accuracy of measurement of blood-lead concentrations can be due to a deviation of the measured sample from the study population (i.e. bias), or to contamination problems during sampling or laboratory analysis. Also, the use of blood-lead measurements taken at a single point in time does not capture temporal variation in exposure to lead. Many sources of exposure, however, are likely to occur virtually continuously (e.g. lead in air, in drinking water, in certain foods or through use of leaded ceramics), limiting temporal variation other than that already accounted for.

### 4.2 UnCERTAINTY IN THE EXPOSURE-RISK RELATIONSHIPS

Body burden of lead and associated health effects
Measurements of the concentration of lead in bone, which reflects longterm exposure, may be a better predictor of health effects than concentrations of lead in blood (Cheng et al. 2001; González-Cossío et al. 1997; Hu et al. 1996), but there are relatively few studies on which to base a global estimate. Also, the evidence on exposure-response relationships has not yet been quantified.

## HEALTH EFFECTS THRESHOLDS AND INDIVIDUAL VARIABILITY

Health effects are likely to occur at lower concentrations of blood-lead than have been considered in this study. There may be no threshold for $\mathrm{IQ} /$ cognitive effects, and both renal and cardiac effects have recently been
reported to occur at low concentrations of blood-lead (Cheng et al. 1998; Payton et al. 1994). Health-effect thresholds are linked to individual variability, for which a number of factors are known to be important, including dietary factors (such as calcium; Harlan et al. 1985), general level of health, and genetic differences (e.g. Glen et al. 2001; Kelada et al. 2001; Schwartz et al. 2000a). Current knowledge does not allow the influence of such factors to be assessed precisely.

THE RELATIONSHIP BETWEEN EXPOSURE AND EFFECT FOR BLOOD-LEAD CONCENTRATIONS AND BLOOD PRESSURE

To quantify uncertainty regarding the effects of exposure to lead on blood pressure, the confidence interval around the risks of $30 \%$ reported by the meta-analysis (Schwartz 1995) was used.

## POPULATION-SPECIFIC BACKGROUND MILD MENTAL RETARDATION

A limitation of the approach used to estimate the risk of mild mental retardation attributable to lead exposure was the lack of studies examining the distribution of IQ scores in different populations. Additionally, population distributions have been found to change over time. In our estimate, the same normal distribution was applied worldwide. For estimating the uncertainty in mild mental retardation rates, we varied the mean IQ score ( 98 and 102, instead of 100). The lower bound for mild mental retardation was estimated by assuming that health effects occurred at $>10 \mu \mathrm{~g} / \mathrm{dl}$ instead of at $>5 \mu \mathrm{~g} / \mathrm{dl}$ as used in the best estimate.

### 4.3 Estimation of upper and Lower uncertainty bounds

To derive an upper estimate for the proportion of people affected by lead exposure, the upper estimates for exposure assessment (i.e. upper estimates for standard deviation and mean of blood-lead concentrations) were multiplied by the upper rates in the risk estimates. A similar approach was used to obtain the lower estimates.

## 5. Results

### 5.1 Loss of IQ points and mild mental retardation

The incidence rates of mild mental retardation in children aged <5 years are summarized in Table 19.6. We assumed that loss of IQ and resulting mild mental retardation occurred only once, during the first year of life. Older age groups were assumed to have already experienced this health impact in previous years. Values presented in Table 19.6 are those estimated for the age group $0-1$ year, but are divided by a factor of 5 (as the age group 0-4 years includes five 1-year cohorts of children).

The highest rates of mild mental retardation caused by exposure to lead occurred in developing countries, where the mean blood-lead concentrations were estimated to be many times higher than those in
Table 19.6 Proportion of children aged 0-I year ${ }^{a}$ affected by loss of IQ points caused by exposure to lead, and incidence rates of mild mental retardation caused by exposure to lead in children aged 0-1 ${ }^{\text {a }}$ year, in the year 2000

developed countries. Latin American regions had relatively high incidence rates despite recent efforts to phase out lead.

### 5.2 Increased blood pressure

The proportion of adult men and women affected by increased blood pressure in age groups ranging from 20 to 79 years, are displayed in Table 19.7. To calculate the burden of disease for ischaemic heart disease, cerebrovascular disease, hypertensive disease and other cardiac diseases, these rates were converted into disease-specific relative risks, according to the methods used for the risk factor in chapter 6.

### 5.3 AnAEMIA AND GASTROINTESTINAL SYMPTOMS

Tables 19.8 and 19.9 summarize the proportion of people affected by anaemia and gastrointestinal symptoms, assuming that these people are not removed from the source of lead or treated in order to reduce their blood-lead concentrations.

As anaemia and gastrointestinal effects were not included in the list of diseases for which baseline global data were available, they could not be quantified in terms of the attributable fraction of total disease or DALYs.

## 6. Discussion

This estimate of the global burden of disease caused by exposure to lead suggests that lead had a significant impact on health in the year 2000, mainly in developing countries where lead reduction programmes have not yet been fully implemented or, in some cases, initiated. In many subregions, relatively large fractions of the population had significantly elevated blood-lead concentrations. In particular, blood-lead concentrations in many developing countries in 2000 were comparable to, or even higher than, concentrations reported in the United States and Europe in the 1970s. The main disease end-points considered in this analysis included mild mental retardation caused by cognitive impairment and reduction of IQ, ischaemic heart disease, cerebrovascular disease, hypertensive disease and other cardiac diseases induced by increased blood pressure. Several additional disease outcomes associated with exposure to lead could not be considered in this analysis, either because the evidence was considered insufficient for a quantitative assessment at this point in time, or because baseline global data were not available. We estimated that 120 million people around the world had blood-lead concentrations of between 5 and $10 \mu \mathrm{~g} / \mathrm{dl}$ in the year 2000 , and about the same number had concentrations of $>10 \mu \mathrm{~g} / \mathrm{dl}$. Forty per cent of all children had blood-lead concentrations of $>5 \mu \mathrm{~g} / \mathrm{dl}$ and $20 \%$ had concentrations of $>10 \mu \mathrm{~g} / \mathrm{dl} ; 97 \%$ of these children were living in developing countries. These exposures resulted in a burden of disease of 9.8 million DALYs caused by mild mental retardation and 229000

The basis for lower and upper estimates is outlined in section 4.
premature deaths and 3.1 million DALYs caused by cardiovascular disease. These two health outcomes alone account for about $0.9 \%$ of the global burden of disease. ${ }^{2}$

Assuming that each cohort of children aged $0-1$ year is exposed to the same amount of lead year after year, the resulting prevalence of mild mental retardation attributable to lead exposure would be the following (obtained from Table 19.6):

- approximately $1-1.2 \%$ in AMR-B and AMR-D;
- approximately $0.5-0.8 \%$ for AFR, EMR, SEAR, WPR-B, EUR-B and EUR-C; and
- $<0.1 \%$ in developed countries.

Prevalences of mild mental retardation reported for developed countries are generally about 1-3\% (meta-analysis by Andersen et al. 1990; Baird and Sadovnick 1985; Murphy et al. 1995; Roeleveld et al. 1997; WHO 1985). Although it is commonly acknowledged that prevalence rates are higher in developing countries than in developed countries, data are scarce. Reported ranges vary greatly (0.4-9.5\%, Roeleveld et al. 1997), and the median of available rates gives a prevalence of mild mental retardation of $6.5 \%$ (Durkin et al. 1998; Roeleveld et al. 1997). While the contribution of lead to the total incidence of mild mental retardation in developed countries is small, in developing countries as much as $15-20 \%$ of mild mental retardation could be caused by exposure to lead. A study from Australia (Wellesley et al. 1991) estimated that $40 \%$ of mental retardation was of genetic origin, $20 \%$ was caused by environmental factors and $40 \%$ was of unknown etiology. Also, the metaanalysis by Roeleveld et al. (1997) concluded that the high prevalence of mild mental retardation observed in developing countries points towards a role for partly avoidable exogenous influences.

An alternative approach for considering the effects of IQ loss was offered by the Dutch Burden of Disease study (Stouthard et al. 1997). This study used a severity weighting of 0.06 for any loss of IQ of between 1 and 4 points, whether this resulted in mental retardation or remained within the normal IQ range. Such an approach would magnify the effects of exposure to lead, but was not employed in this analysis, since incremental IQ loss is not considered to be a disease in the strict sense. At the same time, although in most instances a loss of IQ points does not lead to a recognizable health condition, it can affect physical functioning and life achievement (e.g. survival and earning potential). The Dutch approach is also supported by recent studies relating reduced mental ability to survival and to reduced lifetime earning capacity (Grosse et al. 2002; Korten et al. 1999; Whalley and Deary 2000).

The burden of ischaemic heart disease, cerebrovascular disease, hypertensive disease and other cardiac disorders caused by exposure to lead amounts globally to 3.1 million DALYs, which is about $2 \%$ of the total burden of cardiovascular disease. Worldwide, exposure to lead causes 229000 deaths from these diseases. Ischaemic heart disease and cerebrovascular diseases are the two main contributors to the burden of disease in this group. Again, the burden is borne mainly by developing countries, owing to the higher exposures to lead in these areas. Together with mild mental retardation caused by exposure to lead, this brings the estimated total burden of disease in this analysis to $0.9 \%$, in terms of DALYs. With quantification of additional outcomes discussed in this chapter, in particular, increased delinquent behaviour and its impact on injuries, the burden would most probably exceed $1 \%$ of the global total.

Lead did not contribute significantly to the global burden of anaemia, because other causes, such as iron deficiency, accounted for much higher prevalences of anaemia. The burden of gastrointestinal symptoms caused by lead was also relatively small as compared to that provoked by major risk factors such as unclean water, poor sanitation and hygiene, or unsafe food.

To improve the accuracy of these estimates, more populationrepresentative blood-lead surveys from subregions for which little information has been published so far would be required. Also, additional information on the health impact of low lead levels would be needed in order to make estimates of the burden of disease caused by low doses of lead. The lack of quantitative information on health effects occurring at low exposure levels, the exclusion of data concerning exposure occurring around hot spots or at the workplace, combined with a number of conservative choices made throughout this study, all contribute to a probable underestimation of the burden of disease caused by lead. One particular health effect that could not be quantified but which has been associated in children with low levels of exposure to lead, and which may cause a significant disease burden, although indirectly, is violence.

Intentional injuries represent an important part of the burden of disease, a proportion of which may be attributable to low blood-lead concentrations encountered at high prevalences in many parts of the world.

In addition to the burden of disease, lead exposure may also contribute to socioeconomic burdens. Glotzer et al. (1995) estimated, for example, that in the United States, 45000 cases of reading disability could be prevented by lead reduction programmes, saving more than US $\$ 900$ million per year in overall costs of remedial education. This also has implications for inequalities in health, as exposure to lead tends to be higher in the lower socioeconomic groups of the population (Needleman 1994). These people often live in areas which are more exposed to industrial pollution or in degraded housing. Grosse et al. (2002) estimated that each IQ point raises worker productivity by $1.76-2.38 \%$, resulting in an economic benefit of US $\$ 110-319$ billion for each year's cohort of children.

All of the lead-induced disease burden is, in principle, preventable by phasing out the use of leaded petrol, reducing industrial emissions, removing lead from products such as ceramics, paint, "folk remedies" (traditional medicines) and food and drink cans, and replacing leaded pipes used for drinking-water. The phasing-out of leaded petrol is a particularly effective intervention, having the advantage of being a single action which permanently removes or reduces a health risk to current and future generations.

Although lead is one of the best-studied environmental pollutants, its full impact on population health is only now coming to light. The impacts of many other potentially harmful substances, such as heavy metals, pesticides or solvents, some of which are steadily accumulating in the environment, are as yet largely unknown.

## 7. Projections

Although exposure to lead can occur via a number of routes and from a range of sources, the level of lead in petrol is a key predictor of bloodlead concentrations at a country level. It has been shown that decreases in the use of leaded petrol are closely followed by parallel decreases in blood-lead concentrations (Annest 1983; Annest et al. 1983; Elinder et al. 1986; Schuhmacher et al. 1996; Thomas et al. 1999; Wietlisbach et al. 1995). We based the projected exposure estimates on predicted changes in transportation energy use by subregion (EIA 2001) and estimated completion dates of leaded petrol phase-out programmes (Walsh 2001). For countries that had not embarked upon lead reduction programmes, it was assumed that urban blood-lead concentrations would rise as a consequence of increases in transportation energy use, shown in Table 19.10. Where a lead reduction programme had been initiated, it was assumed that policy would not change and that the programme would be seen through to completion.

Source: Adapted from EIA (2001).

The starting point for the projection was the estimated mean bloodlead concentration for each subregion in the year 2000. In cases where a national lead reduction programme was due to be completed prior to 2010, urban blood-lead concentrations were assumed to converge at $3.1 \mu \mathrm{~g} / \mathrm{dl}$, according to the calculations of Thomas et al. (1999). The exceptions to this assumption were AMR-B and AMR-D. As countries in these subregions possess other important sources of lead, such as leadglazed pottery, blood-lead concentrations were assumed to drop to $4.3 \mu \mathrm{~g} / \mathrm{dl}$, based on the mean of the most recently reported urban bloodlead concentrations in Latin American countries that have phased out leaded petrol (Garcia and Mercer 2001; Sepulveda et al. 2000). Energy use projections were available only until the year 2020; however, in the absence of other data, trends in 2000-2020 were assumed to continue until 2030. As urbanization is expected to increase steadily in most subregions (UN 1997), we also included a predicted change in urbanization in our projections of changes in blood-lead concentrations.

The effect of changes in energy use on blood-lead levels was calculated using the approach employed to adjust for the phasing-out of lead. Thus, as a $50 \%$ change in lead use (generally equivalent to the completion of a five-year leaded petrol reduction programme) is equal to a $39 \%$ change in blood-lead concentrations (see section 2.3 ), a $1 \%$ change in emissions would result in a $0.78 \%$ change in blood-lead concentrations. It was assumed that mean blood-lead concentrations would not increase beyond $30 \mu \mathrm{~g} / \mathrm{dl}$, as means exceeding this have rarely been reported.

Standard deviations were assumed to remain the same as in the year 2000. Projected blood-lead concentrations are presented in Table 19.11 for children and in Table 19.12 for adults. In subregions where many countries have not yet started to phase out lead (i.e. AFR, EMR, and EUR-B and C), it was estimated that blood-lead concentrations would increase steadily owing to the current widespread use of leaded petrol and lack of actions to reduce lead emissions. In most other subregions, lead emissions were predicted to decline gradually, with subsequent reductions in lead in the environment and in food. A large drop in bloodlead concentrations was projected to occur in many subregions between 2000 and 2010, as existing lead reduction programmes begin to take effect. After this period, rises in blood-lead concentrations would be observed due to continuing increases in the number of persons with elevated blood-lead concentrations living in countries and subregions which have not phased out lead.

Table 19.13 shows the projected incidence of mild mental retardation caused by exposure to lead for the years 2010, 2020 and 2030, using the methods described above and assuming constant prevalences of other diseases with cognitive impairment sequelae. As the proportion of people with elevated blood-lead concentrations will decrease in subregions where lead reduction programmes have recently been initiated (see Table 19.12), the incidence of mild mental retardation caused by exposure to lead is predicted to decline. Where no efforts to reduce exposure to lead are made, urbanization and increases in vehicle emissions are predicted to cause an increased incidence in lead-induced mild mental retardation. In the worst cases, in the African and Eastern Mediterranean subregions, exposure to lead could cause nearly $1.5 \%$ of cases of mild mental retardation.

The estimates for the incidence of anaemia and gastrointestinal symptoms caused by exposure to lead probably already carry the highest uncertainties, owing to the fact that these conditions appear at higher blood-lead concentrations, at which the distribution model is less accurate. Therefore projections for these outcomes have not been presented. In addition to the sources of uncertainty inherent in data collection and in the analysis for 2000, a number of additional uncertainties have been introduced into the projections we have made for future exposures, which are dominated by assumptions about policy and technology changes for lead reduction. Although it may well seem unacceptable that leaded petrol could still be in use in 10, 20 or 30 years' time, it must be remembered that lead has not been removed from the petrol supply of any country except by vigorous and concerted efforts by institutions concerned for the health of the public and especially of children.

For certain countries or subregions with significant additional sources of exposure to lead, the projections made here may be too optimistic. In general, however, we expect that appropriate lead-reduction measures will have been taken at a global level towards the end of the next decade.

| a GBD results reported for the 0-4 year age group. |  |  |  |  |  |  |  |  |  |  |  |  |  |  |

In countries where mean population blood-lead concentrations are currently low, it is expected that health effects caused by lead will no longer be a concern for most people. However, exposure to lead is likely to remain a hazard for a minority of people, in particular, the children of the socially disadvantaged, including those living in houses containing leaded paint, or lead piping, or in areas affected by industrial contamination containing lead. Control of these sources will require continuing efforts.

## Note

1 See preface for an explanation of this term.
2 Editorial note: The GBD mortality database includes a small number of deaths (approximately 5000) due to lead-induced mild mental retardation (MMR). These deaths are in fact deaths where MMR, regardless of being caused by lead or otherwise, has been specified as the underlying cause of death in the death registration data from some developed countries. The GBD has not attempted to make consistent estimates of MMR deaths for other regions, or to attribute some of these to lead. Because of the current GBD cause-of-death classification, these deaths are included in the Annex Tables (see the CD-ROM accompanying this book) and summary results in chapters 26 and 27. These deaths are however excluded from the results reported and discussed in this chapter.

## Chapter 20

# Global Climate change 

Anthony J. McMichael, Diarmid Campbell-Lendrum, Sari Kovats, Sally Edwards, Paul Wilkinson, Theresa Wilson, Robert Nicholls, Simon Hales, Frank Tanser, David Le Sueur, Michael Schlesinger and<br>Natasha Andronova

## Summary

Accumulating evidence suggests that the global climate (i.e. conditions measured over 30 years or longer) is now changing as a result of human activities-most importantly, those which cause the release of greenhouse gases from fossil fuels. The most recent report (2001) from the United Nations' Intergovernmental Panel on Climate Change (IPCC) estimates that the global average land and sea surface temperature has increased by $0.6 \pm 0.2^{\circ} \mathrm{C}$ since the mid-19th century, with most change occurring since 1976. Patterns of precipitation have also changed: arid and semiarid regions are becoming drier, while other areas, especially mid-to-high latitudes, are becoming wetter. Where precipitation has increased, there has been a disproportionate increase in the frequency of the heaviest precipitation events. Based on a range of alternative development scenarios and model parameterizations, the IPCC concluded that if no specific actions were taken to reduce greenhouse gas emissions, global temperatures would be likely to rise between 1.4 and $5.8^{\circ} \mathrm{C}$ from 1990 to 2100 . Predictions for precipitation and wind speed were less consistent, but also suggested significant changes.

Risks to human health from climate change would arise through a variety of mechanisms. In this chapter, we have used existing or new models that describe observed relationships between climate variations, either over short time periods or between locations, and a series of health outcomes. These climate-health relationships were linked to alternative projections of climate change, related to unmitigated future emissions of greenhouse gases, and two alternative scenarios for greenhouse gas emissions. Average climate conditions during the period 1961-1990 were used as a baseline, as anthropogenic effects on climate are considered more significant after this period. The resulting models give estimates of the likely future effects of climate change on exposures to thermal extremes and weather disasters (deaths and injuries associated with
floods), the distribution and incidence of malaria, the incidence of diarrhoea, and malnutrition (via effects on yields of agricultural crops). As there is considerable debate over the extent to which such short-term relationships will hold true under the longer-term processes of climate change, we made adjustments for possible changes in vulnerability, either through biological or socioeconomic adaptation. Estimates of future effects were interpolated back to give an approximate measure of the effects of the climate change that have occurred since 1990 on the burden of disease in 2000.

The effects considered here represent only a subset of the ways in which climate change may affect health. Other potential consequences include influences of changing temperature and precipitation on other infectious diseases (including the possible emergence of new pathogens), the distribution and abundance of agricultural pests and pathogens, destruction of public health infrastructure, and the production of photochemical air pollutants, spores and pollens. Rising sea levels may cause salination of coastal lands and freshwater supplies, resulting in population displacements. Changes in the availability and distribution of natural resources, especially water, may increase risk of drought, famine and conflict.

Our analyses suggested that climate change will bring some health benefits, such as lower cold-related mortality and greater crop yields in temperate zones, but these will be greatly outweighed by increased rates of other diseases, particularly infectious diseases and malnutrition in developing regions. We estimated a small proportional decrease in cardiovascular and respiratory disease mortality attributable to climate extremes in tropical regions, and a slightly larger benefit in temperate regions, caused by warmer winter temperatures. As there is evidence that some temperature-attributable mortality represents small displacements of deaths that would occur soon in any case, no assessment was made of the associated increase or decrease in disease burden. Climate change was estimated to increase the relative risk of diarrhoea in regions made up mainly of developing countries to approximately 1.01-1.02 in 2000, and 1.08-1.09 in 2030. Richer countries (gross domestic product [GDP] >US $\$ 6000 /$ year), either now or in the future, were assumed to suffer little or no additional risk of diarrhoea. This modest change in relative risk relates to a major cause of ill-health, so that the estimated associated disease burden in 2000 is relatively large ( 47000 deaths and 1.5 million disability-adjusted life years [DALYs]). Effects on malnutrition varied markedly even across developing subregions, ${ }^{1}$ from large increases in SEAR-D ( $\mathrm{RR}=1.05$ in 2000, and 1.17 in 2030) to no change or an eventual small decrease in WPR-B. Again, these are small relative changes to a large disease burden, giving an estimated 77000 deaths and 2.8 million DALYs in 2000. We calculated much larger proportional changes in the numbers of people killed in coastal floods (RR in EUR-B of up to 1.8 in 2000, and 6.3 in 2030), and inland floods (RR in AMR-

A of up to 3.0 in 2000, and 8.0 in 2030). Although the proportional change is much larger than for other health outcomes, the baseline disease burden is much lower. The aggregate health effect in 2000 is therefore comparatively small (2000 deaths and 193000 DALYs). We estimated relatively large changes in the relative risk of falciparum malaria in countries at the edge of the current distribution. However, most of the estimated attributable disease burden (27000 deaths and 1 million DALYs) is associated with small proportional changes in regions that are already highly endemic, principally in Africa.

Overall, the effects of global climate change are predicted to be heavily concentrated in poorer populations at low latitudes, where the most important climate-sensitive health outcomes (malnutrition, diarrhoea and malaria) are already common, and where vulnerability to climate effects is greatest. These diseases mainly affect younger age groups, so that the total burden of disease due to climate change appears to be borne mainly by children in developing countries.

Considerable uncertainties surround these estimates. These stem partly from the complexity of climate models, partly from gaps in reliable data on which to base climate-health relationships, and, most importantly, from uncertainties around the degree to which current climate-health relationships will be modified by biological and socioeconomic adaptation in the future. These uncertainties could be reduced in subsequent studies by (i) applying projections from several climate models; (ii) relating climate and disease data from a wider range of climatic and socioeconomic environments; (iii) more careful validation against patterns in the present or recent past; and (iv) more detailed longitudinal studies of the interaction of climatic and non-climatic influences on health.

## 1. Introduction

### 1.1 Evidence for climate change in the recent past and PREDICTIONS FOR THE FUTURE

Humans are accustomed to climatic conditions that vary on daily, seasonal and inter-annual time-scales. Accumulating evidence suggests that in addition to this natural climate variability, average climatic conditions measured over extended time periods (conventionally 30 years or longer) are also changing, over and above the natural variation observed on decadal or century time-scales. The causes of this climate change are increasingly well understood. Climatologists have compared climate model simulations of the effects of greenhouse gas (GHG) emissions against observed climate variations in the past, and evaluated possible natural influences such as solar and volcanic activity. They concluded that ". . . there is new and stronger evidence that most of the warming observed over the last 50 years is likely to be attributable to human activities" (IPCC 2001b).

The Third Assessment Report of the IPCC (IPCC 2001b) estimates that globally the average land and sea surface temperature has increased by $0.6 \pm 0.2^{\circ} \mathrm{C}$ since the mid-19th century, with much of the change occurring since 1976 (Figure 20.1). Warming has been observed in all continents, with the greatest temperature changes occurring at middle and high latitudes in the Northern Hemisphere. Patterns of precipitation have also changed: arid and semi-arid regions are apparently becoming drier, while other areas, especially mid-to-high latitudes, are becoming wetter. Where precipitation has increased, there has also been a disproportionate increase in the frequency of the heaviest precipitation events (Karl and Knight 1998; Mason et al. 1999). The small amount of climatic change that has occurred so far has already had demonstrable effects on a wide variety of natural ecosystems (Walther et al. 2002).

Climate model simulations have been used to estimate the effects of past, present and likely future GHG emissions on climate changes. These models are primarily based on data on the heat-retaining properties of gases released into the atmosphere from natural and anthropogenic (man-made) sources, as well as the measured climatic effects of other natural phenomena, as described above. The models used by the IPCC have been validated by "back-casting"-that is, testing their ability to explain climate variations that already occurred in the past. In general, the models are able to give good approximations of past patterns only

Figure 20.1 Observed global average land and sea surface temperatures from 1860 to 2000

[^69]when anthropogenic emissions of non-GHG air pollutants (particulates, dust, oxides of sulfur, etc.) are included along with natural phenomena (IPCC 2001b). This emphasizes that (i) the models represent a good approximation of the climate system; (ii) natural variations are important contributors to climatic variations, but cannot adequately explain past trends on their own; and (iii) anthropogenic GHG emissions are an important contributor to climate patterns, and are likely to remain so in the future.

Considering a range of alternative economic development scenarios and model parameterizations, the IPCC concluded that if no specific actions were taken to reduce GHG emissions, global temperatures would rise between 1.4 and $5.8^{\circ} \mathrm{C}$ from 1990 to 2100 . The projections for precipitation and wind speed are less consistent in terms of magnitude and geographical distribution, but also suggest significant changes in both mean conditions and in the frequency and intensity of extreme events (Table 20.1).

### 1.2 Estimating the effects of climate change on health

Human health is sensitive to temporal and geographical variations in weather (short-term fluctuations in meteorological conditions) and climate (longer-term averages of weather conditions). Weather has not historically been considered as subject to alteration by human actions, although its effects may be lessened by adaptation measures (e.g. Kovats et al. 2000b). While adaptation is also a very important determinant of the health consequences of climate change, the effect of anthropogenic GHG emissions on climate means that climate change can in principle be considered a risk factor that could potentially be altered by human intervention, with associated effects on the burden of disease.

The effects of GHG emissions on human health differ somewhat from the effects of other risk factors in that they are mediated by a diversity of causal pathways (e.g. Figure 20.2; McMichael et al. 1996; Patz et al. 2000; Reiter 2000) and eventual outcomes, typically long delays between cause and effect, and great difficulties in eliminating or substantially reducing the risk factors. An additional challenge is that climate change occurs against a background of substantial natural climate variability, and its health effects are confounded by simultaneous changes in many other influences on population health (Kovats et al. 2001; Reiter 2001; Woodward et al. 1998). Empirical observation of the health consequences of long-term climate change, followed by formulation, testing and then modification of hypotheses would therefore require long timeseries (probably several decades) of careful monitoring. While this process may accord with the canons of empirical science, it would not provide the timely information needed to inform current policy decisions on GHG emission abatement, so as to offset possible health consequences in the future. Nor would it allow early implementation of policies for adaptation to climate changes, which are inevitable owing

Table 20.1 Estimates of confidence in observed and projected changes in extreme weather and climate events

|  | Confidence in observed <br> changes (latter half of 1900s) | Confidence in projected <br> changes (during <br> the 2 Ist century) |
| :--- | :--- | :--- |
| Changes in phenomenon | Likely ${ }^{\text {a }}$ | Very likely ${ }^{\text {a }}$ |

| a | Judgement estimates for confidence: virtually certain (greater than $99 \%$ chance that the result is true); very likely (90-99\% chance); likely (66-90\% chance); medium likelihood ( $33-66 \%$ chance); unlikely (IO-33\% chance); very unlikely (I-I0\% chance); exceptionally unlikely (less than I\% chance). |
| :---: | :---: |
| b | Past and future changes in tropical cyclone location and frequency are uncertain. |

to both natural variations and past GHG emissions. Therefore, the best estimation of the future health effects of climate change will necessarily come from modelling based on current understanding of the effects of climate (not weather) variation on health from observations made in the present and recent past, acknowledging the influence of a large range of mediating factors.

Since the early 1990s, IPCC Working Group II has collated some of the accumulating predictions of climate effects on health (IPCC 2001a). The health effects of climate variability and change have also been reviewed by a national committee in the United States of America

Figure 20.2 Pathways through which climate change may affect health

Source: Adapted from Patz et al. (2000).
(National Research Council 2001a) and, more recently, in a book by the World Health Organization (WHO) (McMichael et al. 2003). As yet, however, there has been no concerted attempt to integrate these various research findings into a single standardized estimate of the likely net health effects of climate change, nor to estimate the possible health gains associated with different mitigation and amelioration strategies. In addition to the uncertainties of future climate projections, there are several obstacles to achieving this aim.

- Not all of the probable health outcomes have been modelled, often due to lack of parameterization data and the complexity of causal pathways. Modelling efforts so far have tended to concentrate on those causal relationships that can more easily be modelled, rather than those with the potentially greatest effects (e.g. extreme temperatures on cardiovascular disease mortality, rather than sea-level rise on the health of displaced populations).
- Little emphasis has been given to the validation of models relating climate change to health. Validation would provide a basis for making uncertainty estimates around projections, and would afford an objective criterion for choosing between different models or modelling approaches.
- Adaptations to climate change (i.e. autonomous or planned responses that reduce the vulnerability of populations to the consequences of climate change) are often not addressed.
- Interactions between the effects of climate change and other changes to human populations (e.g. investment in health infrastructure, level and equity of distribution of wealth) are seldom explicitly estimated.
- The various disease-specific models invariably generate outputs in different units, which may be only indirectly related to disease burden (e.g. populations at risk of disease transmission, rather than disease incidence). This hampers estimation of the aggregated health impacts of different scenarios.
- Little effort has previously been directed to describing and understanding the geographical variations in likely impacts.

The first four obstacles are likely to be at least partially addressed in the future, as disease-specific models become more sophisticated and, perhaps more importantly, through the accumulation of greater quantities of reliable data for model parameterization and testing. In this chapter, we have estimated the relative risk of a series of health outcomes under a range of scenarios of climate change, variously mitigated by reducing GHG emissions. In all cases, care was taken to describe explicitly the scientific basis for our estimation, the assumptions that were built into the quantitative models, and to give realistic uncertainty estimates around projections. Later sections describe ways in which specific disease models may be improved.

## 2. Risk factor definition and measurement

### 2.1 Definitions of risk factor and exposure scenarios

The risk factor was defined as current and future changes in global climate attributable to increasing atmospheric concentrations of greenhouse gases (GHGs).

Composite climate scenarios are adopted instead of the (more preferable) continuous measurements of individual climate variables because (i) climate is a multivariate phenomenon, including temperature, precipitation, wind speed, etc., and therefore cannot be measured on a single scale; (ii) climate changes will vary significantly with geography and time: these are not fully captured in global averages of climate variables; and (iii) all aspects of climate are likely to be altered by GHG levels in the atmosphere.

The exposure categories considered here are global climate scenarios resulting at specified points in time over the coming half-century from:

1. unmitigated emissions trends, that is, approximately following the IPCC IS92a scenario;
2. emissions reduction, resulting in stabilization at 750 ppm CO 2 equivalent by the year 2210 (s750);
3. more severe emissions reduction, resulting in stabilization at 550 ppm $\mathrm{CO}_{2}$ equivalent by the year 2170 (s550);
4. average climate conditions for 1961-1990, the World Meteorological Organization (WMO) climate normal (baseline).

Although future GHG emissions are inherently uncertain, the unmitigated emissions scenario adopted here was, until recently, the IPCC mid-range projection, and was very widely used in climate impact modelling. The stabilization categories used here represent plausible, though economically and technically challenging, projections that are dependent on there being major efforts to curtail emissions. Estimated changes in $\mathrm{CO}_{2}$ concentrations, and associated changes in global temperature and sea level, are shown in Table 20.2 and Figure 20.3. Although alternative emissions scenarios for climate stabilization are available, they have not been applied to a wide range of impact models.

We do not attempt to estimate all health outcomes of specific policy/development pathways through which these, or other, GHG levels could be achieved: for example, compliance with the Kyoto Protocol of the United Nations Framework Convention on Climate Change (UNFCCC), or of the world following one or other of the IPCC Special Report on Emissions Scenarios (SRES)—both of which also include descriptions of alternative future global socioeconomic development scenarios. The costs or additional benefits of specific interventions to

Table 20.2 Successive measured and modelled $\mathrm{CO}_{2}$ concentrations, global mean temperature and sea-level rise associated with alternative emissions scenarios

Figure 20.3 The global average temperature rise predicted from the unmitigated emissions scenario (upper trace), and emission scenario which stabilizes $\mathrm{CO}_{2}$ concentrations at 750 ppm (middle trace) and at 550 ppm (lower trace)

Note: All values are relative to mean values for the period 1961-1990, and may therefore be either positive or negative.
Source: Hadley Centre (1999).
achieve this reduction are artificially separated from the resulting health benefits. For such a distal risk factor, this separation of intervention from exposure and resulting health consequences may potentially introduce inconsistencies: for example, the economic changes necessary to achieve GHG stabilization are more consistent with some projections of levels and distribution of population and GDP than others. These socioeconomic factors are themselves likely to effect disease rates, potentially in interaction with climate. Integrated assessment of all effects of interventions would be conceptually more consistent, but this has not been attempted here, since it would introduce an additional layer of uncertainty and assumptions into the models and has previously only been explored for a few health outcomes (Tol and Dowlatabadi 2001).

The choice of baseline or "theoretical minimum" exposure follows the WMO and IPCC practice of using the observed global climate normal (i.e. averages) for 1961-1990 (New et al. 1999) as a reference point. Alternative baselines, such as pre-industrial climate, are not used,
because of the absence of a published consensus among climatologists on definitions of an appropriate time period and the relative roles of anthropogenic and natural influences before 1961-1990. This choice of a 1961-1990 baseline will therefore generate relatively conservative estimates of change in exposure and associated disease outcomes, as it does not address any human-induced climate change that occurred before this period. Indeed, as explained in section 2.6 below, the further choice of 1990 as the actual baseline year for linear-regression based estimates at current and future years heightens the conservative nature of these estimates.

The approach here treats climate change as a slowly evolving and continuous exposure, with the majority of disease models linked to those changes for which climate models make the most consistent predictions: gradual changes in temperature and, to a lesser extent, precipitation. This is again a limited approach. As shown in Table 20.1, it is very likely that climate change will also increase the frequency of extreme conditions, with likely effects on health. However, quantitative estimates of increased frequency have only very recently become available for some measures of extremes (e.g. wet winters; Palmer and Ralsanen 2002), and are not yet available for different GHG scenarios. The consequences of such changes are modelled here only in the context of inland flooding, but they could potentially be applied to other health end-points in the future.

Finally, there is some concern that disruption of the climate system may pass critical thresholds, resulting in abrupt rather than gradual changes (Broecker 1997; National Research Council 2001a) and associated rapid impacts on health. There is no consensus on the probability of such events, and they have therefore not been included in any published health outcome assessment studies. However, they should be borne in mind as a "worst-case" scenario.

### 2.2 Methods for estimating risk factor levels

Projections of the extent and geographical distribution of climate change were generated by applying the various emissions scenarios described above to the HadCM2 global climate model (GCM) of the Hadley Centre in the United Kingdom of Great Britain and Northern Ireland (Tett et al. 1997). This is one of several alternative GCMs used by the IPCC; it generates projections of changes in temperature and other climate properties which have been verified by back-casting (Johns et al. 2001), and which lie approximately in the middle of the range generated by alternative models.

The HadCM2 model generates estimates of the principal characteristics of climate, including temperature, precipitation and absolute humidity, for each cell of a global grid at resolution $3.75^{\circ}$ longitude by $2.5^{\circ}$ latitude. As for most climate change models, HadCM2 generates daily projections representing both long-term trends and the degree of natural
climate variability, but not necessarily its specific temporal pattern (i.e. the models do not accurately predict the climate of specific days or months). In order to account for such natural variability, the outputs that are most commonly used for modelling consequences of climate change are monthly means for average 30 -year periods centred on the 2020 s, $2050 \mathrm{~s}, 2080 \mathrm{~s}$, etc. The baseline climate (1961-1990) describes the same properties for the land surface of the world at $0.5^{\circ} \times 0.5^{\circ}$ resolution.

The climate model projections describe forecast changes in global climate conditions. Therefore, we did not attempt to estimate the "exposure prevalence": the entire world population was assumed to be exposed to one or other global climate scenario (i.e. exposure prevalence $=100 \%$ ). However, it should be noted that the climate scenarios incorporate geographical variation in both current climate (e.g. the lower temperatures in higher latitudes) and projected climate change (e.g. more rapid and intense warming is predicted in high northern latitudes than elsewhere). Different populations will therefore experience different climate conditions under any one climate-change scenario.

### 2.3 UnCERTAINTIES IN RISK FACTOR LEVELS

Two major sources of uncertainty surround the forecasting of future climate scenarios: (i) uncertainty in changes in factors such as population, economic growth, energy policies and practices on GHG emissions; and (ii) uncertainties over the accuracy of any climate model in predicting the effects of specified emissions scenarios on future climate in specific locations, against the background of substantial natural climate variability over time, and in space (i.e. downscaling). Climatologists have only very recently provided probabilistic measurements of uncertainty incorporating one or both of these sources (Knutti et al. 2002; Stott and Kettleborough 2002), and there is still debate over the reliability and utility of such measures (Schneider 2002). They have not previously been applied in impact studies (Katz 2002), and were therefore not used in this assessment. More importantly, however, there remains considerable uncertainty over the accuracy with which any single model can predict future climate. This is usually addressed by using outputs from a range of models, from independent groups. This was not possible here, as the particular GHG stabilization scenarios have only been applied, and fed through to estimates of likely consequences, for the HadCM2 model.

For this analysis, we did not address the first and last sources of uncertainty explicitly, and assumed that it is incorporated in the various alternative exposure scenarios, reflecting different trajectories of GHG emissions. The second source of uncertainty was partially addressed by using 30-year averages of climate conditions, which helps to "smooth out" the effects of natural climate variability. Further, the single model used was run with slight variations in initial conditions, allowing the calculation of an "ensemble mean". Four runs were used to generate an ensemble mean for the unmitigated emissions scenario. However, only
single climate runs were available for the stabilization scenarios. Therefore, the climate scenarios associated with those emissions scenarios are more uncertain.

Although it was not feasible to generate formal uncertainty ranges and feed these through the disease models, the approximate degree of uncertainty is illustrated in Appendix A. Here, the stabilization scenarios were run on a suite of 14 simple climate models, making different plausible assumptions about climate sensitivity to GHG emissions using the simplified COSMIC climate model described by Schlesinger and Williams (1997). This illustrates the degree of variation between the projections for future temperature and precipitation patterns. (Note that projections for precipitation vary more between models than does temperaturetherefore models that rely on precipitation estimates from single scenarios have an additional component of uncertainty.)

## 3. Risk factor-disease relationship

### 3.1 Outcomes included

The health outcomes addressed here were selected on the basis of observed sensitivity to temporal and geographical climate variation, importance in terms of mortality and/or burden of disease (Longstreth 1999; McMichael et al. 1996; Patz et al. 2000) and availability of quantitative global models (or feasibility of constructing informative models in the time available) (Table 20.3). More detail on evidence for causality and quantitative estimation methods for each health outcome is given below.

Climate change is by and large a relatively distal risk factor for illhealth, often acting through complex causal pathways which result in heterogeneous effects across populations. There is, therefore, a series of additional likely outcomes that have not yet been formally modelled. They include the potential health consequences of climate change on:

Table 20.3 Health outcomes considered in this analysis

| Outcome class | Incidence/ <br> prevalence | Outcome |
| :--- | :--- | :--- |
| Direct effects of heat and cold | Incidence | Cardiovascular disease deaths |
| Foodborne and waterborne diseases | Incidence | Diarrhoea episodes |
| Vector-borne diseases | Incidence | Malaria cases |
| Natural disasters ${ }^{\text {a }}$ | Incidence <br> Incidence | Deaths due to unintentional injuries <br> Other unintentional injuries (non-fatal) <br> Risk of malnutrition |
| Prevalence | Non-availability of recommended daily <br> calorie intake |  |

[^70]- changes in pollution and aeroallergen levels;
- the rate of recovery of the ozone hole, affecting exposure to ultraviolet radiation (Shindell et al. 1998);
- changes in the distribution and transmission of other infectious diseases, particularly other vector-borne diseases, geohelminths and rodent-borne diseases, and possible emergence of new pathogens;
- the distribution and abundance of plant and livestock pests and diseases, affecting agricultural production (Baker et al. 2000; Rosenzweig et al. 2001);
- the probability of crop failure through prolonged dry weather and famine, depending on location and crisis management;
- population displacement due to natural disasters, crop failure, water shortages; and
- destruction of health infrastructure in natural disasters.

### 3.2 Methods for estimating risk factor-disease RELATIONSHIPS

Various methods have been developed for the quantitative estimation of health outcomes of climatic change (reviewed by Martens and McMichael 2002; McMichael and Kovats 2000). It is not yet feasible to base future projections on observed long-term climate trends, for three reasons: (i) the lack of standardized long-term monitoring of climatesensitive diseases in many regions; (ii) methodological difficulties in measuring and controlling for non-climatic influences on long-term health trends; and (iii) the small (but significant) climate changes that have occurred so far are an inadequate proxy for the larger changes that are forecast for coming decades (Campbell-Lendrum et al. 2002).

Instead, estimates are based on observations of the effects of shorterterm climate variation in the recent past (e.g. the effects of daily or interannual climate variability on specific health outcomes) or the present (e.g. climate as a determinant of current disease distribution), or on specific processes that may influence health states (e.g. parasite and vector population dynamics in the laboratory, determining the transmission of infectious diseases). These quantitative relationships were then applied to future climate scenarios (Figure 20.3). Such an approach makes the important assumption that such associations will be maintained in the future, despite changes in mediating factors such as socioeconomic variables, infrastructure and technology. This introduces significant uncertainty, and possibly bias, in the estimates.

The extent and type of modelling applied to different health effects vary considerably. Consequently, several outcomes can only be estimated by crude adaptation of the outputs of available models. For example, some of the predictive models generate health-relevant outputs that do
not correspond directly to categories of disease states used in the Global Burden of Disease (GBD) study. These include the incidence of deaths and injuries due to, specifically, floods (rather than injuries due to all causes), or populations at risk of hunger or malaria infection (rather than prevalence of malnutrition, or incidence of clinical malaria). Currently, there are spatial resolution differences between models, which is not ideal. These relate to how the models account for geographical variation in: (i) baseline climate (potentially differentiated to $0.5^{\circ}$ globally, or higher resolutions for some regions); (ii) climate change (usually at the level of the GCM projections: $3.75^{\circ}$ longitude by $2.5^{\circ}$ latitude); and (iii) aggregation of the final results (occasionally according to regions other than subregions, depending on the purpose of the original model). Levels of spatial resolution for each disease model are described in section 3.6 and onwards. All of the above considerations are represented in the descriptions of strength of evidence and quantitative estimates of uncertainty for specific health outcomes.

## Assumptions

Simplifying assumptions have been made to facilitate clear definition of scenarios and associated consequences.

## Different mechanisms for reducing GHG emissions

The alternative GHG emissions scenarios outlined above could be achieved through an almost infinite variety of changes to economic and social development and energy use policies. As outlined in section 2.1, we did not attempt to estimate the secondary effects of GHG mitigation policies on health. These effects are potentially large. They include relatively direct mechanisms which may be negative, such as the potential negative effects of GHG emissions policies on economic development, personal wealth and vulnerability to disease ( Tol and Dowlatabadi 2001), or positive, such as reduction in the levels of ozone and other outdoor (Kunzli et al. 2000) and indoor air pollutants (Wang and Smith 1999). They may also act through more complex routes, for example, avoiding production of aeroallergens in $\mathrm{CO}_{2}$-enriched environments (Wayne et al. 2002; Ziska and Caulfield 2000).

## Population growth

The models described below estimated the relative per capita incidence of specific health outcomes under the different climate scenarios. The size and distribution of current and future populations therefore affect the relative risk estimates either (i) where the climate hazard is not evenly distributed geographically throughout the region, or (ii) where population is an integral part of the model-for example, in the risk-of-hunger model, where population size has an influence on food availability per capita. In adjusting the relative risks for these population effects, the distribution of future populations was estimated by applying the World

Bank mid-range estimate of population growth either at the national level (for malnutrition), or to a $1^{\circ} \times 1^{\circ}$ resolution grid map of population distribution (Bos et al. 1994) for all other outcomes.

## Modifying factors: adaptation and vulnerability

Factors such as physiological adaptation, technological and institutional innovation and individual and community wealth will influence not only the exposure of individuals and populations to climate hazards, but also the associated hazards (e.g. IPCC 2001a; Reiter 2000; Woodward et al. 1998). For some assessments, simpler modifying factors are integrated into the models for both present and future effects. For example, estimates of changes in the number of people at risk of hunger incorporate continental projections of economic growth, affecting capacity to buy food (Parry et al. 1999). Other models incorporate the effects of existing modifiers when defining current climate-disease relationships, such as estimates of the global distribution of malaria based on current climate associations (Rogers and Randolph 2000). Such models implicitly capture the current modifying effects of socioeconomic and other influences on climate effects, but do not attempt to model future changes in these modifiers. Finally, some models make no estimate of such modifying influences in either the present or future; for example, models that estimate future changes in the geographical range which is climatically suitable for malaria transmission, and associated populations at risk (Martens et al. 1999). To generate consistent estimates in this analysis:

- we attempted to account for current geographical variation in vulnerability to climate, where not already incorporated into the predictive models.
- we attempted to account for future changes in disease rates due to other factors (e.g. decreasing rates of infectious disease due to technological advances/improving socioeconomic status), and for changes in population size and age structure (e.g. potentially greater proportion of older people at higher risk of mortality related to cardiovascular disease in response to thermal extremes). This was addressed by calculating only relative risks under alternative climate change scenarios, which should be applied to GBD projections of disease rates and population size and age structure. The GBD projections take into account the effects of changing GDP, "human capital" (as measured by average years of female education), and time (to account for trends such as technological development) (Murray and Lopez 1996) on the overall "envelope" of cause-specific mortality and morbidity for diseases affected by climate change.
- all quantitative estimates of the health effects of climate change were based on observed effects of climate variations either over short time
periods, or between locations. They therefore made the important assumption that these relationships are also relevant to long-term climate change. To avoid unrealistic extrapolation of short-term relationships, we included consideration of mechanisms by which climate-health relationships may alter over time (i.e. adaptation). We considered whether each disease in turn was likely to be significantly affected by biological adaptation (i.e. either behavioural, immunological or physiological) and/or by generally improving socioeconomic conditions (i.e. increasing GDP) (see Table 20.4). In each case we defined appropriate adjustments to the relative risk estimates, in line with published studies. The different factors for each health outcome were then applied to the same projections of future GDP (WHO/ EIP/GPE, unpublished data, 2001) and changing climate (from our models), to adjust the relative risks over the time course of the assessment. There is, however, substantial uncertainty over the most likely degree of adaptation under different conditions. This was reflected in

Table 20.4 Assumptions on adaptation and vulnerability

|  | Biological ${ }^{\text {a }}$ adaptation <br> affecting RRs | Socioeconomic adaptation <br> affecting RRs |
| :--- | :--- | :--- |
| Direct physiological effects of <br> heat and cold | Yes. Temperature associated <br> with lowest mortality was <br> assumed to change directly <br> with temperature increases <br> driven by climate change | None |

the uncertainty estimates for the relative risks for each disease. Quoted uncertainty estimates therefore describe uncertainties around climate change predictions, about current exposure-response relationships, and around the degree to which these are likely to be maintained in the future. Since, to date, these have not been formally modelled, they were generated here by qualitative assessment in collaboration with the original modelling group. The uncertainty estimates should therefore be interpreted with caution.

- we ignored more complex aspects of future vulnerability. Whereas projected trends for average income (which is included in estimating baseline rates and, where possible, relative risks) are broadly positive, other factors may have opposite effects. These include income distribution, maintenance of disease surveillance, control and eradication programmes, technological change and secondary or threshold effects, such as the protective effect of forests in reducing the frequency and intensity of flooding (e.g. Fitzpatrick and Knox 2000).
- we made no attempt to estimate the effects of actions taken specifically to adapt to the effects of climate change (e.g. the upgrading of flood defences specifically to cope with sea-level rise attributable to climate change). Therefore, our estimates represent a "business-asusual" scenario of the health effects associated with global climate change.

### 3.3 Estimation for different time points

As stated above, climate model outputs are usually presented as averages over 30 -year periods, for example, centred on 2025 and 2055. In order to generate estimates for any specific year, we defined 1990 (i.e. the last year of the baseline climate period) as year 0 . Central, lower and upper estimates of relative risks were calculated for the 2020s (i.e. centred on 2025) and the 2050s, using models described elsewhere. Quoted estimates for the years 2001, 2005, 2010 and 2020 were estimated by linear regression against time between 1990 and 2025. Estimates for 2030 were estimated by linear regression between 2025 and 2055. Using this method, our choice of 1990 as the baseline year rather than the middle of the 1961-1990 period led to conservative estimates of health consequences, particularly in the near future.

### 3.4 Risk reversibility

In the context of this assessment, risk reversibility describes the proportion of the health consequences that would be avoided if the population were shifted to a different exposure scenario. Given the definition of exposure scenarios, complete avoidance of climate change (i.e. populations exposed to baseline climate conditions rather than unmitigated climate change) would avoid all of the health consequences that we have described. Risk reversibility would therefore be $100 \%$ in this case.

### 3.5 CRITERIA FOR IDENTIFYING RELEVANT STUDIES AND FOR estimating strength of evidence

In identifying relevant studies, we have considered all publications reviewed in the IPCC Third Assessment Report (IPCC 2001a), as well as those found in more recent literature searches (Appendix B). However, as the field is relatively new and expanding rapidly, we have also used some studies that are either in-press or submitted for publication (material available on request). As these may not be easily accessible to readers of this report, the major underlying assumptions are described.

There are still relatively few models that link climate change models to quantitative global estimates of health or health-relevant outcomes (e.g. numbers of people flooded or at risk of hunger). Where global models did not exist, we have extrapolated from models that make local or regional projections. Methods for extrapolating to the subregions are described separately for each disease. Where there was more than one published model for a particular outcome, decisions on model selection were based as much as possible on validation against historical/ geographical patterns. We excluded models: (i) that have been shown to be significantly less accurate than equivalent models in predicting historical or geographical trends; or (ii) that have been superseded by later models by the same group; or (iii) that are based on unrealistic biological assumptions; or (iv) that cannot be plausibly extrapolated to a wider area. Given the very limited means for model validation, these results involved choices made in this work among models and resulted in very large uncertainty.

As climate change impact assessment is, at this stage, predominantly a model-based exercise, the assessment of strength of evidence for causality is necessarily indirect. It is based on two considerations: (i) the strength of evidence for the current role of climate variability in affecting the health outcome, and (ii) the likelihood that this relationship between climate and health will be maintained through the process of long-term climate change.

Several of the uncertainties involved in this exercise, particularly those relating to climate modelling and those around the quantitative relationships between climate and health, should decrease through improvements in modelling, and more importantly, through better empirical research. However, estimation of climate change effects is currently a predictive exercise, based on some form of indirect modelling (e.g. analysis of temporal or geographical variation in climate), rather than direct experience (i.e. of a change process that has previously occurred). It is therefore possible that some of the health outcomes listed above may not respond in the predicted manner. On the other hand, we do not yet have direct experience of the full range of health outcomes that may be associated with exposure.

The analyses described here were specifically to estimate the future disease burden, which may be avoided by climate change mitigation policies. However, it must be emphasized that these burdens may also be reduced by adaptation interventions to reduce the vulnerability of populations. Given the "exposure commitment" (unavoidable climate change due to past GHG emissions), and the large gap between even plausible mitigation scenarios and the baseline climate, adaptation strategies are essential to the goal of reducing adverse health effects. These include early warning systems and defences for protection from natural disasters, and improved health infrastructure (e.g. water and sanitation, control programmes for vector-borne diseases) to reduce the baseline incidence of climate-sensitive diseases.

### 3.6 Direct effects of heat and cold on mortality

An association between weather and daily mortality has been shown consistently in many studies in diverse populations. The effect of extreme temperature events (heat-waves and cold spells) on mortality has also been well described in developed countries. However, temperatureattributable mortality has also been found at "moderate" temperatures (Curriero et al. 2000; Kunst et al. 1993).

Causality is supported by physiological studies of the effects of very high or very low temperatures in healthy volunteers. High temperatures cause some well described clinical syndromes such as heat-stroke (see review by Kilbourne 1989). Very few deaths are reported as directly attributed to "heat" (International Classification of Diseases, ninth revision [ICD-9 code 992.0]) in most countries. Exposure to high temperatures increases blood viscosity and it is therefore plausible that heat stress may trigger a vascular event such as heart attack or stroke (Keatinge et al. 1986a). Studies have also shown that elderly people have impaired temperature regulation (Drinkwater and Horvath 1979; Kilbourne 1992; Mackenbach et al. 1997; Vassallo et al. 1995). Clinical and laboratory studies indicate that exposure to low temperatures causes changes in haemostasis, blood viscosity, lipids, vasoconstriction and the sympathetic nervous system (e.g. Keatinge et al. 1986b, 1989; Khaw 1995; Woodhouse et al. 1993, 1994). The strongest physiological evidence is therefore for cardiovascular disease.

Population-based studies also provide evidence that environmental temperature affects mortality due to both cardiovascular and respiratory disease. The best epidemiological evidence is provided by time-series studies of daily mortality. These methods are considered sufficiently rigorous to assess short-term associations (days, weeks) between environmental exposures and mortality, if adjustment is made for longer-term patterns in the data series, particularly the seasonal cycle and any longterm trends, such as gradually decreasing mortality rates over decades (Schwartz et al. 1996).

The effect of a "hot" day is apparent for only a few days in the mortality series; in contrast, a "cold" day has an effect that lasts up to two weeks. Further, in many temperate countries, mortality rates in winter are $10-25 \%$ higher than death rates in summer. The causes of this winter excess are not well understood (Curwen and Devis 1988). It is therefore plausible that different mechanisms are involved and that cold-related mortality in temperate countries is related in some part to the occurrence of seasonal respiratory infections.

Although the physiological evidence for causality of an effect of temperature on mortality is greatest for cardiovascular, followed by respiratory, diseases, temperature has been shown to affect all-cause mortality in areas where cardiovascular disease rates are relatively low and infectious disease mortality is relatively high. Many studies report the seasonal patterns of infectious disease in developing countries, but the role of temperature is not well described. It is likely that seasonal rains influence the seasonal transmission of many infectious diseases. High temperatures encourage the growth of pathogens and are associated with an increased risk of diarrhoeal disease in poorer populations (see section 3.7).

Studies have also described mortality and morbidity during extreme temperature events (heat-waves). However, these events are, by definition, rare. It is therefore difficult to compare heat-waves in different populations and for different intensities. The studies that have been used to describe the effects of heat-waves (episode analyses) also use different methods for estimating the "expected" mortality, which makes comparison difficult (Whitman et al. 1997). An assessment of the health consequences of climate change on thermal stress requires estimation of past and future probabilities of extreme temperature events. The current methods of assessment use 30 -year averages of monthly data, and few scenarios consider change in the frequency or magnitude of extreme events. This is because: (i) suitable methods have not been developed, and (ii) climate model output at the appropriate spatial and temporal resolution is not readily available (Goodess et al. 2001).

There is little published evidence of an association between weather conditions and measures of morbidity such as hospital admissions or primary care consultations (Barer et al. 1984; Ebi et al. 2001; Fleming et al. 1991; McGregor et al. 1999; Rothwell et al. 1996; Schwartz et al. 2001). A study of general practitioner consultations among the elderly in Greater London found that temperature affected the rate of consultation for respiratory diseases but not that for cardiovascular diseases (Hajat et al. 2001). However, it is not clear how these end-points relate to quantitative measures of health burden.

## Estimating The TEMPERATURE-MORTALITY RELATIONSHIP

A review of the literature was undertaken to identify studies that report relationships between daily temperature and mortality (see Appendix B).

The following criteria were used to select studies for deriving the modelled estimates.

- A study that uses daily time-series methods to analyse the relationship between daily mean temperature and mortality.
- A study that reports a coefficient from linear regression which estimates the percentage changes in mortality per degree centigrade changes in temperature above and below a reported threshold temperature.

Several studies have estimated future temperature-related mortality for a range of climate scenarios (e.g. Guest et al. 1999; Kalkstein and Greene 1997; Langford and Bentham 1995; Martens 1998a). These methods were not considered appropriate for this project, as described in Appendix B.

The best characterized temperature-mortality relationships are those for total mortality in temperate countries. Fewer studies have also looked at the particular causes of death for which physiological evidence is strongest: cardiovascular disease, and to a lesser extent respiratory disease. In this study, we used the specific relationships for cardiovascular disease where these were available (temperate and cold-climate zones), and the general relationships for all-cause mortality for climatic regions where such disease-specific relationships could not be found in the literature review (all tropical populations) (Table 20.5).

As outlined in section 2.2, it was assumed that everybody is exposed to the ambient temperatures prevailing under the different climate scenarios. However, populations differ in their responses to temperature variability, which is partly explained by location or climate.

The global population distribution was divided into five climate zones (Table 20.6), according to definitions developed for urban areas by the

Table 20.5 Temperature-related mortality: summary of exposureresponse relationships, derived from the literature ${ }^{\text {a }}$

Australian Bureau of Meteorology (BOM 2001). The population in the polar zone is small ( $0.2 \%$ of world population) and was excluded.

It was necessary to estimate daily temperature distributions in order to calculate the number of attributable deaths. Daily temperature distributions clearly vary a great deal, even between localities within the same country. However, it was not feasible within this assessment to obtain sufficient meteorological data to estimate daily temperature distributions throughout the world at a fine spatial resolution. Therefore, a single distribution was chosen to represent each climate zone. New daily temperature distributions were then estimated for each climate scenario, by shifting the currently observed temperature distributions by the projected change in mean temperatures for each month, and of the variability of daily temperatures as well as changes in the mean.

## Estimating TEMPERATURE-ATTRIBUTABLE MORTALITY

An exposure-response relationship and threshold temperature ( $T_{\text {cutoff }}$ ) was applied within each climate zone (Table 20.7). The average temperature difference above (hot days) and below (cold days) this temperature was calculated for baseline climate and each of the climate scenarios.

The short-term relationships between daily temperature and mortality (Table 20.5) were used to estimate the annual attributable fraction of deaths due to hot days and cold days for each of the climate

Table 20.7 Threshold $T_{\text {cutoff }}$ for each scenario in each climate zone (original $T_{\text {cutoff }}+\mathrm{Dt}_{\text {summer }}$ rounded to integers)

BaU Business-as-usual scenario.
scenarios (i.e. annual temperature distributions based on averages over 30 years). Deaths attributable to climate change were calculated as the change in proportion of temperature-attributable deaths (i.e. heat-attributable deaths plus cold-attributable deaths) for each climate scenario compared to the baseline climate. The $1^{\circ} \times 1^{\circ}$ resolution grid map of population distribution (Bos et al. 1994) was then overlaid on the maps of climate zones in a geographical information system (GIS), to estimate the proportion of the population in each subregion who live in each climate zone. The proportional changes in temperatureattributable deaths were therefore calculated by taking the average of the changes in each climate zone represented in the subregion, weighted by the proportion of the subregion's population living within that climate zone.

## Adaptation

Acclimatization includes autonomous adaptation in the individual (physiological adaptation, changes in behaviour) and autonomous and planned population-level adaptations (public health interventions and changes in built environment). Acclimatization to warmer climate regimes is likely to occur in individuals and populations, given the rate of change in mean climate conditions currently projected by climate models. However, it is uncertain whether populations are able to adapt to non-linear increases in the frequency or intensity of daily temperature extremes (heat-waves). Even small increases in average temperature can result in large shifts in the frequency of extremes (IPCC 2001b; Katz and Brown 1992).

Few studies have attempted to incorporate acclimatization into future projections of temperature-related mortality (Kalkstein and Greene 1997), but all studies report that acclimatization would reduce potential increases in heat-related mortality. Our estimates incorporated an assumption regarding acclimatization of the populations to the changing climate that describes this reduced effect. We assumed that the threshold temperature ( $T_{\text {cutoff }}$ ) is increased as populations adapt to a new
climate regime, reflecting physiological and behavioural acclimatization that can take place over the time-scale of decades. Changes in $T_{\text {cutoff }}$ are region and scenario specific, as they reflect the rate of warming experienced. Therefore, they were assumed to be proportional to the projected change in average summer temperature ( $\mathrm{Dt}_{\text {summer }}$, equal to the mean of the three hottest months) from the climate scenario. The temperature-mortality relationships were assumed not to change over time; that is, populations biologically adapt to their new average temperatures, but remain equally vulnerable to departures from these conditions. We made no explicit adjustment for an effect of socioeconomic development and technological change on temperature-related mortality. The resulting relative risks are given in Table 20.8.

## Short-term mortality displacement

Evidence suggests that the increase in mortality caused by high temperatures is partially offset by decreased deaths in a subsequent "rebound" period (Braga et al. 2001). This indicates that some of the observed increase in heat-related mortality may be displacement of deaths among those with pre-existing illness, which would have occurred soon in any case. However, this effect has not been quantified for temperature exposures and was not included in the model. The estimates are therefore used to calculate only attributable deaths, but not DALYs, as the estimate of attributable years of life lost was highly uncertain.

In subregions with predominantly temperate and cold climates, reductions in cold-related mortality are likely to be greater than increases in heat-related mortality. Therefore, all climate scenarios show a net benefit on mortality in these subregions, consistent with the IPCC conclusions described above. The effect of the adaptation assumption is to reduce relative risks and therefore net mortality.

## UnCERTAINTY ESTIMATES

The principal uncertainty in these estimates, and for all other health effects of climate change, relates to the extrapolation of a short-term climate-health relationship to the long-term effects of climate change. The degree to which this is a reasonable extrapolation relates to the degree to which populations will adapt to changing temperatures, both in terms of reducing the additional mortality attributable to heat, and the possible benefits of avoiding cold deaths. This outcome is unusual, in that the predicted health effects of climate change are negative in some regions, but positive in others. We therefore use slightly different terminology to describe the range of uncertainty around the estimates. The mid-range estimate was given by applying the model described above (i.e. making an adjustment for biological adaptation). The "high-impact" estimate assumes that there was no physiological or behavioural adaptation, and therefore no change in the dose-response relationship over time. This maximizes both positive and negative effects. The low-impact

[^71]estimate assumes complete adaptation to a changing climate, and therefore no change in the relative risk as the climate changes.

There is therefore a need for further time-series studies, applying a standard approach to populations living in as wide a range of climates as possible. Previous analyses have focused mainly on temperate zones, where the winter effects are greatest, potentially causing over-estimation of the reduced burden attributable to climate change (e.g. Martens 1998a). More analyses of temperature-mortality relationships are therefore required in tropical developing countries.

Such studies should attempt to estimate formally the degree to which adaptation may decrease mortality, and to which observed associations between climate and mortality reflect displaced rather than additional deaths. Finally, there is a need for greater investigation of the health burden of morbidity associated with temperature extremes, including, for example, inability to work in extreme temperatures.

### 3.7 Diarrhoeal disease

Diarrhoeal diseases are highly sensitive to climate, showing seasonal variations in numerous sites (Drasar et al. 1978). This observation is supported by regression analyses of the effects of seasonal and longer-term variation in a limited number of sites (Checkley et al. 2000; Singh et al. 2001). The results of a literature search on the associations between diarrhoeal disease and climate are shown in Appendix B, Table B.2. The climate-sensitivity of diarrhoeal disease is consistent with observations of the direct effects of climate variables on the causative agents. Temperature and relative humidity have a direct influence on the rate of replication of bacterial and protozoan pathogens, and on the survival of enteroviruses in the environment (Blaser et al. 1995). Rainfall may affect the frequency and level of contamination of drinking water (Curriero et al. 2001).

Quantitative relationships can be defined between climate variations and incidence, which can in turn be directly linked to the outputs of global climate change models. There are, however, challenges and uncertainties in estimating the magnitude of effects.

- The sites from which these relationships were defined cover only a small part of the spectrum of global climate variation. Different relationships may apply at higher or lower temperatures.
- The relative importance of different pathogens and modes of transmission (e.g. via water, food, insects or human-human contact) varies between locations, and is heavily influenced by level of sanitation (Black and Lanata 1995). As the pathogens are known to vary in their response to climate (e.g. Cook et al. 1990; Chaudhury et al. 1996), this will cause uncertainty in extrapolating temperature relationships from local studies to other regions with different levels of development.
- Pathogens vary in the severity of clinical symptoms, and the likelihood that they will be reported to health services (e.g. Wheeler et al. 1999). Therefore, climate-disease relationships derived only from passive reporting may differ from those based on other methods of surveillance.
- While several studies describe climate effects on particular diarrhoea pathogens (e.g. Eberhard et al. 1999; Konno et al. 1983; Purohit et al. 1998), these cannot be used directly to estimate effects on diarrhoeal disease without information on: (i) their relative contribution to overall disease incidence, and (ii) equivalent data on climate sensitivity and relative prevalence for all other diarrhoea pathogens.
- Despite convincing evidence on the effect of extreme rainfall on waterborne outbreaks of diarrhoea, even in highly developed countries (Curriero et al. 2001), this cannot easily be generalized to the total burden of diarrhoeal disease without information on the relative contribution of such outbreaks to overall diarrhoea incidence.
- Rainfall effects on overall diarrhoea (where observed) are non-linear, and cannot easily be extrapolated to other regions.

In order to minimize these uncertainties, we restricted our estimates to the effect of increasing temperatures on the incidence of all-cause diarrhoea reported to health services (i.e. without attempting to make separate estimates for different pathogens, transmission routes, severities, or for the more complex associations with rainfall). There are important residual uncertainties related to the extrapolation of temperature relationships from specific study sites to others with different temperature regimes and levels of development, and climate effects on reported diarrhoea compared to the true burden of disease. Projections of increasing frequency of extreme wet seasons are very large (e.g. two to five times increase in the regions analysed; Palmer and Ralsanen 2002), and extreme precipitation is associated with increased diarrhoea in both developed (Curriero et al. 2001) and developing (Singh et al. 2001) countries.

Graded maps of $3.75^{\circ}$ longitude by $2.5^{\circ}$ latitude resolution showing the change in temperature under the alternative scenarios were overlaid with $0.5^{\circ} \times 0.5^{\circ}$ resolution maps of predicted population distributions for the 2020s and 2050s in a GIS. The GIS was used to calculate the average change in exposure (temperature) for each population grid-cell.

Although seasonality of diarrhoeal disease is well recognized, the quantitative relationship between climate and overall diarrhoea incidence has only been explicitly measured in two studies. Both studies described relationships with all-cause diarrhoea, that is, specific pathogens were not differentiated. Checkley et al. (2000) used time-series analysis to correlate measurements of temperature and relative humidity against daily hospital admissions at a single paediatric diarrhoeal

Figure 20.4 Hospitalizations for diarrhoea (upper line) correspond closely with temperature (lower line) at a clinic in Lima, Peru

Note: Shaded region corresponds to the 1997-1998 El Niño event.
Source: Checkley et al. (2000).
disease clinic in Lima, Peru (Figure 20.4) for just under 6 years. A total of 57331 admissions were recorded during the study. The analysis showed a $4 \%(95 \%$ CI $2-5 \%)$ increase in admissions for each degree centigrade increase in temperature during the hotter months, and a $12 \%$ ( $95 \%$ CI $10-14 \%$ ) per degree centigrade increase in the cooler months, averaging at an $8 \%(95 \%$ CI $7-9 \%)$ per degree centigrade increase over the course of the study. During the 1997-1998 El Niño period there was an additional increase in admissions above that expected on the basis of pre-El Niño temperature relationships, but no association with relative humidity independent of temperature. No rainfall during that period.

In the Checkley et al. study, exposure (climate) data were recorded at local meteorological stations, and can be considered to have negligible measurement error at the population level. The analysis independently controlled for seasonal variations and long-term trends, imparting high confidence to the observed effect of temperature on the outcome recorded. The positive correlation with temperature is also biologically plausible, as a high proportion of diarrhoea cases in many tropical developing countries are caused by bacteria, entamoeba and protozoa (Black
and Lanata 1995), which are favoured by high temperatures. The principle limitations of the study by Checkley et al. are that the outcome recorded may not be representative of climate effects on: (i) less severe disease (i.e. not requiring hospitalization) or more severe disease (diarrhoeal deaths), or (ii) disease in adults rather than children.

Singh et al. (2001) used similar time-series analyses to correlate monthly reported incidence of diarrhoea throughout Fiji against variations in temperature and rainfall, after allowing for the effects of seasonal variation and long-term trend. The study covered the period between 1978 and 1998, with an average of some 1000 reported cases for each of the 228 study months. Reported incidence increased by approximately $3 \%$ ( $95 \%$ CI $1.2-5.0 \%$ ) for each degree centigrade increase in temperature, by $2 \%$ ( $95 \%$ CI $1.5-2.3 \%$ ) per unit increase in rainfall above average rainfall conditions $\left(5 \times 10^{-5} \mathrm{~kg} / \mathrm{m}^{2}\right.$ per min), and by $8 \%$ per unit decrease below average conditions. The pattern is supported by a positive geographical correlation between temperature and incidence in 18 Pacific Island countries (Singh et al. 2001). Climate measurements were from a $2.5^{\circ} \times 2.5^{\circ}$ cell of a global gridded data set corresponding to Fiji. The use of monthly averages of climate data from this large geographical area may not have reflected the full range of climate exposures of the population; this would have introduced random error and decreased sensitivity. Low rainfall may force use of contaminated water, while high rainfall may contaminate water through flooding. The major limitations of this study are lack of a clear clinical or laboratory definition for diarrhoea, and lack of information on the age distribution of cases.

We are not aware of any similar studies of climate effects on all-cause diarrhoea in developed regions, although studies have been carried out on some subsets of total incidence. Bentham (1997) showed that the incidence of food poisoning, usually caused by bacteria, increased by approximately 9\% per degree centigrade in England and Wales. Konno et al. (1983) demonstrated a non-linear inverse relationship between rotavirus infection and temperature in Japan. The relative importance of pathogens that thrive at lower temperatures appears to be greater in populations with higher standards of living, who have access to clean water and sanitation and for whom there is no clear and consistent evidence for peaks in all-cause diarrhoea in warmer months. This is in contrast to the situation of less well-off populations, where diarrhoea is usually more common in warmer, wetter months, as well demonstrated by clear summer peaks of diarrhoea in black, but not white, infants in Johannesburg during the 1970s (Robins-Browne 1984).

For this assessment we defined developing countries as those with per capita incomes lower than the richer of the two study countries (Fiji) in the year 2000—approximately US\$ 6000/year in 1990 US dollars. For such countries, we applied a dose-response relationship of $5 \%$ increase in diarrhoea incidence per degree centigrade increase in temperature, to
both sexes and all age groups. This is consistent with the relationships derived from the two studies described above. We chose $5 \%$ rather than the arithmetic mean of the constants from the two studies ( $5.5 \%$ ) for two reasons: (i) to avoid giving a false impression of precision based on only two estimates, each with their own confidence intervals, and (ii) in order to be conservative.

Although the confidence intervals around the estimates from the individual studies are relatively small, these clearly cover only a small range of climatic and socioeconomic environments. As described above, Checkley et al. (2000) showed that even in a single socioeconomic setting the temperature dependence of diarrhoeal disease may vary across the temperature range or, less plausibly, with non-climatic seasonal variations. This introduces uncertainty when extrapolating such a single relationship. There is also potential bias: if the temperature-responsiveness is indeed greater at low temperatures, extrapolation of an average value will tend to underestimate effects in areas that are on average colder, and overestimate in hotter regions. However, the average annual temperatures experienced by the residents of the areas to which we extrapolated this relationship was $20.3^{\circ} \mathrm{C}$, as calculated by averaging the temperatures in each $1^{\circ} \times 1^{\circ}$ grid-cell weighted by the population. This is in the mid-range of the temperatures experienced throughout the year in Lima $\left(16-26^{\circ} \mathrm{C}\right)$, and cooler than those in the capital of Fiji $\left(23-27^{\circ} \mathrm{C}\right)$ (World Climate 2002). Our extrapolation tended towards being conservative, but with significant uncertainty. Therefore, we place a wide uncertainty range ( $0-10 \%$ ) on this value.

As there are no such studies published for developed regions, we made the assumption that overall diarrhoea incidence in richer countries is insensitive to climate change, that is, $0 \%(-5$ to $+5 \%$ ) change per degree centigrade temperature change. Relative risks for each country under each scenario were calculated by multiplying the projected increase in temperature by the relevant exposure-response value. The quoted estimate for each subregion is the population-weighted average of the relative risks for each country in the subregion (Table 20.9). In addition to changes in baseline diarrhoeal disease over time, we assumed that the climate sensitivity of diarrhoea in developing countries will decrease as they become better off. For projections of relative risks for years after 2000, we used projections of future changes in GDP (WHO/EIP/GPE, unpublished data, 2000) to apply the relationship used above-that is, overall diarrhoea incidence does not respond to temperature in any country that attains a per capita GDP of at least US $\$ 6000 /$ year. Relative risks for each time point were then calculated as above.

The quantitative estimates in this analysis were highly sensitive to the exposure-response relationship, around which there is substantial uncertainty due to the very small number of analysed time-series. The estimates could be rapidly improved by analysis of climate exposure-response relationships from sites from a wider climatic and

[^72]socioeconomic spectrum. Future studies should also explicitly measure the degree to which economic development and improved levels of sanitation influence vulnerability to the effects of climate variation on diarrhoeal disease.

### 3.8 Malnutrition

Multiple biological and social factors affect the incidence of malnutrition, but one of the fundamental determinants is the availability of staple foods. Climate change may affect this through the balance of the (broadly negative) effects of changes in temperature and precipitation, and (broadly positive) effects of higher $\mathrm{CO}_{2}$ levels on yields of major food crops (e.g. IPCC 1996; Rosenzweig and Parry 1994; see also Appendix B, Table B.4). These effects are likely to vary markedly with geography: productivity is projected to increase in higher-latitude producers such as Canada and the United States, but to decrease closer to the equator. The global food trade system may be able to absorb these effects at the global level. However, climate change can be expected to have significant effects on food poverty in some regions, owing to variation in both productivity and in economic capacity to cope (Parry et al. 1999).

Crop models have been validated at 124 sites in 18 countries over a wide range of environments (e.g. Otter-Nacke et al. 1986). However, estimation of changes in food availability (and by inference malnutrition) requires additional analyses of the geographical variation in effects on food production, and of food trade patterns. Only one modelling group (Parry et al. 1999) has integrated a basic physiological model of climate change effects on region-specific crop production with food trade models, in order to make projections of the numbers of people actually at risk of hunger. All results presented here were based on the model described in Parry et al. (1999) and other work by the same group.

As for other potential effects of climate change, there is considerable uncertainty over the degree to which current relationships, such as those between climate and crops, and food trade systems will remain constant over time. The most important uncertainties probably relate to the ability of the world food trade system to adapt to changes in production (Dyson 1999; Waterlow et al. 1998). Although these are the most complete models currently available, they do not describe the likely effect of climate change on more complex pathways, such as animal husbandry, or the relative importance of fruit and vegetable production. These in turn may affect micronutrient (e.g. vitamin A , iodine, iron and zinc) deficiency.

Global distribution of temperature, rainfall and $\mathrm{CO}_{2}$ were mapped for each of the alternative scenarios, as described above. Climate dose-response relationships have been defined for yields of major grain cereals and soybean, which account for $85 \%$ of world cereal exports.

Effects of temperature and precipitation, and the beneficial effects of higher $\mathrm{CO}_{2}$ levels, have been defined using the IBSNAT-ICASA dynamic crop growth models (IBSNAT 1989). The exposure distributions described above were applied to these crop growth models, and the derived yield functions were extrapolated to other crops and regions on the basis of agro-climatic similarity.

These crop yield estimates are used as inputs for the Basic Linked System world food trade model. This consists of a linked series of 40 national and regional food models, representing food production, the effects of market forces and government policies on prices and trade, and trends in agricultural, economic and technological conditions over time (see Fischer et al. 1988 for a full description).

The model is represented schematically in Figure 20.5. Principal characteristics of this model are:

- no major changes in the political or economic context of world food trade or in food production technology;
- population growth to occur following the World Bank mid-range estimate (World Bank 1994) i.e. 10.7 billion by the 2080s;
- GDP to accumulate as projected by EMF14 (Energy Modeling Forum 1995);
- a $50 \%$ trade liberalization in agriculture is introduced gradually by 2020.

The model results in an estimation of national food availability. This is used to generate an estimate of per capita food availability in each country, assuming that this food is distributed among the population following a skewed (beta) distribution. The final model output is the number or proportion of the population in each subregion who do not have access to sufficient food to maintain a basal metabolic rate of 1.4, which is the Food and Agriculture Organization of the United Nations' (FAO) definition of undernourishment (FAO 1987).

The model generates outputs for continents made up principally of vulnerable developing countries (thus excluding China and the former Soviet Union, countries in North America, and in western and eastern Europe). As these model continents do not map directly on to the subregions, we generated estimates for each subregion by calculating the proportion of the population that lives within each continent in the food availability model. Where more than $90 \%$ of the subregion population live within a single model continent, we quoted the model estimate for that continent. Otherwise an average was calculated, weighted by the distribution of the subregion population among the various continents. While the subregions mapped reasonably well on to the climate change/food availability model continents, the aggregation meant that some of the geographical variation in vulnerability was lost. Most notably, despite severe problems in some countries, EUR-C was assumed

Figure 20.5 Key elements of the crop yields and world food trade study

ET Evapotranspiration.
Source: Rosenzweig et al. (1993).
not to suffer from malnutrition as it lies within the "developed" European continent of the food availability model.

Preliminary analysis correlating estimates for the 1990s at the level of the model regions (data not shown) indicated that the model output was positively related to more direct measures of malnutrition, such as the incidence of underweight, and stunting and wasting in children aged <5 years, as measured by the WHO Global Database on Child Growth and Malnutrition (WHO 2002). The aggregation of the food availability model means that this correlation was based on only a small number of independent data points. We therefore did not attempt to make any quantitative estimate of these relationships. Instead, the relative risk of the incidence of energy shortfall (Table 20.10) was interpreted as being directly proportional to the relative risk of suffering from the risk factor "underweight". The relative risk estimates were therefore applied to all diseases affected by the underweight risk factor (see chapter 2). These include diarrhoea and malaria. We therefore assumed that these diseases are affected in two distinct ways by climate change-through meteorological effects on the pathogens and vectors, and through increased susceptibility of the human population due to undernutrition.

In common with most climate change impact assessments, the published studies do not quote uncertainties around the various relationships in the model, either separately or aggregated. Small variations in the initial conditions of a single climate model (the HadCM2 ensemble) generated only slight variations in projections of crop production and incidence of food shortfall. Using a different climate model (HadCM3), however, generated markedly different projections (Parry et al. 1999). These comparisons relate to only part of the possible error, as they do not address uncertainties in the trade and social components of the model.

From the published descriptions of the model, there is no reason to assume that the estimates generated were systematically biased either upward or downward. In the absence of formal sensitivity analyses of the complete model, however, uncertainty estimates are arbitrary. We presented the relative risks generated above as mid-range estimates, with the upper and lower range covering a complete adaptation to any changes in agricultural output (i.e. no change in risk), to a doubling of the estimate of the relative risk calculated above. However, this uncertainty range should be treated with caution. Priorities for the future are investigations of:

- variation in output when using a wider range of food production models as inputs to the food trade/availability models;
- sensitivity of estimates to the various climate scenarios;
- sensitivity analyses to estimate uncertainty around the exposureresponse relationships;

[^73]- back-casting of climate/hunger relationships for verification of model accuracy;
- a finer geographical (e.g. country level) breakdown of the outputs of malnutrition models;
- correlations between model outputs and health outcomes at a high spatial resolution; and
- investigation of the synergistic effects of water availability and poverty on malnutrition.

### 3.9 DISASTERS CAUSED BY EXTREME WEATHER EVENTS: COASTAL FLOODS, INLAND FLOODS AND LANDSLIDES

Natural disasters are ultimately a function of both the average and degree of variability of weather conditions, which are further modulated by multiple aspects of population vulnerability such as topography, housing quality and early warning systems (Alexander 1993; McMichael et al. 1996). They are therefore likely to be directly affected by the observed and predicted trend towards increasingly variable weather.

In addition to the axiomatic link between extreme weather events and weather-related deaths and injuries, there is strong statistical evidence that long-term weather cycles (e.g. the ENSO quasi-periodic cycle) correlate with incidence of deaths and injuries attributable to natural disasters (Bouma et al. 1997a; Kovats et al. 1999). The evidence for increased frequency of different categories of extreme events in the past, and the likelihood of changes in the future (Table 20.1), has been strengthened by recent demonstrations of increases in the frequency of large floods during the 20th century (Milly et al. 2002). This evidence is reinforced by projections of several-fold increases in the frequency of what are currently considered extreme wet seasons, for various regions over the world, using a range of climate models (Palmer and Ralsanen 2002).

Based on this, we presented estimates of consequences of increasing frequency of coastal flooding caused by sea-level rise, and inland flooding and landslides caused by increased frequency of extreme precipitation events, which are described by IPCC as very likely (90-99\% probability) to increase in many areas under climate change. We did not attempt to estimate the effects of changing frequency and intensity of wind storms, owing to inconsistencies between models (IPCC 2001b) and a lack of quantitative projections of changes in exposure under different climate change scenarios. Our estimates excluded the direct effect of thermal extremes (e.g. heatstroke, increased risk of cardiovascular disease), which are dealt with elsewhere. We also excluded any potential longer-term health consequences arising through mechanisms such as population displacement, economic damage to public health infrastructure, increased risk of infectious disease epidemics and mental illness (Jovel 1989; Menne et al. 1999; WHO 1992).

Climate change is likely to have different effects on the frequency of coastal versus inland floods. Changes in the frequency of coastal floods were defined using published models (Hoozemans and Hulsburgen 1995; Nicholls et al. 1999) that estimate change in sea level for each climate scenario. These changes were applied to topographical and population distribution maps to estimate the change in incidence of exposure to flooding by subregion. The predictions did not account for changes in frequency of storm surges. The global model used here has been shown to be relatively accurate in validations against more detailed assessments at the national level (summarized in Nicholls et al. 1999).

Inland floods and landslides are not affected by sea-level rise, but will be influenced by any increase in the frequency of intense precipitation. Despite the clear causal link, this relationship is poorly researched (Pielke 1999), and has not previously been modelled as a health exposure. There are no published analyses of global relationships between intensity of precipitation, the likelihood of a declared disaster, or the magnitude of health consequences. Clearly, at the local level the frequency of health effects will be determined by the temporal distribution of rainfall (i.e. not only by the average amount of rain over an extended period, but by the peak amount falling in a week, day or hour), and modulated by topography and social aspects of vulnerability (Kundzewicz and Kaczmarek 2000). However, in the absence of detailed data on these variables and their effects, we made the a priori assumption that flood frequency is proportional to the frequency with which monthly rainfall exceeds the 1 in 10 year limit (i.e. upper $99.2 \% \mathrm{CI}$ ) of the baseline climate. We also assumed that determinants of vulnerability are distributed evenly throughout the population of a subregion-so that the change in relative risk of health consequences is proportional to the per capita change in risk of experiencing such an extreme event. For each $1^{\circ} \times 1^{\circ}$ population grid-cell, we estimated the $99.2 \%$ upper CI for the "baseline climate" using means and standard deviations derived from the 1961-1990 averages for each month of the year. Using equivalent data for future scenarios and time points, we estimated the change in frequency with which such a " 1 in 10 year event" occurs.

The difference (in standard deviates of the new distribution) between the new mean and the previously defined " 1 in 10 year limit" is given by:

$$
\left(\left(X_{1}+2.41 \times u_{1}\right)-X_{2}\right) / u_{2}
$$

where $X_{1}, u_{1}=$ mean and intra-annual deviation from 1961-1990 and $X_{2}$, $u_{2}=$ mean and intra-annual deviation under new scenario.

The probability that this difference will be exceeded in any one month under the new distribution was taken from probability tables. This was divided by the frequency of occurrence under the baseline scenario $(=0.008)$ to give the relative frequency of exceeding the 1 in 10 year limit
for each future scenario. Results were weighted by the population in each cell, and averaged across the countries in each subregion. The final measure of exposure was therefore the relative frequency with which each person in a subregion experiences 1 in 10 year rainfall events.

The process of estimating the disease burden of this change in frequency differs from that for other climate-sensitive health outcomes, as flood effects do not have a specific GBD code. Relative risks should therefore be applied to estimates of health consequences such as deaths and injuries attributable to these climate events under baseline climate (i.e. rather than change in total incidence of this outcome).

The EM-DAT database records numbers of deaths and injuries attributed to each natural disaster reported by the media or aid agencies in the last 100 years. Disasters are defined as events that resulted in at least one of the following conditions: (i) >10 people killed, (ii) $>200$ injured, (iii) a call for international assistance. Although this is the best comprehensive data source available on the current health consequences of natural disasters, all such sources may be subject to underreporting (Noji 1997). Estimates of attributable burden of disease derived from these figures are therefore conservative.

Individual events in the database were classified as inland or coastal floods on the basis of geography, or descriptions of events in the database. Total numbers of deaths for each class of event were summed for subregions. Although the EM-DAT database also records the number of injuries in flooding events, these are not included in this assessment, as they are considered particularly unreliable for floods (Guha-Sapir, personal communication, 2002). The effects of events that could not be identified as inland or coastal were assigned in proportion to the distribution of consequences of classified events in each subregion. The annual incidence of flood death under baseline climate conditions was estimated by dividing the annual average over the last 20 years by the subregional population in 1990.

These baseline incidence rates alter over time, depending on the balance between factors that decrease vulnerability (particularly improving flood defences as populations become richer), and those which increase vulnerability (particularly increasing population density in coastal zones and other flood-prone areas). Baseline estimates for future years were therefore adjusted as far as possible for these effects. For coastal flooding, the effects of projected changes in population distribution in relation to coastline and improving coastal defences in line with GDP were incorporated in the model of Nicholls et al. (1999). The baseline estimates of the incidence of deaths and injuries in years after 1990 were therefore scaled by the ratio of the model projections for numbers of people flooded in each year compared to that in 1990 (Table 20.11).

Such vulnerability effects have not been explicitly modelled for inland flooding. However, Yohe and Tol (2002) have carried out a cross-

sectional analysis of the effect of per capita income on the incidence of death due to all natural disasters (as reported in the EM-DAT database) for the period 1990-2000. They conclude that increasing wealth has a protective effect, best described by:
$\operatorname{Ln}$ (proportion of population killed/decade)
$=4.7271-0.3858(\mathrm{Ln}$ GDP per capita)

The effect of income is marginally non-significant at the $5 \%$ level ( $P<0.07$ ), generic to all natural disasters and does not take account of the magnitude of the physical hazard. However, this is likely to introduce noise rather than bias in the relationship, and the relationship represents the only published basis for projection of the protective effects of economic development. The relationship is therefore applied to future projections of GDP (WHO/EIP/GPE, unpublished data, 2000). Our projected baseline incidence of deaths for years after 1990 were scaled by the ratio of the projections of deaths due to all natural disasters in that year divided by the estimate for 1990 (Table 20.12).

Some evidence from studies of a small number of earthquakes (Beinin 1981) and famines (Rivers 1982) suggests that women and young children are more vulnerable than men to the acute effects of natural disasters. However, there are insufficient data to derive subregional estimates

of the relative vulnerability of different age groups and sexes to the consequences of flooding: we therefore made the assumption, that all age groups are equally at risk.

The models presented here for coastal flooding assumed that protection evolves over time in proportion to projected increases in GDP. The mid-range estimates presented therefore incorporated an effect of increasing wealth, not only in the baseline estimates, but assumed the same proportional change in the relative risks (i.e. as described by Yohe and Tol 2002). This accounted for the effect of increasing wealth not only in reducing the likely health consequences of "baseline" (i.e. climate change independent floods), but also providing better adaptive capacity for increases driven by climate change. The mid-range estimates did not include any further adjustments for biological/behavioural adaptation to increased flood risk (Table 20.13).

As for other health outcomes of climate change, the only published sensitivity analyses relate to an unmitigated emissions scenario applied to the HadCM2 model with four slightly varying sets of initial conditions, and a comparison with the same emissions scenario run on the HadCM3 model. These resulted in almost no difference in model outputs over the time-scale considered in this assessment. Uncertainties in the model relate to the degree and manner to which individuals respond to

the increased risk (Hoozemans et al. 1993). The lower estimates therefore assumed that $90 \%$ of the risk could be avoided either by highly efficient coastal defences or individual adaptations. The higher estimates assumed no adaptation either with increasing GDP or individual level measures.

The model for inland flooding was subject to the same uncertainty over adaptive responses. Both the baseline and relative risks were assumed to change with GDP, as described for coastal flooding. As outlined above, however, the uncertainty is also greater for a hazard driven by the magnitude and temporal variation of precipitation (which varies considerably between climate models), rather than the more predictable process of temperature-driven sea level rise. This consideration is particularly important as only one climate model was used in this assessment. Although the relative risks estimated by our method (e.g. 5.53 for our estimates for EUR-A by the year 2030 under an unmitigated emissions scenario) were broadly comparable to estimates of changes in frequency of extreme wet seasons generated using multi-climate model analyses (fivefold for northern Europe for the period 2060-2080; Palmer and Ralsanen 2002), more formal analyses would be necessary to give more accurate estimates. We therefore gave a larger uncertainty range around these predictions than for coastal flooding, by assuming a $50 \%$ greater exposure and no adaptation with GDP for the high estimate, and no increase in risk under any scenario for the lower estimate (Table 20.14). As for the other outcomes, this uncertainty range should be interpreted with caution.

The potential health consequences of changing frequency and intensity of extreme weather events are surprisingly poorly researched. Substantial improvements in assessment could be made through better estimates of the current health impacts of natural disasters, which suffer from poor baseline data and probably severe underreporting, particularly in developing countries (Noji 1997). Analyses could also be greatly improved by geo-referencing and more detailed descriptions of disasters to allow differentiation of inland and coastal events, detailed analysis of the relationships between intensity of precipitation and health effects, and projections of future precipitation at higher temporal and spatial resolution, using output from a range of climate models. In order to generate better uncertainty estimates, formal sensitivity analyses of the contributions of each model parameter to the final uncertainty estimates are required.

Finally, it should be stressed that the estimates given here represent the immediate acute consequences of natural disasters, which are likely to be only one component of the total attributable disease burden. Other outcomes of these natural disasters need to be considered, such as the probability of outbreaks of water, vector- and rodent-borne diseases, the effects of sequential disasters on both public health defences and stability of natural ecosystems limiting disease outbreaks (Epstein 1999), and

[^74]longer-term effects such as post-traumatic stress after floods (e.g. Phifer 1990) and of population displacement through coastal flooding. More importantly, it is necessary to expand the range of natural disasters beyond those considered in this chapter. There is an obvious causal chain between apparently increasing variability in precipitation frequency of droughts and their associated health consequences, particularly food shortages and possible famine (UNDMTP 1990; WHO/PTC 1995). While these impacts may be expected to increase under climate change, no models have yet been developed to link climate scenarios, frequency of drought, and associated health effects, so that quantitative estimation of climate change effects is not currently possible. Given the global importance of drought-related disease (WHO/EHA 1998) and the effectiveness of early preparation and rapid response for avoiding health impacts (Gupta 2000; WHO/EHA 2002), this is clearly a priority area for research.

### 3.10 Vector-borne diseases

Viruses, bacteria, protozoa and helminths transmitted by biting insects and other intermediate hosts are among the most important causes of ill-health in tropical regions (WHO 2000b). The climate sensitivity of such diseases has long been recognized (e.g. Celli 1933), and knowledge of the relationships has been used to help predict epidemics of vectorborne diseases since at least the early years of the last century (e.g. Christophers 1911; MacDonald 1957). More recently, there have been many quantitative studies of the effects of climate variables on the population biology of vectors and pathogens in the laboratory (e.g. reviews by Martens 1998b; Massad and Forattini 1998), and on spatial and temporal variations in vector abundance and disease incidence in the field (review by Kovats et al. 2000a). The results of a literature review are shown in Appendix B, Tables B. 5 and B.6.

This climate sensitivity has prompted several studies correlating longterm changes in vector distribution (Lindgren et al. 2000) or disease incidence (e.g. Bouma et al. 1996; Loevinsohn 1994) with local climate trends, which apparently reflect global climate change. However, many of the inferences about resulting health consequences have been called into question, due to concurrent local changes in crucial non-climatic factors, such as human behaviour, disease reporting or control programmes (Hay et al. 2002; Mouchet 1998; Randolph 2001; Reiter 2001).

As for other health effects, it is unlikely that simply correlating longterm trends in disease against trends in climate will soon (or perhaps ever) give unequivocal evidence of the effects of gradual climate change. As climate varies naturally between years, long time-series (i.e. two to three decades) will be needed for statistical tests of association in longterm trends. It is almost inevitable that non-climatic determinants of risk will also change over such long periods, either obscuring or offering
alternative explanations for any effects of climate change. In addition, reliable multi-decadal time-series for vector-borne diseases in developing countries are rare, and it is problematic to interpret analyses of a few data sets as evidence of a general global pattern. Recent reviews therefore suggest that a general effect of climate change on vector-borne disease, while suspected and possible, is highly dependent on other nonclimatic factors that act at a small scale (IPCC 2001a; Kovats et al. 2001, Reiter 2001, Reiter et al. 2003).

Despite the practical problems in making direct correlations with recent trends, the extreme climate sensitivity of vector-borne diseases means that it is almost inevitable that they will respond in some way to climate change, in some settings and to some degree. The most reliable basis for estimating such changes should come from information on the relationships between variations in climate and disease in either the past or present. Several studies have used such data to model the effect of predicted climate change on either the distribution of vector-borne diseases, and/or measures of risk within existing or predicted newly endemic areas. The data, techniques and assumptions used in the various analyses are reviewed in detail in later sections.

Whatever the quality of the data and modelling techniques used for predictions, they will remain contingent upon other determinants of disease. Socioeconomic conditions, control programmes, human immunity and the specific combinations of climate variables required by particular vector species or transmission cycles also affect disease incidence, and may be more important than global climate trends, particularly at small spatial scales (Mouchet and Manguin 1999; Randolph et al. 2000; Reiter 2001; Rogers and Randolph 2000; Sutherst 1998).

The IPCC has reviewed the observed and predicted effects of climate variability and change in the context of the other factors listed above (IPCC 2001a). On balance, the IPCC concludes that climate change is likely to expand the geographical distribution of several vector-borne diseases, including malaria, dengue and leishmaniasis to higher altitudes (high confidence) and higher latitudes with limited public health defences (medium/low confidence), and to extend the transmission seasons in some locations (medium/high confidence). For some vector-borne diseases in some locations, climate change may decrease transmission by reductions in rainfall or temperatures too high for transmission (medium/low confidence).

The associations between climate and infectious diseases have also been reviewed by the United States National Research Council (National Research Council 2001b). The review highlights the climate sensitivity of vector-borne diseases, and describes some studies modelling the potential consequences of future climate change on vector-borne diseases. The report re-emphasizes the need for caution when making future projections, and stresses the importance of public health provision in mitigating increases in incidence driven by climate change. No judgement is
made on the likely effects of future climate change on specific diseases, owing to the limited evidence.

Aside from analyses of the potential effect of gradual changes in average climate conditions, predicted increases in climate variability, including possible increases in the frequency and intensity of El Niño events (IPCC 2001b), may also affect vector-borne diseases. There is evidence that the El Niño cycle causes inter-annual variations in disease incidence in several areas (e.g. Bouma et al. 1997b). However, even in these sites, other determinants such as seasonal variations and control programmes exert a larger influence, and epidemic cycles also occur in areas where El Niño has little or no effect on climate, apparently driven by gradual post-epidemic waning of herd immunity (Hay et al. 2000). As the effect of climate variability differs so greatly between sites, global projections of the associations described so far are unlikely to be informative.

## Modelling of specific diseases

Most modelling of the effects of climate change has focused on malaria, and to a lesser extent dengue. These are therefore the only vector-borne diseases considered here. Some preliminary modelling work has been carried out on schistosomiasis (Martens et al. 1997), but this is based on a relatively small data set and has not been validated against current distributions. Randolph and Rogers (2000) have also modelled the potential effects of climate change on tick-borne encephalitis (TBE) in Europe, demonstrating that increased temperatures are likely to reduce the endemic range. Although TBE is a relatively small public health problem in global terms, and was not covered in this assessment, this study does demonstrate that climate change may potentially decrease, rather than increase, the transmission of some diseases. Effects on other major vector-borne diseases have been investigated either qualitatively (e.g. Carcavallo and Curto de Casas 1996 for American trypanosomiasis) or in terms of distribution of vectors rather than human disease (e.g. Rogers and Packer 1993 for African trypanosomiasis).

## Falciparum malaria

Falciparum malaria is unusual in that several research groups have independently modelled the relationships between climate and disease distribution (Appendix B, Table B.5). The models used can be broadly classified as structural/biological, based on aggregating the effect of climate on the individual components of the disease transmission cycle, or "statistical", derived from direct correlations between geographic or temporal variations in climate, and associated variations in disease incidence or distribution, either in the present or recent past.

Published biological models for the global distribution of falciparum malaria use laboratory data to define the relationship between temperature and the extrinsic incubation period of the parasite, and therefore
the probability of completing development during the lifetime of the mosquito and completing the transmission cycle (Martin and Lefebvre 1995). Later models incorporate temperature effects on the survival probability and biting frequency of mosquitoes (Jetten et al. 1996; Martens et al. 1995a, 1995b, 1999). In these later models, the various temperature-dependent relationships are aggregated into the entomological version of the equation for $R_{o}$, the number of cases arising from each new case in a completely susceptible population (Anderson and May 1991; Dye 1992; Garrett-Jones 1964). Because of the lack of data on several key parameters, these are set as biologically plausible constants, allowing the calculation of the critical vector density required for sustainable disease transmission (i.e. $R_{0}>1$ ). This threshold is lower under more suitable (generally warmer) climate conditions. The inverse of the critical density threshold, the "transmission potential", is used as a relative measure of transmission intensity under different climatic conditions. The models also assume a threshold level of transmission potential required to sustain transmission, which allows the identification of areas that are climatically suitable for transmission under both observed and projected climate scenarios.

These studies highlight the extreme climate sensitivity of several stages of the malaria transmission cycle. By aggregating these effects into a single measure related to $R_{o}$, they demonstrate that even small temperature increases could potentially cause large relative increases in risk, particularly at the edges of the distribution where temperature may be a limiting factor. They also suggest that those areas climatically suitable for Plasmodium falciparum transmission could expand substantially.

While valid for their original purpose as sensitivity analyses for relative changes in risk, these models are not ideal for defining the most probable changes in either geographical distribution or disease burden within endemic areas. Both outputs require the calculation of absolute rather than relative values of $R_{\mathrm{o}}$, so as to identify areas where $R_{0}>1$, allowing disease transmission to persist. In these incomplete biological models, such calculations are partly dependent on parameter values that are arbitrarily defined in the absence of empirical data (Rogers and Randolph 2000). As the models are based on temperature relationships derived from the laboratory, they also rely on the assumption that meteorological station data accurately represent the climatic conditions that mosquitoes and parasites experience in the field-which disregards the possibility that vectors might exploit microhabitats that are very different from those in meteorological stations. Since the outputs from these models have not been validated against current disease distributions, they were not used in this assessment.

In the absence of data to generate complete biological models of all stages in the transmission cycle, an alternative approach is to use statistical relationships to define only the distributional limits of disease. Although this approach does not allow disaggregation of the specific
mechanisms driving the climate-sensitivity of vector-borne diseases, it is generally considered more objective than the use of incomplete biological models, in that model outputs are not dependent on arbitrarily defined parameter values.

The international MARA (Mapping malaria risk in Africa) collaboration generated a model that used a combination of biological and statistical approaches to define the limits of climate suitability for falciparum malaria in Africa (Craig et al. 1999). Laboratory data on the rate of development of falciparum parasites (Detinova 1962) and laboratory and localized field observations of temperature effects on mosquito survival (Haddow 1943; Jepson et al. 1947; Le Sueur 1991; Maharaj 1995) were used to define upper and lower thresholds for mean monthly temperatures, and winter minima, which would allow both mosquito survival and the completion of the parasite extrinsic incubation period during the lifetime of mosquitoes, thereby permitting transmission. Rainfall thresholds were defined by comparing regions with and without stable malaria transmission, which have similar temperature conditions but different precipitation profiles. In order to take account of uncertainty about the precise values of the upper and lower bounds of temperature and rainfall necessary for transmission, climatic conditions near to the thresholds were not defined as either entirely suitable or unsuitable. Instead, they were assigned a probability of suitability between 0 and 1, defined by a "fuzzy membership curve", which is assumed to follow a pre-specified sigmoidal shape between the plausible values for the upper and lower thresholds for each climate variable (e.g. a decreasing probability of suitability between mean temperatures of 32 and $40^{\circ} \mathrm{C}$ ). These relationships were applied to high-resolution interpolated maps of climate throughout Africa (Hutchinson et al. 1996) to define areas that meet all suitability conditions (i.e. both temperature and rainfall) throughout the continent. For validation, model outputs were visually compared with independent high-resolution maps of the edges of the distribution, based either on field surveys or expert opinion. The model showed a good fit to the observed distributions in both southern Africa and East Africa.

The main advantages of this approach are that the model:

- describes only the cut-offs for any level of transmission, rather than quantitative estimates of transmission risk: it therefore does not rely on arbitrarily defined parameter values to complete the $R_{o}$ equation;
- represents uncertainty around the edges of the distribution;
- allows description of seasonal patterns of transmission, based on the suitability of individual months; and
- most importantly, has been compared with current and historical distribution maps which are apparently independent of the model building process.

The main caveats are:

- the reliance on laboratory data and a small number of field studies to define climate cut-offs;
- apparent subjectivity in at least one parameter estimate (the proportion of mosquitoes that need to survive the sporogonic cycle in order to maintain transmission, which defines the precise value of the lower temperature cut-off);
- the need to make an assumption about the shape of the "fuzzy membership curve"; and
- lack of systematic empirical validation (validation by visual comparison, rather than calculating diagnostic statistics).
While each of the assumptions can legitimately be questioned, the visual validation suggests that the data and assumptions used are at least reasonably accurate. Again, there are further caveats in using the model to try to describe the true global distribution of falciparum malaria (rather than just climatically suitable areas), either now or in the future. To use such models, it is necessary to make the assumptions that distributions vary directly with climate, without any interactive effect of control programmes, or socioeconomic conditions. The comparisons of model outputs with current data suggest that this is a reasonable assumption for most of sub-Saharan Africa, although control programmes have altered distributions in South Africa. The assumption is much less secure for other endemic regions, which are invariably richer.

The relationship between climate variables and the global distribution of malaria can also be defined in statistical terms. Rogers and Randolph (2000) converted WHO maps (WHO 1997) of the limits of reported malaria distribution in the 1990 s into $0.5^{\circ} \times 0.5^{\circ}$ resolution grids, coding each cell as either endemic or non-endemic. These grid maps were overlaid on $0.5^{\circ}$ grid maps describing climate surfaces for the period 1961-1990. A statistical model was generated by randomly selecting a subsample of $50 \%$ of the observations of disease presence or absence. First, grid-cells were assigned by applying $k$-means clustering to six groups based on climatic similarity, thereby allowing for potentially different climate-disease relationships in different ecological zones. Stepwise discriminant analysis was applied to find the combination of temperature, rainfall and humidity parameters that gave the greatest statistical differentiation between positive vs negative grid cells within each cluster. The model was then applied to the remaining $50 \%$ of the observations to assess model accuracy. The fit of the predicted distributions to the observed WHO malaria maps was found to be significantly better than for previous falciparum malaria models: $77.71 \%$ of grid cells correctly predicted for this model vs $75.79 \%$ for Martin and Lefebvre (1995) and $67.26 \%$ for Martens et al. (1999).

The principal advantage of this approach is that it is entirely data driven. The relationships between global climate and malaria distributions are defined using transparent statistical techniques, applied to both disease and climate data from throughout the globe. They therefore do not require either unsupported assumptions of parameter values in order to complete a biological model, or global extrapolation of data from a limited number of observations. In addition, by mapping the observed distribution rather than climatically suitable areas, such analyses do not require the assumption that distributions are defined only by climate.

Despite these advantages, the quality of the data available at the global scale places several limitations on global statistical models. WHO maps of observed distributions are based on a combination of field observations and expert opinion to draw "inclusive" boundaries of the extremes of distributions. In many cases the maps define large areas as endemic (e.g. all of sub-Saharan Africa north of South Africa, Namibia and Botswana), although significant areas are actually disease free, often apparently due to unsuitable climate. WHO maps (and therefore the statistical relationships) also do not differentiate between malaria caused by P. falciparum and Plasmodium vivax, which have quite different sensitivities to temperature (Detinova 1962; MacDonald 1957). It is unclear what effect these two simplifications may have on the climate sensitivity of the model.

For this assessment, projected changes in temperature and rainfall under each of the alternative climate scenarios relative to the baseline (1961-1990) climate were mapped at the resolution of the HadCM2 climate model ( $3.75^{\circ}$ longitude by $2.5^{\circ}$ latitude). Maps of future climate were then generated by adding these values to maps of baseline climate for the 1961-1990 climate at $0.5^{\circ}$ resolution ( $0.05^{\circ}$ resolution for the MARA malaria model in Africa; Hutchinson et al. 1996).

An adapted version of the MARA climate model described in detail above (Tanser et al. 2003) was used to generate the mid-range estimates for this assessment. This decision was based on the independent (though continental rather than global) verification, plus the fact that the model was developed and tested using data from throughout Africa (where the overwhelming majority of the burden of malaria currently occurs, and where accuracy is therefore most important), and the potential for developing projections of increased force of infection and disease incidence in the near future.

The model was applied to the global climate maps for baseline climate, and for the unmitigated emissions scenario for the 2020s and 2050s. Relative risk estimates presented here were the ratios of the projected population at risk (i.e. living in areas climatically suitable for $>1$ month falciparum malaria transmission per year) in each subregion under climate change, relative to the population at risk under the 1961-1990 climate. As an approximation, estimates for the s750 and s550
scenarios were derived proportionately by multiplying the relative risks under unmitigated climate change by the ratio of global temperature change under each scenario/change under unmitigated emissions (Table 20.15). This model gave considerably larger estimates of changes in population at risk than the statistical model of Rogers and Randolph (2000), which predicted approximately no overall change under an unmitigated emissions scenario by the 2050s. In the absence of further comparisons and formal uncertainty assessments, our lower range estimate therefore included the possibility of no change in risk in any subregion. The upper range estimate is a doubling of the mid-range estimate from the MARA model. We emphasize that given the difficulties in validating any specific model and its suitability for extrapolation to other subregions, the choice of MARA climate model over the other possible models was somewhat arbitrary.

In addition, the calculation of disease burdens requires estimates of change in incidence within each subregion, rather than population at risk. In the absence of models for changes in malaria incidence within endemic regions, we therefore made the assumption that relative changes in incidence will vary in direct relation to predicted changes in population at risk-that is, a doubling of the population at risk within a region will lead to a doubling of the clinical disease incidence.

These measures are related in broad terms: countries or regions with higher populations at risk tend to have higher incidence and disease burdens. However, this relationship is a crude generalization, as it assumes that these relationships will remain constant as the population at risk expands or contracts. This may lead to underestimation of effects, if there is an increase in transmission within already at-risk populations, driving up infection incidence. Alternatively, this relationship may overestimate risk, depending on the extent to which increasing vectorial capacity promotes herd immunity (Rogers et al. 2002), and causes first infections to occur earlier in life, when patients suffer less severe clinical symptoms for some diseases, potentially conferring immunity on the more clinically vulnerable older age-groups (Coleman et al. 2001; Snow and Marsh 1995). In addition, socioeconomic conditions and control programmes clearly influence vector-borne diseases. Future changes in these factors are likely to affect (and hopefully reduce) transmission, as they have done in some regions in the past (e.g. Jetten and Takken 1994; Reiter 2001). The role of adaptation was discussed in section 2.5.

By applying relative risks to baseline incidences of zero in some subregions, our assessment did not allow for the spread of disease from endemic subregions to non-endemic subregions. This is a reasonable, but conservative assumption: non-endemic subregions have better developed health systems and a less amenable socioeconomic environment, in addition to usually being cooler. These factors may protect against reestablishment of vector-borne disease transmission (IPCC 2001b; Kuhn et al. 2003), providing they are maintained.
Table 20.15 Central, low and high estimates of the relative risk of falciparum malaria for alternative climate scenarios relative to baseline climate

[^75]
## Dengue

Several studies have explored the relationship between climate and the distribution of intensity of dengue transmission (see Appendix B, Table B.6). Most are derived from a series of biological models that relate climate variables to determinants of the population biology of Aedes vectors (Focks et al. 1993a, 1993b) and dengue transmission (Focks et al. 1995). Adaptations of these models to map climate relationships at the global scale (Jetten and Focks 1997; Martens et al. 1997; Patz et al. 1998) have used field and laboratory data to define the relationships between temperature and the length of the gonotrophic cycle (and the associated feeding frequency), larval weight (and therefore the need to take multiple feeds within a single cycle), and the extrinsic incubation period of dengue virus within the vector. Mosquito survival, human biting habit and the duration of human infectiousness are set as tem-perature-independent constants, with parameter values defined using field data from a number of sites.

As for the biological models of malaria, these relationships are aggregated into a simplified version of the $R_{o}$ equation, excluding measures of vector abundance. This equation is again used to define the critical density threshold (the number of mosquitoes which would be required to maintain $R_{0}>1$ ), and its inverse, "transmission potential" or "transmission intensity". The model has been applied to local climate data in a series of sites, and the rank order of monthly predicted values of transmission potential showed good correspondence with the observed seasonal distribution of dengue cases (e.g. Pearson's $R=0.837$ in San Juan, Puerto Rico).

These models have similar characteristics to the biological models for malaria. By aggregating temperature effects from various stages of the transmission cycle, they demonstrate that overall dengue risk is likely to be extremely sensitive to even small changes in temperature. Sensitivity analyses show that a $2^{\circ} \mathrm{C}$ increase in global temperature would lead to large (commonly 1-5 times) increases in transmission intensity in many regions of the world. However, these models are also subject to the same caveats. As there are no data available on mosquito abundance throughout the globe, or the relationship between vector abundance and climate variables, the transmission potential remains a relative rather than absolute measure of $R_{0}$. It is consequently unsuitable for defining the conditions under which transmission can persist, and therefore mapping the distributional limits of dengue either now or in the future. In addition, although the validation exercise demonstrates that transmission potential is correlated to the incidence of infection and clinical disease, in that months with higher transmission potential have more cases, the quantitative relationships have not been explicitly defined. It is therefore difficult to interpret exactly what effect a doubling of transmission potential (for example) would have on the burden of disease caused by dengue.

Methods similar to those used by Rogers and Randolph (2000) for malaria have recently been applied to define the relationship between multiple climate parameters and the reported geographic distribution of dengue. Hales et al. (2002) used WHO data (WHO 2000a) to map reports of dengue transmission during the period 1975-1996 at the level of the country, or smaller administrative area when this was specified in the report. These were converted into grid maps at $0.5^{\circ}$ resolution. Logistic regression analysis was then used to correlate presence or absence of reported transmission against the average values of various climate parameters (monthly average rainfall, vapour pressure, and maximum, minimum and mean temperature) for the corresponding gridcells throughout 1961-1990. Vapour pressure (approximately equivalent to absolute humidity, and reflecting both temperature and precipitation) gave the best discrimination between areas with and without reported dengue transmission, with no other climate variables adding significant explanatory power. The accuracy of the model was assessed by crossvalidation, repeatedly using $95 \%$ of the data to generate predictions for the remaining $5 \%$. The model gave correct predictions of observed presence or absence for an average of $89-92 \%$ of grid-cells, with the precise accuracy depending on the radius over which vapour pressure was considered. The limitations of this model are similar to the statistical model for malaria. To be consistent with the choice and exclusion of models for malaria, the model of Hales et al. (2002), which is similar to the excluded model of Rogers and Randolph (2000), was not used in the estimates of disease burden.

## Future research

A comprehensive analysis would require the generation of predictive models for other important vector-borne diseases. There is also a need to investigate the effect of the predicted increases in climate variability (e.g. more frequent or more extreme El Niño events), especially on the frequency and intensity of epidemics.

Most importantly, more reliable estimation would require models that cover all stages of the causal chain from climate change to clinical outcome. These should explicitly address the role of socioeconomics and control in determining absolute, rather than relative, measures of $R_{0}$. This would allow better definition both of the geographical limits of transmission, and of variations in the incidence within existing or potentially newly endemic regions. They should also address the role of hostimmunity in protecting individuals and populations from clinical disease, as exposure to infection changes. Such models would represent a considerable advance over the assumption made here, that changes in the proportion of the populations at risk within a subregion will be reflected in proportional changes in the burden of disease.

For the purpose of health assessments, the nature of the model (i.e. whether each of the biological processes are modelled separately and
then aggregated, or whether climate is statistically related directly to empirical measures of disease burden) is probably less important than model accuracy. There is a clear need for greater model validation, by comparison of predictions with geographical and temporal patterns of infection and disease in the present and recent past. The most urgent requirement for all of these objectives is the availability of better quality surveillance data on infection and disease, from a wide variety of geographical and socioeconomic settings.

Finally, the potential effects of future climate change on vector-borne diseases (or other diseases) should not divert attention or resources from current control efforts. On the contrary, they provide the additional argument that disease control now should also reduce vulnerability to climate change in the future.

## 4. Results

Summary measures of the effects of climate change on health are presented in this chapter only for the estimated current effects, using the relative risks obtained by extrapolation of the future predictions, as described in section 2.6. The estimates presented here did not attribute DALYs to cardiovascular deaths due to thermal extremes, and excluded any increase due to dengue (see sections 3.6 and 3.10 ). They should be interpreted with caution as, in contrast to most other risk factors, they relied on modelled rather than directly observed outcomes. They did, however, indicate the estimated distribution of impacts both among geographical regions and among the various causes of disease (Tables 20.16 and 20.17). The models may also be useful for the secondary purpose of indicating the magnitude of health impacts that might already be caused by climate change, but which may not be detected by direct observation using current surveillance systems.

The various causes considered here differed markedly in their contribution to the estimates of the overall burden of disease. In our analysis, climate-change effects on malnutrition, diarrhoea and vector-borne diseases appeared considerably more important than effects on flooding, or on deaths attributable to thermal extremes. It should be noted that, with the exception of malaria, these outcomes are relatively poorly studied in comparison with the direct effects of thermal stress.

The health consequences of climate change are distributed very unevenly among regions. Estimated DALY burdens per capita are several hundred times greater in the poorer regions of Africa, parts of the Eastern Mediterranean region and South-East Asia than in western Europe, North America and the more developed regions of the Western Pacific. This is largely a reflection of the much higher baseline incidence of the most important climate-sensitive diseases (malaria, diarrhoea and malnutrition) in these poorer regions, but also of greater vulnerability to climate change effects. Because these major climate-sensitive diseases

CVD Cardiovascular disease. As described in section 3.6, the estimated cardiovascular deaths represent temperature-related mortality displacement. Therefore no disease burden is estimated for deaths from this cause in Table 20.I7.
mainly affect younger age groups, the health burden associated with climate change appears to be borne mainly by children rather than adults.

## 5. Discussion

The collective scientific evidence indicates that anthropogenic climate change has already begun and will continue, with potential consequences for human health. Global warming over the past quarter-century was of the order of half a degree centigrade. Such a gradual change is partly obscured by natural climate variability and affects health through complex causal pathways. These characteristics, coupled with considerably larger effects of other factors in the most vulnerable populations, mean that it is inherently difficult to measure directly net health losses or gains attributable to the climate change that have occurred until now.

However, climate change differs from most other health determinants in that considerable effort has been devoted to generating and evaluating formal models to forecast future climate, in response to likely trajectories of atmospheric gas composition. These models are in general agreement that over the next $50-100$ years global warming will be approximately five times greater than has been experienced in the last

25 years, with associated changes in other potentially hazardous climate characteristics, such as the frequency of extreme precipitation events.

Such modelling is at a relatively early stage. Few modelling studies have estimated health effects at the global scale, and not all of these directly estimate incidence or prevalence of GBD outcomes. However, they provide the best current basis for making indicative forecasts in order to inform policy decisions. These models nevertheless make only crude adjustments for the effects of other variables (such as decreasing poverty), which may both determine the vulnerability of populations to potential health effects of climate change, and exert much larger independent effects on health. Taking each disease in turn:

1. We estimated a small proportional decrease in cardiovascular and respiratory disease mortality attributable to climate extremes in tropical regions and a slightly larger benefit in temperate regions, caused by warmer winter temperatures. Although these proportional changes are modest, they apply to significant causes of death. Uncertainties around these estimates are largely due to lack of knowledge of the degree to which populations physiologically and behaviourally adapt to increasing temperatures.
2. The relative risk for diarrhoea in 2030 in developing regions was estimated to be between 1 and 1.1 under unmitigated emissions compared with baseline climate. Richer countries (GDP > US\$ 6000/year),
either now or in the future, were assumed to suffer little or no additional risk of diarrhoea. Again, these small changes in relative risk relate to a major cause of ill-health. Uncertainties were mainly due to poor characterization of variations in the relationship between climate and diarrhoea in more or less developed regions, which have different balances between pathogens preferring higher or lower temperatures.
3. Estimated effects on malnutrition varied markedly across subregions. By 2030, the relative risks for unmitigated emissions relative to no climate change varied from a large increase ( $\mathrm{RR}=1-1.33$ ) in SEAR-D to a small decrease ( $\mathrm{RR}=1-0.99$ ) in WPR-B. Developed countries were assumed to be immune to climate change effects on malnutrition. There was no consistent pattern of reduction in relative risk with intermediate levels of climate change stabilization. Apparent inconsistency in the estimates may be due to the high sensitivity of the models to regional variations in precipitation, for which future projections are much more uncertain than for temperature. Although these estimates are somewhat unstable, they are relatively large, and again relate to a major disease burden.
4. We estimated much larger proportional changes in the numbers of people killed in coastal floods (RR of up to 6.3 in EUR-B for unmitigated emissions compared to baseline conditions in 2030), but applied to a very low burden of disease. Consequences of inland floods were predicted to increase by a similar order of magnitude $(R R=$ $1-18.5$ in AMR-A), and are generally more common. In contrast to most other outcomes, the increase in relative risk tended to be at least as high in developed as developing subregions. However, these apply to baseline rates that are much higher in developing than developed countries. Both estimates are subject to uncertainty around the likely effectiveness of adaptation measures. Inland floods are subject to additional large uncertainties around the quantitative relationships between changes in the intra-annual variation in precipitation (on which our model is based), the magnitude and geographical distribution of extreme precipitation events, and in turn the frequency of flooding and its health consequences. The suggestion of a trend towards decreasing incidence with increasing GHG emissions in some regions is probably due to the uncertainties in predicting precipitation trends. As projections for precipitation are less secure than for temperature, mid-range estimates and uncertainties around the effects of inland floods could be much better described using multiple climate models, rather than the single model used in this assessment.
5. We estimated relatively large changes in the relative risk of falciparum malaria in countries at the edge of the current distribution, for example, increases in relative risk of falciparum malaria of between

1 and 1.83 in WPR-B by 2030. Relative changes were much smaller in areas that are already highly endemic for these diseases. The principal uncertainties specific to these estimates related to the reliability of extrapolations made between subregions, the relationship between changes in the population at risk of these diseases, and incidence (and therefore disease burden), and over the degree to which changes in the non-climatic influences on vector-borne diseases could affect not only the baseline rates of disease, but also interact with climate change to affect the relative risks.

The estimates for the year 2000 (Tables 20.16 and 20.17) suggest that, according to models summarizing our current knowledge of the relationships between climate and health, past climate change may already be causing some health consequences.

These relative risk estimates are much greater for projections into the future, as climate change continues. Both current and future estimates show extreme variations in the estimated effects among geographical regions. Negative consequences are overwhelmingly concentrated in the developing regions of the world (particularly in Africa and the poorer regions of the Eastern Mediterranean and South-East Asia). This is partly a function of variation in baseline climate (hot regions suffer more from increases in temperature), but more importantly due to population vulnerability (e.g. developed countries are assumed to be completely immune from some diseases, such as malnutrition).

Global models have not yet addressed all of the likely effects of climate change on health. The potential omissions are many infectious diseases, the health consequences of drought and famine (beyond those included in current estimates of malnutrition), population displacement, destruction of health infrastructure in natural disasters, increased pollution and aeroallergen levels, effects of plant pests and diseases on agriculture, and risk of conflict over declining natural resources. It is likely that these health consequences will be larger than those estimated in this chapter.

Although incomplete and encompassing a wide uncertainty range, the results of these analyses suggested that the attributable burden of climate change is likely to be significant, even under the relatively short (in climatological terms) time-scale considered for the comparative risk assessment (CRA). The effect of plausible reductions in climate change was estimated to be relatively small over this assessment period. However, the health gains would clearly be much greater over longer time periods. Given the long time-lag and apparent irreversibility of climate change, early mitigation should therefore result in long-term health benefits. Our results therefore indicate the urgent need for: (i) consideration of optimal policies to reduce climate change; (ii) strengthening of current actions to control climate-sensitive diseases, both as ends in themselves, and as adaptation to future climate change; and (iii) con-
tinued research to revise and narrow the uncertainty range around the estimates of disease burdens.

This assessment has highlighted the most important gaps in data and understanding that should be addressed for the next global burden of disease assessment. Marked improvements in our assessment of this risk factor would come from:

- the use of multiple climate models;
- climate-health relationships derived from a greater range of climatic and socioeconomic environments;
- more explicit and routine validation of the accuracy of disease models in the present or recent past;
- formal analyses to aggregate uncertainty arising from multiple causes (i.e. GHG emissions scenarios, climate models, climate-health relationships, and effect modifiers);
- efforts to formally model climate change effects through to disease burden, rather than intermediate indicators such as population at risk;
- a greater emphasis on investigating the consequences of increased climate variability, rather than gradual changes in mean conditions; and
- the development of analytical tools to assess outcomes acting through more complex causal mechanisms.

## Acknowledgements

To Matthew Livermore, Tim Mitchell, David Viner, Pim Martens for provision of data and advice; Richard Tol for provision of unpublished data; Debarati Guha-Sapir for advice on EM-DAT disaster data; Clive Davies, Paul Coleman, Sandy Cairncross, Bo Draser, Alessandro Loretti, Charles Delacollette, Monika Blössner, Mercedes de Onis, Rosalie Woodruff, Will Checkley; and nine referees, for helpful review comments.

## Steering committee

Carlos Corvalan, Annette Prüss-Ustün, Roberto Bertollini, Bettina Menne, Andy Haines and Alistair Woodward.

## Note

1 See preface for an explanation of this term.

## Appendix A: Uncertainty around climate predictions

Results presented here were generated using COSMIC (Country Specific Model for Intertemporal Climate) (Schlesinger and Williams 1997). This contains simplified versions of the 14 different climate models used by the IPCC, and gives output at the country level. Each model was run specifying three different plausible sensitivities (1.5, 2.5 and $4.5^{\circ} \mathrm{C}$ ) to the effects of a doubling of atmospheric $\mathrm{CO}_{2}$, generating 42 alternative future climate scenarios for each GHG emissions scenario. Estimates for changes in annual average temperature and precipitation were generated for each subregion by taking population weighted averages of the country level estimates. Means, ranges and $95 \%$ confidence intervals assume independence, and equal probability for each future model and climate sensitivity. All values in figures and tables are for changes relative to 1990.

Figure A.I Mean and $95 \% \mathrm{Cl}$ of COSMIC model outputs for temperature change in the 2020s (relative to 1990) for each subregion under each GHG emissions scenario

## Appendix B: Literature review

For all impacts, we attempted to find all models that directly related climate change to the selected health effects, either at the global or largeregional level. We describe all such models, and outline reasons for using or not using them in the assessment. Note that the comments given relate to their relative suitability for generating the estimates required for this assessment, rather than a general judgement on their merits. For the effects of thermal extremes, we also include a summary of the study populations that were used to derive the heat and cold estimates used in this assessment.

Where existing global or large scale regional models are not considered appropriate (thermal extremes), or do not exist at all (diarrhoea and floods), the literature search describes the procedure for identifying relevant studies from which to derive new quantitative climate-health relationships and generate models.
THERMAL EXTREMES
Information sources:

- Medline search for all references (1966-2002) containing the terms "temperature"; "mortality"; "cardiovascular disease"
(or CVD); "respiratory"; "weather"
- references cited in these papers.
Table B.I Results of literature search for effects of climate change on deaths due to thermal extremes ${ }^{\text {a }}$

| Reference | Method | Inputs | Region | Key findings | Suitability for generating estimates for this assessment |
| :---: | :---: | :---: | :---: | :---: | :---: |
| Langford and Bentham (1995) | Regression model: monthly mortality and temperature series (flu included) | Seasonal average dT from United Kingdom scenarios (Warrick and Barrow 1991) | England and Wales | Winter deaths avoided: <br> 2010: all cause 3301, IHD I308, CVD 429 <br> 2030: all cause 6353, IHD 2550, CVD 836 <br> 2050: all cause 8922, IHD 363I, CVD 1187 | No population growth, ageing. No seasonal adjustment. <br> Local rather than global |
| Martens (1998a) | MIASMA vI.0—empiricalstatistical model, meta-analysis. A single temperature-mortality relationship was applied to all cities | ECHAMI-A, UKTR, GFDL89 (IPCC scenarios) | Cause+age specific. Global20 cities | Changes in mortality rates for CVD ( $<65$ ), CVD (>65), respiratory, and total mortality Net reductions in mortality in all cities except respiratory mortality in a few cities | Lack of control for seasonal variations, perhaps over-estimating heat effects |
| McMichael et al. (2000b) | MIASMA v.I.0—as for Martens (1998a) | HadCM2, ensemble mean+HadCM3 | Global- <br> 20 cities | Net reductions in mortality in all cities except Athens, due to decreases in winter mortality | As for Martens (1998a) |

Table B.I Results of literature search for effects of climate change on deaths due to thermal extremes ${ }^{\text {a }}$ (continued)

| Reference | Method | Inputs | Region | Key findings | Suitability for generating estimates for this assessment |
| :---: | :---: | :---: | :---: | :---: | :---: |
| Kalkstein and Smoyer (1993) | Model derived from observed relationship between synoptic air masses and mortality | GCM scenarios, no downscaling | Global- <br> 27 cities | Significant increases in heat-related mortality under various climate change scenarios, with or without acclimatization, projected for all cities | Methods used rely on synoptic classification of local air masses; therefore cannot be directly related to changes in temperature described by climate scenarios |
| Kalkstein and Greene (1997) | Model derived from observed relationship between synoptic air masses and mortality | GCM scenarios, no downscaling | 44 cities in the USA | Increases in heat-related mortality are much larger overall than decreases in cold-related mortality | Methods used rely on synoptic classification of local air masses; therefore cannot be directly related to changes in temperature described by climate scenarios |
| Duncan et al. (1997) | Model derived from observed relationship between synoptic air masses and mortality | Climate scenarios for Canada | 10 cities <br> in Canada | 240-1140 additional heat-related deaths/year in Montreal by 2050; 230-1220 additional deaths in Toronto, assuming no acclimatization. No climate/mortality relationship in some cities | Country specific |
| Guest et al. (1999) | Regression model: daily mortality and synoptic indices | CSIRO Mark 2 model, $\mathrm{CO}_{2}$ doubling; high and low scenarios estimated | 5 cities in Australia | Net decrease in heat-related mortality, particularly in the age group $\geq 65$ years; range of 47-62 fewer deaths/year in all 5 cities. Significant increase in summer deaths in Sydney (76-239) | Country specific |
| Dessai (2003) | Empirical statistical model, observedexpected | 2 regional climate models-PROMES and HadRM2 | Lisbon, Portugal | Heat-related death rates increase by $57-113 \%$ by 2020 s, by $97-255 \%$ by 2050s. Acclimatization assumptions, reduce estimates | Country specific |

Key: CVD, cardiovascular disease; IHD, ischaemic hearth disease; GCM, global climate model.
A total of 76 other publications were not used, either because they were analyses of specific episodes ( 35 studies), or because they did not match the criteria outlined above ( 41 studies).

## Estimates of temperature-MORTALITY relationship

Table B. 2 below lists all studies $(n=4)$ that meet the following criteria for inclusion in the meta-analysis. The study:

- uses daily time-series methods to analyse the relationship between daily mean temperature and mortality;
- Reports a coefficient from log linear regression that estimates the percentage changes in mortality per degree centigrade change in temperature, above a reported threshold temperature;
- has controls for the following confounders: season, air pollution and influenza;
- is published in English language only; and
- reports confidence intervals around the coefficient and is within the range of other reported estimates.

The studies are classified according to climate zone. The Netherlands population is used to approximate a population in the "cold" zone as there are no other appropriate time-series studies.

Note that some studies are included that are not yet published. However,

- they are the only studies available that provide estimates for developing country populations; and
- the results will be submitted to peer reviewed journals and the methods are at least as rigorous as those applied in previous published studies.

All estimates have been rounded to one decimal place. Where more than one estimate was available, the average estimate was calculated.
Table B. 2 Results of literature search for temperature-mortality relationship

| Population/ climate zone | Age | Cause of death | \% change ${ }^{\text {a }}$ per <br> $1{ }^{\circ} \mathrm{C}$ decrease | Cut-point ( ${ }^{\circ} \mathrm{C}$ ) | Lag | \% change ${ }^{\text {a }}$ per <br> $1{ }^{\circ} \mathrm{C}$ increase | Cut-point ( ${ }^{\circ}$ C) | Lag | Reference |

Table B. 6 Results of literature search for effects of climate change on malaria (continued)

| Study | Model type | Model output | Area covered | Conclusions | Suitability for generating estimates for this assessment |
| :---: | :---: | :---: | :---: | :---: | :---: |
| Bryan et al. (1996) | CLIMEX model | Vector distributions only | Northern <br> Australia | Change in distribution under CC | Single vector, local rather than global predictions |
| Jetten et al. (1996) | Biological modelMIASMA vI. 0 | Maps of TP and change in TP | Global | Expansion of distribution, increasing TP under CC | Prediction of climate suitability for transmission, rather than actual transmission. Uncertainty over cut-off values to define endemic/non-endemic areas. Vector distributions not considered |
| Martens (1997) | MIASMA vi. 0 | Maps of TP and change in TP, P. vivax and P. faliiparum | Global | Expansion of distribution, increasing TP under CC | Prediction of climate suitability for transmission, rather than actual transmission. Uncertainty over cut-off values to define endemic/non-endemic areas. Vector distributions not considered |
| Lindsay and Martens (1998) | MIASMA vI.0— biological model based on vectorial capacity | Maps-epidemic potential | African Highlands | Increase in latitude under CC | Regional projections only |
| Rogers (1996) | Empirical statistical mapping | Maps of distribution of Anopheles gambiae | Southern Africa | Change in distribution under CC | Regional projections only |
| Martens et al. (1999) | Biological model, overlaying a population grid. MIASMA v2.0 | Maps of TP, maps of changes in seasonal transmission, additional population at risk | Global | Expansion of distribution, increasing TP under CC | Prediction of climate suitability for transmission, rather than actual transmission |

| Arnell et al. (2002) | Biological model, overlaying a population grid. MIASMA v2.0 | Maps of changes in $P$. falciparum TP, population at risk, seasons suitable for transmission relative to 1961-1990 | Global | Expansion of distribution, increasing TP under CC | Prediction of climate suitability for transmission, rather than actual transmission |
| :---: | :---: | :---: | :---: | :---: | :---: |
| Rogers and Randolph (2000) | Empirical-statistical model | Changes in populations at risk: P. falciparum | Global | Approximately no change in distribution under climate change | Additional population at risk $\pm 25$ million. Validation of model derived from a subset of the data against the remaining observations. (Used to inform uncertainty range around the projections) |
| Tanser et al. (2003) | MARA biological/ statistical model (Craig et al. 1999) | Changes in populations at risk-months suitable for transmission | Africa | Expansion in population at risk under CC | Biological model based on localized field studies, used to predict population at risk and numbers of months at risk throughout Africa, but not elsewhere. Potential for developing into predictions of incidence. Validated against detailed independent data set. (Used to determine mid-range estimates of population at risk, as a relative measure of change in incidence) |

Key: CC, climate change; EIP, extrinsic incubation period; TP, transmission potential (also called EP, epidemic potential).
${ }^{\text {a }} \quad$ A further 41 publications were rejected due to lack of relevance for making global projections (mainly reviews, local studies).
DENGUE
Information sources:

## - all relevant papers cited in IPCC (2001a)

- Medline search for all references (1966-2002) containing the terms "Dengue and climate (or climatic) change"
- Secondary references cited in these papers.
Table B. 7 Results of literature search for projected effects of climate change on dengue ${ }^{\text {a }}$

| Study | Model type | Model output | Area covered | Conclusions |
| :--- | :--- | :--- | :--- | :--- |

| Patz et al. (1998) | Biological model summarizing climate effects on vector- and parasite population dynamics | Maps of change in epidemic potential under climate change | City specific (Athens, Bangkok, Mexico City, Philadelphia, Puerto Rico, San Juan) | Large increase in transmission potential with small temperature increase | Model is most accurate for nonendemic areas bordering endemic areas and may underestimate changes in transmission in temperate zones. Relationship between TP and disease incidence not characterized |
| :---: | :---: | :---: | :---: | :---: | :---: |
| Jetten and Focks (1997) | Biological model summarizing climate effects on vector- and parasite population dynamics | Maps of changes in Critical Density Threshold | Global | Large increase in areas suitable for transmission and length of transmission season under climate change | Relationship between TP and disease incidence not characterized. <br> Uncertainty over setting of cut-offs for transmission |
| Hales et al. (2002) | Empirical statistical model | Maps of population at risk for dengue transmission | Global | Absolute humidity accurately explains current distribution of dengue. Large increases in population at risk predicted under climate change | Validation of model derived from a subset of the data against the remaining observations. (Used to determine population at risk, as a relative measure of change in incidence) |

## Chapter $2 I$

# Selected occupational risk factors 

Marisol Concha-Barrientos, Deborah Imel Nelson, Timothy Driscoll, N. Kyle Steenland, Laura Punnett, Marilyn A. Fingerhut, Annette Prüss-Üstün, James Leigh, SangWoo Tak and Carlos Corvalan

## Summary

Many of the 2.9 billion workers across the globe are exposed to hazardous risks at their workplaces. This chapter examines the disease and injury burden produced by selected occupational risk factors: occupational carcinogens, airborne particulates, noise, ergonomic stressors and risk factors for injuries. Owing primarily to lack of data in developing countries, we were unable to include important occupational risks for some cancers, reproductive disorders, dermatitis, infectious diseases, ischaemic heart disease, musculoskeletal disorders (MSDs) of the upper extremities, and other conditions such as workplace stress. Mesothelioma and asbestosis due to asbestos exposure, silicosis and coal workers' pneumoconiosis are almost exclusively due to workplace exposure, but limitations in global data precluded a full analysis of these outcomes.

The economically active population (EAP) aged $\geq 15$ years, which includes people in paid employment, the self-employed, and those who work to produce goods and services for their own household consumption, were considered the group at risk of exposure to occupational hazards. Both formal and informal sectors of employment are included in the EAP, but child labour was excluded. Exposure was quantified based on the economic sector (where people do the work) and on occupation (what people do). Our sources of data to delineate categories of exposed workers included economic databases and publications of the International Labour Organization (ILO) and the World Bank and the published scientific literature. For most risk factors the workers were grouped into high- and low-exposure categories, and the exposed population was distributed by age, sex and subregion. ${ }^{1}$ Risk estimates for the occupational hazards were obtained from the published epidemiological literature, particularly from studies of large populations, reviews and meta-analyses when available.

The occupational risk factors in our study accounted for an estimated $37 \%$ of back pain, $16 \%$ of hearing loss, $13 \%$ of chronic obstructive
pulmonary disease (COPD), $11 \%$ of asthma, $8 \%$ of injuries, $9 \%$ of lung cancer and $2 \%$ of leukaemia. These work-related risks caused 775000 deaths worldwide in 2000. There were five times as many deaths in males as in females ( 647000 vs 128000 ). The leading occupational cause of death among the six risk factors was unintentional injuries ( $41 \%$ ) followed by COPD $(40 \%)$ and cancer of the trachea, bronchus or lung (13\%). Workers who developed outcomes related to the occupational risk factors lost about 22 million years of healthy life. By far the main cause of years of healthy life lost (measured in disability-adjusted life years [DALYs]), within occupational diseases, was unintentional injuries with $48 \%$ of the burden. This was followed by hearing loss due to occupational noise ( $19 \%$ ) and COPD due to occupational agents ( $17 \%$ ). Males experienced almost five times greater loss of healthy years (DALYs) than females. Low back pain and hearing loss have in common the fact that they do not directly produce premature mortality, but they cause substantial disability and have multiple consequences for the individual and society, particularly for workers suffering the outcomes at an early age.

The major source of uncertainty in our analysis was characterizing exposure, which was based solely on economic subsectors and/or occupations and involved a large number of extrapolations and assumptions. High-quality exposure data are lacking, especially in developing countries, and European and American exposure estimates were thus applied in many instances in developing regions. This extrapolation could have substantial impact on the accuracy of analysis for the developing regions if exposures, as usually occur, vary from place to place and over time. Diseases with long latency (e.g. cancers) are more susceptible to the assumptions and extrapolations. In addition to problems produced by the length of the latency period, the magnitude of the excess risk may vary depending on the age of the person when exposure began, the duration and strength of exposure and other concomitant exposures. The turnover of workers is another issue that affects both exposure and risk assessment. Sources of uncertainty in hazard estimates (relative risk and mortality rates) include variations determined from the literature (once again caused by the use of different exposure proxies), extrapolations to regions with different working conditions, the application to females of risk measures from male cohorts, and the application of the same relative risk values to all age groups (e.g. carcinogens). Restricting the analysis to persons aged $\geq 15$ years excludes the quantification of child labour. The exclusion of children in the estimation was due to the wide variation in the youngest age group for which countries reported economic activity rates (EARs). In addition to inconsistent data on EARs for children, there were virtually no data available on their exposure to occupational risk factors or the relative risks of such exposures. Specific, focused research on children is needed to quantify the global burden of disease due to child labour and the resulting implications.

## 1. Introduction

Throughout the world, most adults-and many children-spend much of their waking hours at work. Work provides a number of economic and other benefits. At the same time, people at work face a variety of hazards owing to chemicals, biological agents, physical factors, adverse ergonomic conditions, allergens, a complex network of safety risks, and many and varied psychosocial factors. In addition to injuries, more than 100 occupational diseases have been classified according to the tenth revision of the International Classification of Diseases and Related Health Problems (ICD-10). Broadly, these include respiratory, musculoskeletal, cardiovascular, reproductive, neurotoxic, skin and psychological disorders, hearing loss and cancers.

Of the wide variety of work-related exposures, only the most widespread are evaluated here. Other criteria for selection of risk factors include adequacy of exposure information and the applicability of health outcome data to all regions of the globe, and the inclusion of the relevant health outcomes in the global burden of disease (GBD) database of diseases and injuries.

Exposure to occupational hazards can adversely affect the human body. Adverse effects range from asymptomatic physiological and biochemical changes to symptoms of illness, to diagnosed diseases and, finally, to death. For some risk factors there is a very clear connection between the exposure and the disease. For example, the primary route of exposure to airborne particulates, gases and vapours is inhalation, whereby these agents gain access to the respiratory system and are either deposited (in the case of particulates) or enter the circulatory system (gases and vapours). Many risk factors cause more than one type of outcome of interest. For example, exposure to asbestos can result in malignant conditions of the lung and the pleura, malignant conditions of the peritoneum, and nonmalignant conditions of the lung (asbestosis). Some exposures, such as occupational noise, are well characterized. Others have not been well characterized or are multi-faceted, but the condition they cause is clear (such as occupational injuries).

Following a general description of methods and data sources, individual sections provide details of specific aspects of methodology and results for each of the selected occupational health risk factors that were analysed: occupational carcinogens, occupational airborne particulates, occupational noise, occupational ergonomic stressors and occupational risk factors for injuries.

In this study, the term "occupational risk factor" is defined as a chemical, physical, biological or other agent that may cause harm to an exposed person in the workplace and is potentially modifiable. Figure 21.1 shows the selected risk factors along with related health outcomes. Owing to complex etiology and lack of data, a different approach was developed for some conditions such as asthma and low back pain, using

Figure 21.I Relationship between occupational risk factors and outcomes ${ }^{\text {a }}$

anly selected relationships were quantified.
occupation as a proxy for exposure to the causative agents. The utility of this work as a risk-based framework has thus been limited.

### 1.1 EXCLUDED EXPOSURES AND OUTCOMES

No effects specific to the hazards associated with child labour are addressed in this report owing to a lack of data. Other excluded risks or outcomes include respiratory diseases other than COPD and asthma; some infectious diseases; less widespread cancers and carcinogens (e.g. bladder cancer and cancer of the liver); MSDs such as carpal tunnel syndrome; intentional injuries in the workplace; organ and systemic diseases resulting from occupational exposure to solvents, pesticides and heavy metals such as lead or mercury; maternal and perinatal conditions resulting from occupational exposures; skin disorders, including dermatitis, dermatosis and melanoma; ischaemic heart disease and other outcomes associated with work-related stress.

Malignant mesothelioma of the pleura and peritoneum is virtually uniquely due to asbestos exposure. Occupational dusts can also result in
nonmalignant respiratory diseases other than asthma and COPD. The most important of these are silicosis, asbestosis and coal workers' pneumoconiosis, which are caused by exposure to silica, asbestos and coal dust, respectively. While evidence for a causal relationship is strong, lack of data on accumulated exposure, especially in developing countries, restricted the ability to provide a detailed assessment of attributable mortality and disease burden for these outcomes. Preliminary estimates are provided in the note under Table 21.62 in Section 7.

Because of lack of available data and difficulties in quantification, it was not possible to conduct a global quantitative analysis for the health consequences of stress at work. Overall, the evidence indicates that incidence of stress-related cardiovascular disease is likely to be higher in the blue-collar occupations when the following factors are present: restricted discretion, shiftwork (particularly nightshift), effort-reward imbalance, high demands, poor psychosocial work environment, social isolation, physical inactivity or occupational violence. These risk factors may be interactive. Nurminen and Karjalainen (2001) estimated for Finland an attributable fraction of $16.9 \%$ ( $18.9 \%$ for men and $9.1 \%$ for women) for ischaemic heart disease due to the combined occupational risk factors of shiftwork, noise, and exposure to engine exhaust and environmental tobacco smoke. For ischaemic heart disease, Steenland et al. (2003) used an attributable fraction of $6-18 \%$ for individuals in the United States of America aged 24-64 years, based on the combined effects of noise, job strain (stress), shiftwork and environmental tobacco smoke. Occupational dermatitis accounts for about $10 \%$ of all occupational disease in the United States (Emmett 2002) but exposure data are lacking at global level.

Although there were adequate global data to analyse the risks to health care workers from contaminated sharps (e.g. syringe needles and scalpels), the full analysis has been omitted from this chapter. Since health care workers make up only $0.6 \%$ of the global population, the contribution to hepatitis B, hepatitis C and HIV/AIDS infections on a global level was close to zero. However, health care workers are at high risk of preventable infection from bloodborne pathogens, owing to occupational exposure to infected blood and body fluids.

### 1.2 Choice of theoretical-Minimum-Risk EXPOSURE DISTRIBUTIONS

For some occupational hazards, a theoretical minimum exposure of zero is not possible, as there is some low-level environmental exposure. Two occupational risk factors (carcinogens and airborne particulates) involve workplace exposure at concentrations higher than the environmental or background levels of these substances. For noise, the theoretical minimum was defined as less than 80 dBA , a level found not to have an increased risk of causing hearing loss (NIOSH 1998). For the other risk factors (ergonomic stressors and work-related risk factors for injuries), a category of workers with the lowest risks was identified as the com-
parison group for occupational categories of workers with higher risks. Thus, the theoretical minimum risk corresponds to "no occupational exposure above levels found in the defined comparison group". Selection of a defined comparison group provides a realistic basis for a theoretical minimum, but it does not establish the lowest rate of adverse outcome that could ever be experienced. While it is not expected that occupational exposures will be eliminated in the foreseeable future, it is possible to control exposures through recognized industrial hygiene practices. Engineering controls (including prevention, substitution of materials, process automation, enclosure, process elimination, isolation of workers and process change) constitute effective methods of minimizing exposures (Burton 1997). Administrative controls (such as education and training, work practice controls, worker rotation, maintenance and housekeeping) provide another means of risk reduction.

### 1.3 Data sources

A systematic assessment of the literature was carried out to identify studies on occupational exposures and health outcomes. This included searching Medline, occupational health and safety databases such as OSHROM and NIOSHTIC and databases of various organizations; reviewing relevant references cited in publications identified through the initial literature search and of references cited in these secondary references; communicating with relevant experts; and seeking other information recommended by referees following the initial review of the draft manuscript. PubMed was searched using keywords for exposures and health outcomes, including (separately and in combination, with no limit on year of publication): exposure, occupational, cancer, carcinogen, silica, silicosis, benzene, asbestos, asbestosis, pneumoconiosis and developing country. Names of regions (e.g. Africa, Asia) and specific countries were also used as keywords. A systematic search was conducted using Ovid Healthstar and the former HealthSTAR databases, covering the period 1975-2001. Keywords included: asbestos; asthmagens; chronic obstructive lung disease; cancer and diesel exhaust; arsenic; benzene and leukaemia; ionizing radiation and leukaemia; back (for low back pain); injury; accidents; ergonomics; and hearing impairment and noise.

Studies of large populations, reviews and meta-analyses were specifically sought. Reports and publications were critically assessed to determine their methodology, validity and the characteristics of the population studied.

### 1.4 Estimating risk factor levels

In general, since the types of risk factor to which workers are exposed are primarily influenced by where the work is performed (economic sector) and the type of work they do (occupation), the assessment of proportion of population exposed in each subregion was based on (Figure 21.2):

Figure 21.2 Exposure assessment overview

- economic sector distribution (total nine sectors), used for carcinogens and agents leading to COPD) (Equation 1);
- occupational distribution (occupation within economic sector) (total seven occupations), used for asthmagens, noise and ergonomic stressors (Equation 2); and
- exposure could not be estimated for injury risk factors, and thus estimates of disease burden were made based on the reported rates of the outcome (injury mortality) rather than on exposure.

$$
\begin{align*}
& \operatorname{PEP}(\mathrm{r}, \mathrm{~g}, \mathrm{a})=\operatorname{EAR}(\mathrm{r}, \mathrm{~g}, \mathrm{a}) \times \mathrm{OT}(\mathrm{r}) \\
& \quad \times \operatorname{EPF}(\mathrm{r}) \sum_{i=1}^{9}(\operatorname{PW}(\mathrm{es}(\mathrm{r}, \mathrm{~g}) \mathrm{i}) \times \operatorname{PEW}(\mathrm{es}(\mathrm{r}, \mathrm{~g}) \mathrm{i})  \tag{1}\\
& \operatorname{PEP}(\mathrm{r}, \mathrm{~g}, \mathrm{a})=\operatorname{EAR}(\mathrm{r}, \mathrm{~g}, \mathrm{a}) \times \mathrm{OT}(\mathrm{r}) \\
& \quad \times \operatorname{EPF}(\mathrm{r}) \sum_{i=1}^{7}(\operatorname{PW}(\mathrm{oc}(\mathrm{r}, \mathrm{~g}) \mathrm{i}) \times \operatorname{PEW}(\mathrm{oc}(\mathrm{r}, \mathrm{~g}) \mathrm{i}) \tag{2}
\end{align*}
$$

where
$\operatorname{PEP}(\mathrm{r}, \mathrm{g}, \mathrm{a})=$ proportion of the population occupationally exposed to a specific risk factor in that subregion, by sex and age, at low or high level
$\operatorname{EAR}(\mathrm{r}, \mathrm{g}, \mathrm{a})=$ economic activity rate, by subregion, sex and age
$\mathrm{OT}(\mathrm{r})=$ occupational turnover, if applicable, to account for workers exposed in the past, by subregion
$\operatorname{EPF}(\mathrm{r})=$ exposure partitioning factor, by subregion, to delineate proportion exposed at low or at high levels
$\operatorname{PW}(\mathrm{es}(\mathrm{r}, \mathrm{g}) \mathrm{i})=$ proportion of the population working in economic subsector (i), by subregion and sex

PEW $(e s(r, g)$ i) $=$ proportion of workers in economic subsector (i) with exposure to the specific risk factor, by subregion and sex
$\mathrm{PW}(\mathrm{oc}(\mathrm{r}, \mathrm{g}) \mathrm{i})=$ proportion of the population working in occupational category (i), by subregion and sex

PEW $(\mathrm{oc}(\mathrm{r}, \mathrm{g}) \mathrm{i})=$ proportion of workers in occupational category (i) with exposure to the specific risk factor, by subregion and sex

The differences between the two equations are the term $\operatorname{PW}(\mathrm{es}(\mathrm{r}, \mathrm{g}) \mathrm{i})$ in Equation 1, which is used when exposure data are available by economic sector, and the term PW (oc(r,g)i) in Equation 2, which is used when exposure data are available by occupational category. Occupational turnover (OT), defined as "the rate of replacement of workers due to departures from the workplace", was utilized for carcinogens because health effects due to these risk factors occur many years after exposure (latency) and it was therefore necessary to know how many persons had been exposed in the past to these risk factors. The effects of noise, ergonomic stressors and risk factors for injuries are relatively immediate; latent effects were therefore not a consideration for these risk factors. Additional detail on each term is provided below in the text, and is also summarized in Table 21.1.

The primary data sources used for the exposure assessment and the determination of some of the risk measures (see Table 21.2) included: the World Bank, ILO, the European Union carcinogen exposure (CAREX) database, published literature on prevalence and level of exposure to occupational risk factors, and published literature on epidemiology of health outcomes linked to occupational risk factors, as cited in the relevant sections for each risk factor.

## ECONOMIC ACTIVITY RATE

EAR is defined as the proportion of the economically active population (EAP) among the overall population. EAR was calculated for each region and sex in persons aged $\geq 15$ years, and used to estimate the proportion of the population potentially exposed to occupational risks. EAR provides the most comprehensive accounting of persons who may be exposed to occupational risks, as it includes people in paid employment, the self-employed, and people who work to produce goods and services
Table 2l.I Summary of determinants of population exposure to occupational risk factors

| Term | Comments | Application | Primary data sources |
| :---: | :---: | :---: | :---: |
| EAP | Economically active population is calculated by application of the EAR to the national population | Used for injuries | ILO (2002a) |
| EAR | Economic activity rate, calculated as the EAP in each age group compared to the number of people in that age group, males and females $\geq 15$ years | Used in exposure assessments of all risk factors | ILO (2002a) |
| PW(es) | Proportion working, i.e. fraction of EAP in economic sector. Data on distribution of EAP into three economic sectors (agriculture, industry, service) or nine economic subsectors. Country-level data were weighted by working-age population to develop subregional averages | Used for carcinogens, selected airborne particulates (agents leading to COPD) | World Bank (2001) |
| PW(oc) | Proportion working, i.e. fraction of EAP in occupational category. Country-level data for about 31 countries were weighted by working-age population to develop subregional averages. Owing to lack of country-level data, EMR-B was based on EMR-D data, EUR-C was based on EUR-B data and WPR-A was based on AMR-A data | Used for asthmagens, noise, ergonomic stressors | ILO (1995a); World Bank (200I) |
| PEW | Proportion exposed working, i.e. fraction of population working in economic sector (or in an occupational category) with exposure to risk factor. Owing to data limitations, data from developed countries were usually applied to developing countries, verified where possible by data on specific risk factors from specific countries | PEW(es): carcinogens PEW(es): selected airborne particulates (agents leading to COPD) <br> PEW(oc): selected airborne particulates (asthmagens) <br> PEW (oc): noise <br> PEW(oc): ergonomic stressors | FIOH (1999); Kauppinen et al. (2000) FIOH (1999); Kauppinen et al. <br> (2000); Korn et al. (1987); USEIA (2001) <br> Karjalainen et al. (2002); Kogevinas et al. (1999) <br> NIOSH (1998) <br> Leigh and Sheetz (1989) |
| EPF | Exposure partitioning factor, i.e. proportion of PEW with low- or high-level exposure to risk factor | Carcinogens, selected airborne particulates, noise | NIOSH (1998, 1999, 2000a); Pearce et al. (1994); Yin et al. (1987) |
| OT | Occupational turnover factor. Used only for risk factors for which latent effects must be considered (carcinogens, selected airborne particulates). A factor of 4 was estimated on the basis of published data on labour turnover rates, published cohort data and modelling of cohorts with various mean lengths of exposure. Higher value used for specific regions for coal mining | Carcinogens | K. Steenland, personal communication, 2002 |

Table 21.2 Key sources, data supplied and special characteristics of the sources used to estimate exposure

| Source | Data supplied | Comments |
| :--- | :--- | :--- |
| ILO (1995a, 2000, 2002b) | Employment in economic <br> sectors and subsectors, and <br> in occupations within economic <br> sectors; EARs by age and sex <br> for selected countries | Collected by national EAP <br> surveys. Differences among <br> and within countries (e.g. <br> applicable ages, time period <br> covered) limit international <br> comparability |
| World Bank (200I) | Distribution of EAP (males and <br> females) in agriculture, industry <br> and services; participation of <br> females in the EAP | Based on ILO data |
| FIOH (1999); Kauppinen | Proportion of the working <br> population with occupational <br> exposure to carcinogens in <br> the European Union, by <br> economic sector and subsector, <br> at the 3-digit classification level | Applicable to A subregions, <br> extrapolated to B, C, D <br> and E subregions |
| ElA (200I) | Country-level data on coal <br> production <br> Country-level data on number <br> of coal miners |  |
| ILO (I995b) | Data on noise exposure of <br> American workers | Applicable to A subregions, <br> extrapolated to B, C, D <br> and E subregions |
| NIOSH (I99I, I998); |  |  |

for their own household consumption. According to ILO (2002b), the majority of those who work in the informal sector are included in the "employed" category, and the remainder are in the "unemployed" category; thus, the informal sector workers are included in this analysis. At the same time, persons in precarious or contingent employment often face an increased risk of occupational health and safety hazards, which are not quantified here (Quinlan 2002). The use of EAR for persons aged $\geq 15$ years excludes children under 15 who work.

Estimates and projections of EAP were developed by ILO by applying estimates and projections of activity rates, by sex and age group, to the population estimates and projections assessed by the United Nations (ILO 1996). ILO estimates and projections of economic activity are taken primarily from population censuses and/or sample surveys carried out between 1975 and 1994. ILO also takes data from specific publications by national, interregional and/or international institutions.

Country-level data from the ILO electronic database were used to develop subregion-specific EARs for ages 15 years and above, for males and females (Table 21.3). EARs were estimated for $60-69$-year olds by using data for $60-64$-year olds. Data for people aged $\geq 65$ years were

[^78]applied to the $70-79$ age group. The $\geq 80$ age group was estimated at one half of the rate for the $\geq 65$ age group (by comparison with countrylevel data, which is reported by some countries for elderly workers) (ILO 2001).

## Proportion of the population working in an economic sector or occupational category

The distinction between "where people work", i.e. economic sector and "what they do", i.e. occupation, is important in exposure characterization. For example, within the economic subsector of manufacturing there

are people who work as production workers, but also people who work as clerical or sales people (Table 21.4). EAP was used for injuries. EAP by economic sector and subsector was used for carcinogens and agents leading to COPD, because available data do not distinguish exposures by occupational category within economic sectors. For asthmagens, noise and ergonomic stressors, the analyses were conducted on the basis of exposure by occupational category within economic sectors.

The approach used here is based on the International Standard Industrial Classification of All Economic Activities (ISIC), an economic classification system of the United Nations, which organizes all economic activities by economic sectors and relevant subgroupings (ILO 1987; UN 2000). The ISIC system is used almost universally by national and international statistical services to categorize economic activity, and therefore allowed us to make global comparisons. Table 21.4 illustrates the ISIC classification scheme of economic sectors, economic subsectors and occupational categories that were used to estimate exposures to workers in this project. We did not subdivide agriculture into economic subsectors.

## Economic sector

For each subregion, a weighted proportion of working men and women (EAP) in each of the three economic sectors was constructed (Table 21.5) (World Bank 2001, data from 1990 and 1996-1998). Economic sector employment data were used to subdivide the number of workers in industry into the economic subsectors of mining, manufacturing, electricity (and other utilities) and construction. In a similar manner, the data for the service sector were subdivided into the economic subsectors of trade, transport, finance and services. The agriculture sector was not subdivided.

| Note: AFR-D and AFR-E (combined), EMR-B, EMR-D and SEAR-D data are based on 1990 employment data from the World Bank world develop limited. All others are taken from 1996-1998 World Bank EAP data. Subregional averages were calculated using country values weighted by |  |  |  |  |  |  |  |  |  |  |  |

## Occupational category

Regional tables of occupation within economic sector distributions were constructed using the number of employed people by occupation and economic sector. For comparison purposes, data were obtained from one source (ILO 1995a). For a subregion with only one country represented, the distribution of occupation within economic sector was assumed to represent the regional employment patterns. Where more than one country was represented, a weighted average was constructed. Where there were no data for the subregion, patterns for the most similar subregion were applied (EMR-B based on EMR-D, EUR-C based on EUR-B and WPR-A based on AMR-A). Because of limited data on occupational distribution by sex within an economic sector, the same distribution (i.e. proportional division) was applied within a subregion to ages 15 and above, and to males and females. The A subregions had higher proportions of EAP in the professional, managerial and administrative categories, while the $\mathrm{B}, \mathrm{C}, \mathrm{D}$ and E subregions had proportionally more workers in the production categories.

## Proportion of workers in an economic sector or occupational CATEGORY WITH EXPOSURE

Worldwide data on worker exposure are limited. Therefore, several assumptions were made, validated where possible, to establish the proportion of workers exposed to a specific risk factor within an economic sector (PEW). More detail is presented in the sections on specific risk factors.

## EXPOSURE PARTITIONING FACTOR (EPF)

In order to partition into high and low exposure groups those workers exposed to carcinogens, we chose the United States Occupational Health and Safety Administration (OSHA) Permissible Exposure Levels (PELs). For most carcinogens we were then able to estimate the risks for the low and high exposure groups from the literature.

The OSHA PELs state a level of the agent that can never be exceeded in the workplace (usually based on eight-hour time-weighted average exposures), and these have had the force of law in the United States as maximum limits of exposure since the creation of OSHA in 1971. Similar occupational exposure limits (OELs) have been promulgated as law by many countries, particularly in the A subregions, and as recommendations by professional expert groups. It is generally considered that a longterm mean exposure in a "minimally controlled" work environment will be in the range 0.3-0.5 times the PEL (Hewett 1996). For example, the American Industrial Hygiene Association suggests that a typical longterm average exposure may be one third of an eight-hour PEL (Roach 1992).

A different approach was used for asthmagens and agents leading to COPD. The actual disease-causing exposures themselves, within these occupations, are either generic (e.g. dust) or too numerous to be useful (e.g. there are over 200 known asthmagens). In both instances there were no international data on the number of workers exposed, which dictated the approach of using occupations or economic subsectors. For asthma, different relative risks were available for eight large occupational groups, while for COPD we partitioned the overall relative risk for the exposed population into high and low relative risks, and assigned these to different economic subsectors according to Korn et al. (1987).

## Occupational turnover (OT)

Cancers and lung diseases have long latency periods and once the disease process has begun the worker continues to be at risk, even after exposure ceases. This means that persons who were exposed in the past must be considered as ever-exposed, even if they are currently working in nonexposed jobs or have retired. Furthermore, OT increases the number of persons ever exposed to an occupational risk. This approach was consistent with cohorts represented in the epidemiological studies from which relative risks were taken. The OT factor was not utilized in estimating the numbers of workers exposed to noise, ergonomic stressors or risk factors leading to occupational injuries, as these risk factors do not have latent effects. No turnover was estimated for asthma and COPD owing to a lack of sufficient information on the applicability to studies in which relative risk was measured. Table 21.6 presents data from the literature on annual OT rates in various countries and industries throughout the world, organized by subregion. These reports did not indicate if employees were new to the job or to the industry, although several studies were at the company level, indicating that the worker was new to the company. Therefore, to account for previously unexposed workers entering jobs with carcinogen or dust exposures, an annual turnover rate (ATR) of $10 \%$ was selected for all subregions.

An adjustment factor (noted as OT) to account for annual turnover in jobs with exposure to occupational carcinogens was determined as follows:

Computation of adjustment factor to correct for occupational turnover (OT)

$$
\begin{align*}
& \text { Adjustment factor, } \mathrm{OT}=\mathrm{P}_{\mathrm{t}} / \mathrm{P}_{0} \\
& \quad=[\text { original workers }+ \text { new workers }- \text { deaths }] / \text { original workers }  \tag{3}\\
& =\left\{\mathrm{P}_{0}+\left[\mathrm{P}_{0} \times \text { ATR } \times \mathrm{t}\right]-\left[(\text { mortality rate })\left(\mathrm{P}_{0}+\left(\mathrm{P}_{0} \times \text { ATR } \times \mathrm{t}\right)\right]\right\} / \mathrm{P}_{0}\right.
\end{align*}
$$

where
$P_{t}=$ the proportion who have ever been occupationally exposed, during a period of 40 years, still living
Table 21.6 Turnover rates in various industries and countries

| Country or area | Basis of measurement | Annual turnover rate (ATR) | Comments | Source |
| :---: | :---: | :---: | :---: | :---: |
| A subregions Italy | Metal—mechanical engineering industry | 13.4\% | Industry level, based on 2729 observations | Lucifora (1998) |
| Italy |  | 26\% | Total worker turnover rate, including accession and separation | Lucifora (1998) |
| Spain Basque | Industrial production cooperative (manufacturing) | 3\% | 65 firms-cited as low rate | Johnson and Whyte (1977) |
| United States | Restaurant industry | 500\% | 8 southern restaurants | Butler and Twaddle (1979) |
| United States | Garment manufacturing | 140\% | I53 female workers at a single plant in the south-west | Koch and Rhodes (1981) |
| United States | One interstate trucking firm | 40\% | Expected rate for 1997-truck drivers | EIU (1997a) |
| United States California | Silicon Valley, one financial firm | 25\% | Software services group | EIU (1997f) |
| United States <br> New Mexico | State-wide survey by New Mexico Department of Labor, January-March 2001 | 25\% per quarter, ranging from $29 \%$ in agriculture to $15 \%$ in public administration | Agriculture rates show greatest seasonal variation | Moffett (2002) |
| B subregions Brazil | Brazilian labour market | 47\% | Cited as higher than most markets for which data are available | EIU (1997b) |

Table 21.6 Turnover rates in various industries and countries (continued)

| Country or area | Basis of measurement | Annual turnover <br> rate (ATR) | Comments |
| :--- | :--- | :--- | :--- | :--- | (1996a)

$\mathrm{P}_{0}=$ the proportion who are occupationally exposed at time $\mathrm{t}=0$
ATR $=$ turnover/year, taken as 0.10
$\mathrm{t}=$ time, taken as 40 years, a typical working lifetime
mortality $=20 \%$ of total cohort, based on published death rates of about 5 deaths per thousand over a period of 40 years (Minino and Smith 2001).

Equation 3 results in an adjustment factor of OT=4 to correct for occupational turnover over a 40 -year period with a median exposure duration of 10 years.

In addition to knowing the numbers of workers exposed to agents with latent health effects, in some cases it was also useful to know the duration of exposure to agents with latent effects for outcomes for which the risks were based on cumulative exposure. Cohort modelling was conducted to determine the typical duration of exposure (K. Steenland, personal communication, 2002). This modelling assumed that people worked for a maximum of 40 years, that $10 \%$ of the workers were replaced each year, and that $20 \%$ died over the 40 -year period. Exposure durations were randomly selected from a log-normal distribution. Persons were also randomly assigned a starting age at entry between 20 and 45 years, and were assumed to retire at age 65 years if they had not already left the cohort by that age. A steady-state working population was produced by using a log-normal distribution for exposure with a geometric mean of 9 years. Using this, the mean length of exposure (in years) at the end of 40 years could be estimated (by age) for all persons ever exposed in the cohort. The average estimated length of exposure, as shown in Table 21.7, was 9.8 years, which is consistent with data on a wide range of cohorts presented in the published literature (Steenland et al. 1991a, 1991b, 2001b).

### 1.5 RISK FACTOR-DISEASE RELATIONSHIP

Risk measures (relative risks or mortality rates) for the health outcomes resulting from exposure to the risk factors considered in this study were determined primarily from peer-reviewed, published studies. Adjustments were made, as appropriate, to account for differences in levels of exposure, exposure duration and/or age, sex and subregion.

- For carcinogens leading to cancer of the lung, trachea or bronchus, and for leukaemogens, composite values were taken from the literature and adapted to exposure patterns in the various subregions.
- For asthma, the relative risks for different occupations were taken from Karjalainen et al. (2002), with the exception of work in agriculture, for which the relative risk was taken from Kogevinas et al. (1999).

Table 21.7 Exposure duration after 40 years in model cohort

| Age group (years) | Number | Total exposure (years) | Average exposure (years) |
| :--- | :---: | :---: | :---: |
| $15-29$ | 12 | 50 | 4.2 |
| $30-44$ | 86 | 575 | 6.7 |
| $45-59$ | 117 | 1182 | 10.1 |
| $60-69$ | 105 | 1195 | 11.4 |
| $70-79$ | 53 | 618 | 11.7 |
| $\geq 80$ | 19 | 234 | 12.3 |
| All ages | 392 | 3854 | 9.8 |

- For COPD, the relative risks for different economic subsectors were taken from Korn et al. (1987).
- For noise, relative risks of noise-induced hearing loss were calculated from data on hearing loss in workers with different levels of noise exposure in the United States (NIOSH 1998).
- The relative risks of low back pain, given employment in different occupational categories, were taken from Leigh and Sheetz (1989).
- Owing to heterogeneity of factors leading to occupational injuries, relative risks could not be extrapolated from one setting to another. As a result, the mortality rates for workers exposed to risk factors leading to injuries were estimated for different subregions from various sources, including Laborsta (ILO 2001).

## 2. OcCupational Carcinogens

The International Agency for Research on Cancer (IARC 2002) has classified 150 chemical or biological agents or exposure situations as known or probable human carcinogens. IARC has classified 87 agents, mixtures or exposure circumstances as Group 1 (carcinogenic to humans), including various chemical compounds, pharmaceuticals and bacterial and viral infections. Many are encountered in occupational settings, e.g. asbestos and cadmium. An additional 63 agents, mixtures or exposure circumstances have been classified as Group 2A (probably carcinogenic to humans). Those with occupational significance include diesel fumes and benzidine-based dyes (IARC 2001). Although IARC classifies agents according to their overall carcinogenicity, specific sites are also considered.

Work-related malignant conditions can arise from a large variety of occupational exposures. However, the main groups of conditions are relatively few-lung cancer and leukaemia. The exposures selected for assessment in this study were based on how common they may be, the
risk arising from exposure, the strength of evidence and the availability of data. Table 21.8 shows the definition of each of the chemical and physical agents, along with the related cancer.

The analysis included relevant Group 1 and 2A carcinogens, with the following exceptions.

- Tetrachloroethylene and trichloroethylene, both classified in Group 2A, were not included as carcinogens because the evidence for cancer is weak.
- The aromatic amines and dyes, including 2-naphthylamine, benzidinebased dyes, benzidine and 4,4'-methylenebis(2-chloroaniline) (also known as MOCA) were excluded owing to lack of data for developing countries.
- Occupational carcinogens with extremely limited exposures (e.g. bischloromethyl ether, also known as BCME) were not included.
- Compounds for which exposure estimates were not available from the CAREX database (e.g. soot, xenylamine, 4-nitrobiphenyl and polycyclic aromatic hydrocarbons) were not included.
- Although radon is an IARC Group I carcinogen with large estimated exposures, it was excluded from consideration owing (i) to worldwide differences in naturally occurring radon emissions, (ii) to wide variations in climate and construction methods, which substantially affect the concentration of radon retained in buildings, and (iii) to difficulties in separating occupational and nonoccupational radon exposures.

Other conditions have insufficient relevant exposure data, insufficient risk data or insufficient number of cases worldwide to allow them to be usefully included. These conditions include:

- bladder cancer (aromatic amines, benzidine dyes, MOCA);
- liver (vinyl chloride);
- nasal cavity and middle ear (hardwood dust, chromium VI compounds, nickel compounds);
- bone and articular cartilage (ionizing radiation);

Table 21.8 Occupational carcinogens and health outcomes

| Occupational carcinogen | Outcome |
| :--- | :--- |
| Arsenic, asbestos, beryllium, cadmium, chromium, diesel exhaust, | Cancer of the trachea, <br> bronchus or lung <br> nickel, silica |
| Benzene, ethylene oxide, ionizing radiation | Leukaemia |

- skin (arsenic, by-products of distillation, ionizing radiation); and
- lung cancer due to passive smoking in the workplace.

### 2.1 EXposure variable and theoretical-minimum-risk EXPOSURE

Exposure was divided into three categories: background, low and high. The occupational risk factors for cancer involve workplace exposure, at concentrations higher than background level, to various chemical and physical agents that are known to cause malignant neoplasms. Thus, the theoretical minimum risk corresponds to "no occupational exposure to physical, chemical or biological agents or other factors above background levels".

### 2.2 Estimating risk factor levels

The general exposure assessment methodology was described earlier. This assessment was based on the distribution of the EAP by economic subsector, because the primary exposure data sources used in this analysis organized carcinogen exposure data by economic subsector (Equation 1). The regional distributions of workers into economic subsectors were adjusted by data on the carcinogens to which people in the various economic subsectors were exposed. As described earlier, an adjustment factor of 4 was used to account for turnover in jobs with exposure to occupational carcinogens.

The primary data source on work-related exposure to carcinogens for each economic subsector $(\operatorname{PEW}(\mathrm{es}(\mathrm{r}, \mathrm{g}) \mathrm{i})$ in Equation 1) is the CAREX database (FIOH 1999), which presents data on the number of workers in the European Union exposed to 139 carcinogens (IARC Group 1, 2A and selected 2B agents) at levels above background in 1990-1993. Table 21.9 lists the CAREX data for the carcinogens in our study. These estimates were based on national workforce data and exposure prevalence estimates from Finland and the United States, adjusted for the economic structure of each country, then refined by national experts.

It was assumed that the proportion of workers exposed to a particular carcinogen in a specific economic subsector was constant throughout the world. To check the validity of this assumption, the literature was searched for estimates of the number of workers exposed to silica. Silica was chosen as an indicator because there are more data on silica available for developing countries than on other carcinogens. This search yielded a range of study types, from rough estimates (Zou Changqi et al. 1997) to studies in which air concentrations were measured in workplaces (Yin et al. 1987). Estimates of the number of workers exposed to silica in China, Thailand and Viet Nam, and to benzene in China, were compared to the number of persons employed in that country, either in a specific economic sector or overall. The results obtained were compared with CAREX data. With a few exceptions, the estimated fraction
Table 21.9 Mean proportions of workers exposed to selected carcinogens, by economic sector and subsector, in the

[^79]of workers exposed to silica was equal to or higher in these countries than indicated by CAREX (Juengprasert 1997; T. Nguyen, personal communication, 2001; NIEHS 1999; Phan Hong Son et al. 1999; Yin et al. 1987; Zou Changqi et al. 1997). For example, the proportion of workers exposed to silica in manufacturing in Viet Nam is $3.7 \%$, compared to the CAREX estimate of $2.3 \%$.

It was assumed that, within a given economic subsector, both male and female workers and younger and older workers had the same probability of exposure. For example, if $2.3 \%$ of people working in manufacturing were exposed to silica, it was assumed that $2.3 \%$ of males and $2.3 \%$ of females working in manufacturing were exposed to silica, young and old alike. There were, however, fewer females working in manufacturing, so that at the population level the proportion of females with exposure to silica was lower than that of males.

There are few data on the distribution of exposure monitoring values, which are needed to accurately estimate the proportion of workers exposed to above or below a specific value ( $\mathrm{EPF}(\mathrm{r}$ ) in Equation 1). Therefore, the demarcation between low and high exposure was established as the PELs enforced by OSHA. Some reasons for selecting the PELs as partitioning values include the following.

- Exposure data for the United States are often reported based on "compliance with" or "exceeding" the PELs.
- The risks corresponding to low or high exposure have been linked to the PELs.
- As cancers have long latency periods, the exposures of concern have occurred several decades in the past. The OSHA PELs for many carcinogens have not changed since their adoption in 1971, allowing a stable benchmark for comparison (Table 21.10).

The peer-reviewed literature was searched for studies that included proportions of workers exposed above and below particular levels. There are many reports of exposures to contaminants in the literature, and even on the distribution of exposures at low and high levels in developed countries. However, there are few data on distribution of exposure values for developing countries. A summary of the major sources used to decide how to partition exposure values for carcinogens for the $\mathrm{B}, \mathrm{C}, \mathrm{D}$ and E subregions is presented in Tables 21.11 and 21.12 for benzene and metals, respectively.

The following data were used to partition exposure for A subregions:

- Finnish data (Partanen et al. 1995), indicating 11-94\% exposed above $0.2 \mathrm{mg} / \mathrm{m}^{3}$ respirable silica in a range of industries;
- NIOSH (1999) estimates of proportions of workers exposed above the PELs of $4 \%$ (asbestos) and $13.6 \%$ (silica); and

Table 21.10 OSHA permissible exposure levels (PELs) for carcinogens

| Chemical/ physical agent | PEL | Source | Comment |
| :---: | :---: | :---: | :---: |
| Arsenic | Inorganic: $10 \mu \mathrm{~g} / \mathrm{m}^{3}$ | OSHA, 29 CFR 1910.1018 | Effective 1978 |
|  | Organic: $0.5 \mathrm{mg} / \mathrm{m}^{3}$ | OSHA, 29 CFR 1910.1000, Table Z-I | Effective 1971 |
| Asbestos | Varied ${ }^{\text {a }}$ |  |  |
| Benzene | 10 ppm | OSHA, 29 CFR 1910.1000, Table Z-2 | Effective 1971 |
|  | I ppm | OSHA, 29 CFR 1910.1028 | Effective 1987 |
| Beryllium | $2 \mu \mathrm{~g} / \mathrm{m}^{3}$ | $\text { OSHA, } 29 \text { CFR I910.1000, }$ <br> Table Z-2 | Effective 1971 |
| Cadmium | Fume: $0.1 \mathrm{mg} / \mathrm{m}^{3}$ | $\begin{aligned} & \text { OSHA, } 29 \text { CFR 1910.1000, } \\ & \text { Table Z-2 } \end{aligned}$ | Effective 1971 |
|  | Dust: $0.2 \mathrm{mg} / \mathrm{m}^{3}$ | OSHA, 29 CFR 1910.1000, <br> Table Z-2 | Effective 1971 |
|  | $5 \mu \mathrm{~g} / \mathrm{m}^{3}$ | 29 CFR 1910.1027 | Effective 1992 |
| Chromium | Chromic acid and chromates: $0.1 \mathrm{mg} / \mathrm{m}^{3}$ Chromium metal: $1 \mathrm{mg} / \mathrm{m}^{3}$ | OSHA, 29 CFR 1910.1000, <br> Table Z-2 (ceiling) <br> OSHA, 29 CFR 1910.1000, <br> Table Z-I | Effective 1971 <br> Effective 1971 |
| Diesel exhaust | NA |  |  |
| Ethylene oxide | 1 ppm | OSHA, 29 CFR 1910.1047 | Effective 1984 |
| lonizing radiation | Rems/calendar quarter: whole body, I.25; hands, forearms, feet, ankles, 18.75; skin, 7.5 | OSHA, 29 CFR I910.1096, Table G-I8 | Effective 1974 |
| Nickel | Metal, insoluble and soluble compounds: $1 \mathrm{mg} / \mathrm{m}^{3}$ | OSHA, 29 CFR 1910.1000, Table Z-I | Effective 1971 |
| Silica | Respirable quartz: $\left(10 \mathrm{mg} / \mathrm{m}^{3}\right) /$ (per cent $\mathrm{SiO}_{2}+2$ ) | $\text { OSHA, } 29 \text { CFR I910.1000, }$ <br> Table Z-3 | Effective 1971. <br> For $100 \%$ silica dust, this is equivalent to $0.1 \mathrm{mg} / \mathrm{m}^{3}$. Halve this value for cristobalite and tridymite |

NA Not applicable.
a As shown in this table, most of the PELs have not changed since they were put in place. However, there were considerable changes in the United States PEL for asbestos during the years of interest to the current analysis, with a level before 1972 of 12 fibres $/ \mathrm{ml}$ before the first OSHAissued PEL in 1972 decreasing, through several steps, to 0.1 fibres $/ \mathrm{ml}$ in 1994 (Martonik et al. 2001; Nelson 1997).

Table 21.12 Occupational exposures to metals in developing countries

| Country | Industry | Concentration | Year (or year reported) |
| :--- | :--- | :--- | :---: |
| China | Tin mine | Arsenic: $0.42 \mathrm{mg} / \mathrm{m}^{3}$, mean | 1952 |
|  |  | Arsenic: $0.01 \mathrm{mg} / \mathrm{m}^{3}$ | 1980 s |
| China | Cadmium refining | Cadmium: $0.04-0.074 \mathrm{mg} / \mathrm{m}^{3}$ | 1970 s |
| Singapore | Storage battery factory | Cadmium: $0.13-58.3 \mathrm{mg} / \mathrm{m}^{3}$, | 1980 |
|  |  | geometric means of three <br> sets of samples |  |
| China | Chromate production | $0.02-21.3 \mathrm{mg} / \mathrm{m}^{3}$ | $1960 \mathrm{~s}-1980$ |
|  |  | $0.55 \mathrm{mg} / \mathrm{m}^{3}$, mean | $(1989)$ |

Source: Pearce et al. (1994).

- NIOSH (2000b) data on miners, indicating silica exposures above the PEL for $8 \%$ of coal mine samples, $16 \%$ of metal mine samples, $9 \%$ of stone mine samples and $8 \%$ of sand and gravel facility samples.

For the $\mathrm{B}, \mathrm{C}, \mathrm{D}$ and E subregions, important evidence includes:

- Chinese data (Dosemeci et al. 1995), indicating roughly three quarters of samples above $0.1 \mathrm{mg} / \mathrm{m}^{3}$ respirable silica;
- a study of a South African brickworks (Myers et al. 1989), in which $45 \%$ of presented sample values were above $0.1 \mathrm{mg} / \mathrm{m}^{3}$ and roughly two thirds and four fifths of samples in medium and dusty areas, respectively, were above $0.1 \mathrm{mg} / \mathrm{m}^{3}$ respirable silica;
- a study of a South African pottery (Rees et al. 1992), where roughly three quarters of samples that included silica analysis were above the Threshold Limit Value (TLV); and

Table 21.13 Exposure partition factors for carcinogens for the A and for the $B, C, D$ and $E$ subregions

| Subregion | Proportion of exposed workers with <br> low exposures (at or below the PEL) | Proportion of exposed workers with <br> high exposures (above the PEL) |
| :--- | :---: | :---: |
| A | 0.90 | 0.10 |
| B, C, D and E | 0.50 | 0.50 |

- the Chinese benzene study (Yin et al. 1987), in which $35 \%$ of over 50000 workplaces had concentrations at or above $40 \mathrm{mg} / \mathrm{m}^{3}$, in comparison to the current OSHA PEL of $3.2 \mathrm{mg} / \mathrm{m}^{3}$ for benzene, and in which the benzene concentration in $86 \%$ of 141 shoe factories was above $25 \mathrm{mg} / \mathrm{m}^{3}$.

Based on these data, partition factors for carcinogen exposures were determined for the A and for the $\mathrm{B}, \mathrm{C}, \mathrm{D}$ and E subregions, as shown in Table 21.13.

## LUNG CARCINOGENS

The proportions of the population exposed to the occupational lung carcinogens included in the study (Table 21.8) are shown in Tables 21.14 and 21.16 by subregion, age, sex and level of exposure.

## LEUKAEMOGENS

The proportions of the population exposed to occupational leukaemogens (Table 21.8) are presented in Table 21.15 by subregion, age, sex and level of exposure.

### 2.3 RISK FACTOR-DISEASE RELATIONSHIPS

Relative risk estimates were used for lung carcinogens and leukaemogens. Table 21.17 summarizes the chemical or physical agent, the specific cancer and the key data sources that provided evidence of the link between the two. These review studies assessed risk measures for the main sites of occupational cancer, including the lung (which, for the purposes of this study, includes the trachea, bronchus and lung), the haematopoietic system (represented in this study by leukaemia) and malignant mesothelioma.

Relative risks for lung cancer and leukaemia were taken from studies of cohorts of workers with variable exposure durations and intensities, variable periods from the last exposure and variable lengths of followup. They therefore compare exposed with unexposed groups. In preparing relative risk estimates for exposure outcomes of interest, several assumptions were made:

Table 21.14 Proportions of the population exposed to lung carcinogens by subregion, age, sex and level of exposure

Table 21.17 Examples of sources used to assess the risk factor-disease relationship for selected occupational carcinogens

| Selected risk factor | Health outcome | Examples of key sources of evidence of causality |
| :--- | :--- | :--- |
| Lung carcinogens | Cancer of the trachea, <br> bronchus or lung | Nurminen and Karjalainen (200I); Steenland <br> et al. (1996, 2003) |
| Leukaemogens | Leukaemia | Lynge et al. (1997); BEIR V (I990); IARC <br> (1997) |

- that relative risks are the same for men and women;
- that relative risk values are constant with age; and
- that the relative risks apply equally to the risk of developing the malignant condition (incident cases) and to the risk of dying from the condition (fatal cases); where relative risk values were based on disease incidence studies, the incidence ratio was comparable to the corresponding mortality risk ratio.

Steenland et al. (1996) estimated for the United States the relative risk of exposure to nine lung carcinogens (arsenic, asbestos, beryllium, cadmium, chromium, diesel fumes, nickel, silica and radon). They did not consider agents to which relatively few workers were exposed (BCME, coke oven and coal gasification fumes and soot) and they did not consider smoking, beyond the selection where possible of relative risk factors that had been adjusted for smoking. Combined relative risk values (ranging from 1.31 to 3.69 ) were calculated for all but radon, using inverse variance and a random-effects model and relying on major cohort studies of the specific agents. The authors estimated that 9000-10000 men and 900-1900 women develop lung cancer annually in the United States owing to past exposure to occupational carcinogens (except radon). This would account for approximately $9 \%$ of lung cancer deaths in males and $2 \%$ in females, or $0.5 \%$ of all deaths annually in the United States.

Steenland et al. (2003) examined the population-attributable risk (PAR) from several studies (including Steenland et al. 1996). They applied the PAR to deaths occurring in 1997 in the United States to determine occupational deaths from lung cancer, among other outcomes. The authors determined a PAR for lung cancer in the range $6.1-17.3 \%$ for men and $2 \%$ for women. For overall cancer they determined a PAR of $7-19 \%$ for men and $11 \%$ for women. For leukaemia, a combined PAR for men and women of $0.8-2.8 \%$ was calculated.

Nurminen and Karjalainen (2001) estimated the proportion of fatalities related to occupational factors in Finland. The average number of exposed workers in Finland was estimated from census data by sex, age, occupation and industry, and the FINJEM national job-exposure matrix.

Relative risks were obtained from a review of epidemiological studies, focusing on risk estimates that were most valid for the Finnish exposure circumstances. The attributable fraction methodology was used to determine the proportion of deaths in the population attributable to occupational factors. The authors reported that $30 \%$ of deaths due to occupational disease in Finland in 1996 were caused by cancer. Occupational lung cancer accounted for $0.9 \%$ of all deaths. They attributed $24 \%$ of cancer of the bronchus and lung ( $29 \%$ for men and $5.3 \%$ for women) to occupational exposure to combined risk factors. The attributable fractions for urinary cancer were $10.3 \%$ overall- $14.2 \%$ for men and $0.7 \%$ for women. Combined occupational risk factors resulted in $10.9 \%$ ( $18.5 \%$ for males, $2.5 \%$ for females) of leukaemia deaths being attributed to occupational exposures, the majority ( $17.8 \%$ and $2.3 \%$, respectively) from electrical occupations, in contrast to $0.7 \%$ and $0.2 \%$, respectively, from benzene. An average of $71.3 \%$ ( $90 \%$ for males, $25 \%$ for females) of malignant mesothelioma was attributed to occupation.

The three review papers described above (Nurminen and Karjalainen 2001; Steenland et al. 1996, 2003) provided summary measures, or information that can be used to determine summary measures, of relative risk for one or more of the main agents and outcomes of interest. The study by Nurminen and Karjalainen (2001) focused on Finland, and preferentially used studies based in Scandinavia or thought to be most relevant to Finland. Most of its relative risk estimates relate to lung cancer, with attributable fractions presented for leukaemia. The paper by Steenland et al. (1996), although focused on the United States, was more inclusive of studies of suitable quality. The other paper by Steenland et al. (2003) provided information on relative mortality risks similar to the first (1996) paper. All papers provided similar summary measures of relative risk for lung cancers, but the Steenland et al. (1996) results were used preferentially because they are generally based on a broader range of studies. However, the Steenland paper provided information only on lung cancer. Table 21.18 gives a summary of the risk measures for each of the carcinogens and the relevant outcomes. The basis for these risk estimations is described in more detail below.

## LUNG CANCER

The evidence for substance-specific relative risk values, which were used to calculate the overall relative risk for the eight lung carcinogens, is briefly discussed below, relying heavily on the review paper by Steenland et al. (1996). The data in the paper provide a summary relative risk of 1.6 for occupational exposure to the set of lung carcinogens considered here.

Smoking is the main important potential confounder of lung cancer, and potentiates the effect of some exposures (notably with asbestos and lung cancer). In this analysis, where possible, studies were used that produced risk estimates for lung cancer after controlling for smoking.
Table 21.18 Summary of risk measures (relative risk and mortality rates) for occupational carcinogens

| Health outcome | Risk measure | Estimate and 95\% confidence interval (CI) | Comments | Primary data sources |
| :---: | :---: | :---: | :---: | :---: |
| Cancer of the trachea, bronchus and lung | Relative risk | Low exposure: 1.22 (I.09-1.35) to 1.32 (I.17-1.48) <br> High exposure: 1.79 (1.59-1.97) to 1.93 (1.71-2.16) | Composite relative risk based on individual relative risk of arsenic, asbestos, beryllium, cadmium, chromium, diesel exhaust, nickel and silica | Steenland et al. (1996) |
| Leukaemia | Relative risk | Low exposure: 1.67 (1.5I-2.00) to 1.93 (1.76-2.17) <br> High exposure: 3.06 (2.64-3.80) to 3.86 (3.48-4.32) | Composite relative risk based on individual relative risk of benzene, ionizing radiation and ethylene oxide | BEIR V (I990); IARC (2000); <br> Lynge et al. (I997); <br> Steenland et al. (2003) |

## Arsenic

Arsenic is accepted as a Group 1 carcinogen (IARC 1980, 1987a). The six principal epidemiological studies (covering nearly 18000 workers) reviewed by Steenland et al. (1996) indicated a combined relative risk of 3.69, with a range of $1.31-15.2$ reported for individual studies and a clear dose-response relationship. The lowest relative risk arose from a study in which exposures mostly ranged from 7 to $13 \mu \mathrm{~g} / \mathrm{m}^{3}$, compared to the OSHA level of $10 \mu \mathrm{~g} / \mathrm{m}^{3}$ (Enterline et al. 1987). Excess cancers in other studies were probably due to high exposures that occurred largely in the past. A combined relative risk of 3.69 ( $95 \%$ CI 3.06-4.46) was determined by the Steenland et al. (1996) review, whereas 3.2 was used by Nurminen and Karjalainen (2001).

## Asbestos

Both serpentine and amphibole asbestos have been shown to cause lung cancer in humans, with a clear dose-response relationship and a synergy between asbestos and tobacco (Lee 2001). Over 100 cohort studies and many case-referent studies, plus animal and cellular studies, provide ample evidence for causation. In six cohort studies of nearly 6000 asbestosis patients, the standardized mortality rate ranged from 3.5 to 9.1, with a combined relative risk of 5.9 . In 20 studies of over 100000 asbestos workers, the standardized mortality rate ranged from 1.04 for chrysotile workers to 4.97 for amosite workers, with a combined relative risk of 2.00. It is difficult to determine the exposures involved because few of the studies reported measurements, and because it is a problem to convert historical asbestos measurements in millions of dust particles per cubic foot to gravimetric units. Nevertheless, little excess lung cancer is expected from low exposure levels. These studies have been the subject of several reviews (IARC 1977; IPCS 1998; Nurminen and Karjalainen 2001; Steenland et al. 1996). The main papers provided a range of relative risks (1.04-7.4), with summary relative risks of 2.0 (Steenland et al. 1996) and 2.3 (Nurminen and Karjalainen 2001) cited in the two most recent reviews. The lower value $(2.0,95 \%$ CI 1.90-2.11), which is based on a wider range of studies, is accepted for this analysis.

## Beryllium

Beryllium is an IARC Group 1 carcinogen (IARC 1993), although epidemiological evidence is rather limited. A standardized mortality rate for lung cancer of 2.0 was determined from a registry cohort of 689 women and men (Steenland and Ward 1991), and an overall standardized mortality rate of 1.24 was found in a study of 9225 male workers from seven beryllium plants ( 1.49 at plants with higher exposure) (Ward et al. 1992). Steenland et al. (1996) utilized a smoking-adjusted relative risk of 1.49 (no $95 \%$ CI reported), based on a beryllium plant with high exposures.

## Cadmium

Cadmium is an IARC Group 1 carcinogen (IARC 1993). The best epidemiological evidence of its relationship to lung cancer comes from a cohort study by Stayner et al. (1992), although the evidence for carcinogenicity is stronger in animals and has recently been questioned in humans (Jarup and Nordberg 1998). The most recent follow-up study suggests a relative risk of 1.49 (95\% CI 0.96-2.22) (Steenland et al. 1996). Nurminen and Karjalainen (2001) used 1.2, based on a Scandinavian study.

## Chromium

Chromium is an IARC Group 1 carcinogen (IARC 1990a). There is ample epidemiological evidence of its causal association with lung cancer, with many cohort studies showing a dose-response relationship. Based on the largest and best designed studies of chromium production workers, producers of chromate paints and chromate plating workers, the overall relative risk is 2.78 ( $95 \%$ CI 2.47-3.52) (Steenland et al. 1996). Nurminen and Karjalainen (2001) used a lower relative risk of 1.4 from a hospital-based case-referent study.

## Diesel exhaust

Polycyclic aromatic hydrocarbons comprise the main components of diesel exhaust, which contains a mixture of substances. Diesel exhaust has been accepted as a Group 2A carcinogen (IARC 1989) and was scheduled for further review in 2001. Owing to limitations in exposure assessment to diesel exhaust, human epidemiology has been difficult to conduct. However, cohort studies and meta-analyses confirm a relationship between diesel exhaust exposure and lung cancer, with summary relative risks in the range 1.3-1.5 (Bhatia et al. 1998; Lipsett and Campleman 1999). Based on six relatively consistent recent studies with good documentation of exposure to diesel exhaust, in which the number of cases ranged from 50 to 1256, Steenland et al. (1996) determined a combined relative risk of 1.31 ( $95 \%$ CI 1.13-1.44), and Nurminen and Karjalainen (2001) used the same estimate.

## Nickel

Nickel is an IARC Group 1 carcinogen (IARC 1990a). Based on data from the 1990 report of the International Committee on Nickel Carcinogenesis in Man (ICNCM 1990), Steenland et al. (1996) calculated a combined relative risk of 1.56 ( $95 \%$ CI 1.41-1.73). Nurminen and Karjalainen (2001) used an estimate of 1.4 based on a Finnish study.

Silica
On the basis of detailed reviews, silica has been classified as an IARC Group 1 carcinogen (IARC 1987b, 1997). Several cohort studies in silica-
exposed and silicosis patients showed a dose-response relationship between silica exposure and lung cancer relative risk, and this was confirmed by meta-analyses and a pooled study (Steenland and Sanderson 2001). Animal and cellular studies provided supporting evidence. Controversy remains as to whether silicosis is a necessary precursor for the development of lung cancer, but this does not affect the underlying status of silica as a carcinogen (Checkoway 2000; Hnizdo and Sluis-Cremer 1991; Soutar et al. 2000). Steenland et al. (1996) based their combined relative risk of 1.33 ( $95 \%$ CI 1.21-1.45) on 13 large cohort and case-control studies of silica-exposed workers. These studies included granite workers, stone workers, pottery workers, brick workers, gold miners and diatomaceous earth miners, and covered a range of workers generally numbering from almost 1000 to over 5000. Half of the studies controlled for smoking. Nurminen and Karjalainen (2001) used a slightly higher estimate of 1.4.

## Combined estimates

A common methodology, similar to that used by Steenland et al. (1996) and Nurminen and Karjalainen (2001), was used in this analysis for all lung carcinogens, in that occupational exposure to carcinogens was estimated and applied to relative risk estimates to enable the determination of attributable fractions. A mean relative risk of 1.63 was determined for eight lung carcinogens (not including radon), using data reported by Steenland et al. (1996). This was done by calculating a weighted average of the substance-specific relative risks, and weighting the substance-specific relative risks by the proportion of workers exposed to each substance to determine a mean relative risk for workers exposed to the eight lung carcinogens. This was done separately for each subregion, using the proportion of workers in each subregion exposed to specific agents to weight the relative risk for each of the agents. However, the resulting average relative risks were not clearly different from each other (all were close to 1.6).

In addition, to estimate an uncertainty range for the initial mean relative risk, a weighted average was calculated of the lower and upper $95 \%$ CI values of the relative risk reported for each substance (except beryllium, for which there were no estimated CI). These values (not to be confused with the partitioned relative risk values for low- and highlevel exposure) were within $15 \%$ of the mean relative risk values. This is demonstrated for the AMR-A subregion (Table 21.19).

To produce relative risk estimates for low and high exposure, it was necessary to partition the mean relative risks into values that correspond to low- and high-level exposure. A mean relative risk (of 1.6) was determined for the United States. Based on the estimates of $90 \%$ of American workers exposed at or below about one fifth of the PEL values and $10 \%$ exposed at or above the PEL values, and an estimate of the American population-attributable fraction of lung cancer due to occupation

Table 21.19 Lung cancer relative risk, substance-specific and weighted average, for the AMR-A subregion

| Carcinogen | Combined relative risk ${ }^{\text {a }}$ (95\% Cl) | Proportion of workers exposed |
| :---: | :---: | :---: |
| Silica | 1.33 (1.21-1.45) | 0.0248 |
| Cadmium | 1.49 (0.96-2.22) | 0.0015 |
| Nickel | 1.56 (1.41-1.73) | 0.0039 |
| Arsenic | 3.69 (3.06-4.46) | 0.0011 |
| Chromium | 2.78 (2.47-3.52) | 0.0055 |
| Diesel fumes | 1.31 (1.13-1.44) | 0.0217 |
| Beryllium | 1.49 | 0.0005 |
| Asbestos | 2.00 (1.90-2.11) | 0.0094 |
| Total ${ }^{\text {b }}$ | 1.59 (1.41-1.77) |  |
| a Derived from major epidemiological studies. |  |  |
| Weighted summary relative risk, weighted by the proportion of workers exposed to each contributing carcinogen. |  |  |
| Source: Steenland et al. (1996). |  |  |

of $9 \%$ (Steenland et al. 1996), the mean relative risk of 1.6 was partitioned into a relative risk of 1.3 for low-level exposure to lung carcinogens, and 1.9 for high-level exposure. The United States ratios of the lower (1.3/1.6) and the higher (1.9/1.6) relative risks to the average relative risk were then applied to the average relative risks estimated for each subregion to produce estimated relative risks at low and high exposures for each subregion. In the same manner, upper and lower 95\% CI were produced for these relative risks, based on the limits estimated for the average relative risks. The results of this process are shown in Table 21.20.

## LEUKAEMIA

Leukaemia has been linked to exposure to benzene, ionizing radiation and ethylene oxide, all of which are IARC Group 1 carcinogens (IARC 2001; WHO 1999). There is also some evidence that exposure to low-frequency electric fields may be leukaemogenic (Nurminen and Karjalainen 2001; WHO 2001). However, as this physical agent has not been included in CAREX, it has been excluded from this study.

## Benzene

The causal relationship between leukaemia and benzene is well recognized, including data from cohort studies in China and the United States covering workers in chemical plants, refineries, machine production, and textile and cloth factories. Excesses of nonlymphocytic, myelogenous and acute myeloid leukaemias occurred. There is also limited evidence in

Table 21.20 Weighted summary relative risks for lung cancer for all subregions

a Weighted summary relative risk, weighted by the proportion of workers exposed to each contributing carcinogen in each subregion.
mammals (Hayes et al. 1997; IARC 1990b). A recent review (Lynge et al. 1997) provides a low-exposure relative risk of 2.0 ( $95 \%$ CI $1.8-2.2$ ) and a high-exposure relative risk of 4.0 (3.6-4.4).

## Ionizing radiation

The causal relationship between ionizing radiation and leukaemia is well recognized. There is consistency across numerous studies, strong association between exposure and outcome, and evidence of a dose-response gradient. Excess leukaemia has been observed in survivors of the atomic explosions at Hiroshima and Nagasaki, and also among patients medically treated with X-rays or $\gamma$-rays. The risk of leukaemia increases over fivefold at sufficiently high doses (BEIR V 1990; IARC 2000; ICRP 1991). Models describing risk have been proposed as: Linear RR model $1+5.5$ _ dose in Sv, quadratic $R R=1+0.24$ dose +0.27 dose $^{2}$ (dose in Sv) (BEIR V 1990). Relative risks of 1.22 (1.07-1.70) for low exposure and 1.57 (1.18-2.88) for high exposure are accepted as the best available estimates (BEIR V 1990; IARC 2000).

## Ethylene oxide

Workers have exposure to ethylene oxide either as a sterilant or as a chemical intermediary or final product. In a study in the United States,
ethylene oxide used as a sterilant was associated with lymphatic leukaemia and non-Hodgkin's lymphoma, with a rate ratio of 1.2 estimated for 45 -year exposure to 1 ppm . Other studies in Sweden and the United Kingdom of Great Britain and Northern Ireland showed nonsignificant excesses of these cancers. Of six studies of chemical plant workers (two in Sweden and one each in Germany, Italy, the United Kingdom and the United States), two found significant excesses, two found nonsignificant excesses and two found expected rates (IARC 1997). Relative risk was found to range from 1.1 to 3.5 (Steenland et al. 2003).

An approach similar to that used for lung carcinogens was applied to the leukaemogens. The separate relative risks for the development of leukaemia arising from exposures to the main relevant occupational carcinogens were combined into single summary relative risks, one for low exposure and one for high exposure. This was done separately for each subregion, using the exposure prevalence of the workforce in each subregion to weight the exposure-specific risks. However, the resulting average relative risks were not clearly different from each other. CI were estimated in the same manner, weighting the estimated CI for benzene and ionizing radiation (there were no estimated CI for ethylene oxide). Unlike lung cancer, the low- and high-exposure relative risks were available for each exposure, and these were directly incorporated into lowand high-exposure summary measures through the weighting process. An example of this approach is shown in Table 21.21, using the WPRB subregion. The results of this approach for each subregion are shown in Table 21.22.

Table 21.2I Leukaemia relative risk, substance-specific and weighted average, for the WPR-B subregion

| Carcinogen | Low exposure | High exposure |  |
| :---: | :---: | :---: | :---: |
|  | Combined relative risk ${ }^{\text {a }}$ (95\% CI) | Combined relative risk ${ }^{\text {a }}$ (95\% CI) | Proportion of workers exposed |
| Benzene | 2.0 (1.8-2.2) | 4.0 (3.6-4.4) | 0.0051 |
| lonizing radiation | 1.22 (1.07-1.7) | 1.57 (1.18-2.88) | 0.0010 |
| Ethylene oxide | 1.1 | 3.5 | 0.0003 |
| Total ${ }^{\text {b }}$ | 1.84 (1.68-2.12) | 3.60 (3.20-4.16) |  |

[^80]Table 21.22 Weighted summary relative risks for leukaemia for all subregions

| Subregion | Low exposure | High exposure |
| :---: | :---: | :---: |
|  | Combined relative risk ${ }^{\text {a }}$ (95\% Cl) | Combined relative risk ${ }^{\text {a }}$ (95\% CI) |
| AFR-D | 1.88 (1.72-2.15) | 3.73 (3.34-4.24) |
| AFR-E | 1.89 (1.73-2.15) | 3.75 (3.37-4.25) |
| AMR-A | 1.91 (1.74-2.16) | 3.80 (3.41-4.28) |
| AMR-B | 1.77 (1.61-2.07) | 3.38 (2.98-4.01) |
| AMR-D | 1.91 (1.74-2.16) | 3.78 (3.39-4.27) |
| EMR-B | 1.87 (1.70-2.13) | 3.66 (3.26-4.19) |
| EMR-D | 1.89 (1.72-2.15) | 3.73 (3.33-4.23) |
| EUR-A | 1.93 (1.76-2.17) | 3.86 (3.48-4.32) |
| EUR-B | 1.83 (1.67-2.11) | 3.57 (3.18-4.13) |
| EUR-C | 1.67 (1.51-2.00) | 3.06 (2.64-3.80) |
| SEAR-B | 1.89 (1.73-2.15) | 3.76 (3.37-4.26) |
| SEAR-D | 1.81 (1.65-2.10) | 3.51 (3.1I-4.09) |
| WPR-A | 1.90 (1.73-2.15) | 3.77 (3.38-4.26) |
| WPR-B | 1.84 (1.68-2.12) | 3.60 (3.21-4.16) |

a Weighted summary relative risk, weighted by the proportion of workers exposed to each contributing carcinogen in each subregion.

## Estimates of risk reversibility

There are limited data on risk reversibility from occupational exposure to carcinogens. The studies from which the estimated risks arise are based on cohorts of people exposed for different periods of time, followed up for various periods of time and with various periods of time between exposure cessation and follow-up, with follow-up periods varying between zero (still exposed) and many decades. Therefore, most of the absolute and relative risks produced by the studies already depend on whatever change in risk might occur once exposure ceases. However, some indication of the extent of risk reduction that might occur is given by a recent paper by Peto et al. (2000), which examined changes in the risk of developing lung cancer as a result of stopping smoking. The study estimated that, compared to the risk in persons who continued to smoke, the risk of lung cancer in males declined to about 0.66 within 10 years, to 0.44 between 10 and 20 years, to 0.2 between 20 and 30 years, and to 0.1 after 30 years.

## 3. Occupational airborne particulates

There are a vast number of respiratory conditions that can arise directly or indirectly from work. However, estimating exposures, risks and attrib-
utable proportions is not possible for many of these on an international (or even national) scale, because of lack of appropriate data sources. Therefore, only the more important of the work-related respiratory conditions, in terms of the total number of cases or the risks arising from exposure, are included here. All of these arise from exposure to particulates. Malignant respiratory disease is not included here because it is described in section 2.
